Changes in fragility of the erythrocytes also attracted early attention. A progressive increase of osmotic fragility was noted in bloods stored in media isotonic with respect to electrolytes (1 to 6, 9 to 15). The addition of glucose in small amounts slows the progressive increase of fragility during storage (1 to 6, 9 to 14, 16, 17). Decrease of blood pH has a qualitatively similar but less pronounced effect (2, 4 to 6). In electrolyte-poor media, fragility is often altered peculiarly, depending on the character of the preservative fluid. In De Gowin's or Rous-Turner solutions there is noted early an increased fragility which may revert to normal if the cells are washed free of excess glucose (4, 7, 10). In solutions of sucrose, dextrins, or corn syrup, substances which do not permeate the erythrocytic membrane, the cells exhibit an exceedingly low fragility, which does not change in a uniform manner during storage (1, 2, 4, 7, 10).

A gradual increase of varying degree in the corpuscular volume of erythrocytes in nearly-iso-

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Children's Hospital of Cincinnati.

tonic media has been described by most earlier observers. In electrolyte-poor media variable alterations have been found; while cells in Rous-Turner's and De Gowin's solution increase progressively to almost hemolytic (bursting) volumes, they swell only transiently and to a minor degree or may even shrink in solutions which contain dextrin, sucrose or other non-permeating carbohydrates (2, 4, 11, 17). Changes in shape and surface of erythrocytes during storage have been described (18, 19), the cells becoming more spheroidal in shape, and crenated. The increase in the mechanical fragility of erythrocytes during storage apparently bears no constant relationship to osmotic fragility, spontaneous hemolysis, or survival *in vivo* (1, 4, 7, 9).

Among the chemical properties of stored blood, changes of pH have been determined (4, 6, 20). Unfortunately most measurements have been carried out at a temperature far removed from that in the refrigerator or in the body and are therefore not easily related to actual conditions of use. It has been found that in general the pH of blood decreases during storage because of glycolysis with lactic acid formation. Liberation of ammonia (2, 21 to 23) and the exchange of potassium and sodium across the cellular membrane (2, 19, 20, 24 to 27) soon after blood is drawn have been noted by several workers. These changes appear to be somewhat retarded at lower blood pH values (19, 25). The alteration in the distribution of sodium and potassium in the cell seems reversible *in vivo* following transfusion of the stored blood (28).

Changes in the phosphorus distribution have also attracted the attention of some observers (2, 6, 11, 29, 30), who found that during storage the organic acid-soluble phosphorus of the erythrocytes decreased in concentration while the inorganic phosphorus rose. Because of the slowness of the outward diffusion great differences between cells and plasma in the concentration of inorganic phosphorus occurred. An association between the changes of the organic acid-soluble phosphorus, in particular the easily-hydrolyzable fraction, and preservability of the cells was indicated by the data (29, 30), although the observers emphasized that parallelism between the chemical change and survival *in vivo* was by no means perfect (11). Among other chemical constituents mention should be made of hemoglobin. Present evidence indicates that over long periods of storage hemoglobin maintains its oxygen-carrying capacity and that the rate of reaction between hemoglobin and oxygen is unimpaired (12, 31).

As can be seen from the summary of the information existing at present, the attempts to utilize *in vitro* changes as a measure of the behavior of the blood cells in the circulation of the recipient have led to results contradictory and disappointing to most observers. While some workers have unqualifiedly used *in vitro* tests as indices of preservation of blood on the assumption, either voiced or obviously implied, that these measurements reflected the behavior of the erythrocytes in the recipient's circulation (3, 7 to 9, 15), others, in particular those observers who used preservative solutions of high carbohydrate content, came to the conclusion that *in vitro* testing was worthless as a measure of survival of erythrocytes (4, 10, 11).

Plan of study

The study to be reported was undertaken on the basic assumption that the erythrocyte constitutes a functional unit and that therefore its physical and chemical properties are interrelated and dependent on the metabolic activity of the cell. Therefore, one would expect to find a close correspondence between suitably selected and measured physical, osmotic, and chemical indices of the cell, on the one hand, and the ability of erythrocytes to survive in the body of the recipient on the other. It was hoped that comprehensive and integrated information on the behavior of erythrocytes during storage might provide the basis for reliable *in vitro* testing procedures and for improvements of preservative technique in the light of a deeper insight into the deteriorative processes during storage. With this concept in mind a variety of measurements were carried out simultaneously and seriatim on samples of stored blood, including the dimensions of the erythrocytes, their osmotic behavior, and several chemical constituents. In the chemical studies, emphasis was put on the measurement of glycolysing ability of the cells and of correlated changes in the acid-soluble phosphorus compounds. This emphasis was based on the consideration that glycolysis is the main metabolic activity of red cells and is closely related to their acid-soluble phosphorus compounds.

In addition, studies of the changes of sodium and potassium were carried out. Recognizing that the behavior of blood cells in electrolyte-poor media may be qualitatively different from that observed in solutions near isotonicity with respect to electrolytes, it was decided to limit the first study to a comparison of the behavior of blood stored in 3 solutions, representative of the main types of nearly-isotonic preservatives in practical use at present.

Composition of preservative solutions

The solutions studied were: (*1*) simple citrate solution, (*2*) a neutral citrate-glucose solution containing glucose in a sufficient amount to raise the level in stored blood by 0.6 gram per 100 ml., and (*3*) a citrate-glucose mixture acidified by the addition of citric acid originally used by Loutit and Mollison (6, 32). The solutions were added in 15-, 20-, and 25-ml. amounts respectively, to 100 ml. of blood. For the last mixture, in this paper the term ACD–I (an abbreviation of acid citrate-dextrose), which has gained currency in the United States, will be used interchangeably with acid citrate-glucose. Table I summarizes the essential data concerning the preservative solutions used. As indicated in the table, the first 2 mixtures are approximately neutral, although it must be remembered that the pH values of such weakly buffered solutions are largely dependent on minor extraneous influences. The pH value of 5.03 for the acid preservative, which corresponds in composition to a solution of disodium citrate, may be predicted from the molar ratios of sodium citrate and citric acid present in it, on the basis of the known pK′ values of the 3 acid groups of citric acid. When this solution is added to blood, only the citric acid significantly affects the pH of blood, since at the pH range prevailing in blood, trisodium citrate has an insignificant buffering power.

TABLE I

Composition of preservative solutions

Mixture	Na citrate*	Citric acid*	Glucose*	pH	Volume added to 100 ml. of blood
	grams per 100 ml.	*grams per 100 ml.*	*grams per 100 ml.*		*ml.*
1. Citrate	3.20			(7.5)**	10
2. Citrate-glucose†	2.13		5.0	(7.5)**	15
3. Acid citrate-glucose† (ACD–I)	1.33	0.47	3.0	5.03	25

* Tri-sodium citrate $\cdot 2H_2O$, citric acid $\cdot H_2O$, glucose anhydrous.

** The pH values of these weakly buffered solutions, owing to their dependence on minor extraneous influences, are given in parentheses.

† In preparing the neutral citrate-glucose solution, sterile glucose solution was added aseptically to a sterilized bottle containing the sodium citrate solution, since heating of glucose with neutral citrate results in caramelization to a considerable degree. The acid citrate-glucose mixture (ACD–I), identical with that reported by Loutit (6), was sterilized for 30 minutes at 20 lbs. pressure in a steam autoclave, with minimal signs of discoloration.

TABLE II

Citrate, glucose and acid increments in blood after mixture with preservative solutions

Solution	Citrate		Glucose increment	Acid increment
	Blood	Plasma*		
	mM. per liter	*mM. per liter*	*grams per 100 ml.*	*meq. per liter*
Citrate	10	17	0	0
Citrate-glucose	11	19	0.65	0
Acid citrate-glucose	13	21	0.60	16.5

* The values were calculated on the assumption that citrate-ion does not permeate the cell-membrane, with an assumed volume of packed cells in blood of 45 per cent. Water shifts between cells and plasma were neglected.

In Table II are presented the calculated increments of citrate, glucose, and acid resulting in blood from mixing with the preservative solutions. In the first column is listed the citrate concentration in blood; in the next is recorded the more significant value of citrate in the supernatant plasma, calculated on the basis of the well substantiated assumption that the cell membrane is impermeable to citrate ions. The values listed are in excess of those required to suppress the effect of calcium ion on clotting, calculated by Maizels to be 10 meq. per liter (33). In the next column are given the calculated increments of glucose in blood. It may be seen that the 2 glucose-containing preservatives are like each other in this respect. In the last column is listed the amount of acid added to blood with the acid preservative solution. This amount would produce a shift in the blood pH of about 0.5 unit if no bicarbonate were displaced—a condition which undoubtedly does not prevail.

Actually, as described in a later section dealing with pH change during storage, the pH of blood was initially shifted by about 0.3 pH unit. The osmotic properties of the preservative solutions and their calculated and observed effects on blood are dealt with in a later section concerning the osmotic behavior of erythrocytes.

HANDLING OF THE BLOOD AND METHODS USED

For serial sampling, 100-ml. amounts of blood were drawn aseptically into bottles containing appropriate amounts of the preservative solution being tested. After mixing, 20-ml. portions of the blood were distributed into vials of 30-ml. capacity, similar in shape to the standard blood bank bottles. The blood samples were then placed in a refrigerator maintained at 4° C. At suitable intervals individual vials were removed for analysis. For the study of the behavior of blood under routine conditions, samples were procured from the blood bank of the Cincinnati General Hospital, where they had been drawn from donors acceptable by the standards of the blood bank, but otherwise unselected, and stored at 4° C. For testing, the bloods were transported to the laboratory under suitable precautions and sampled within 20 minutes after removal from storage.

The methods used in this laboratory for the determination of the dimensions and of the osmotic behavior of the

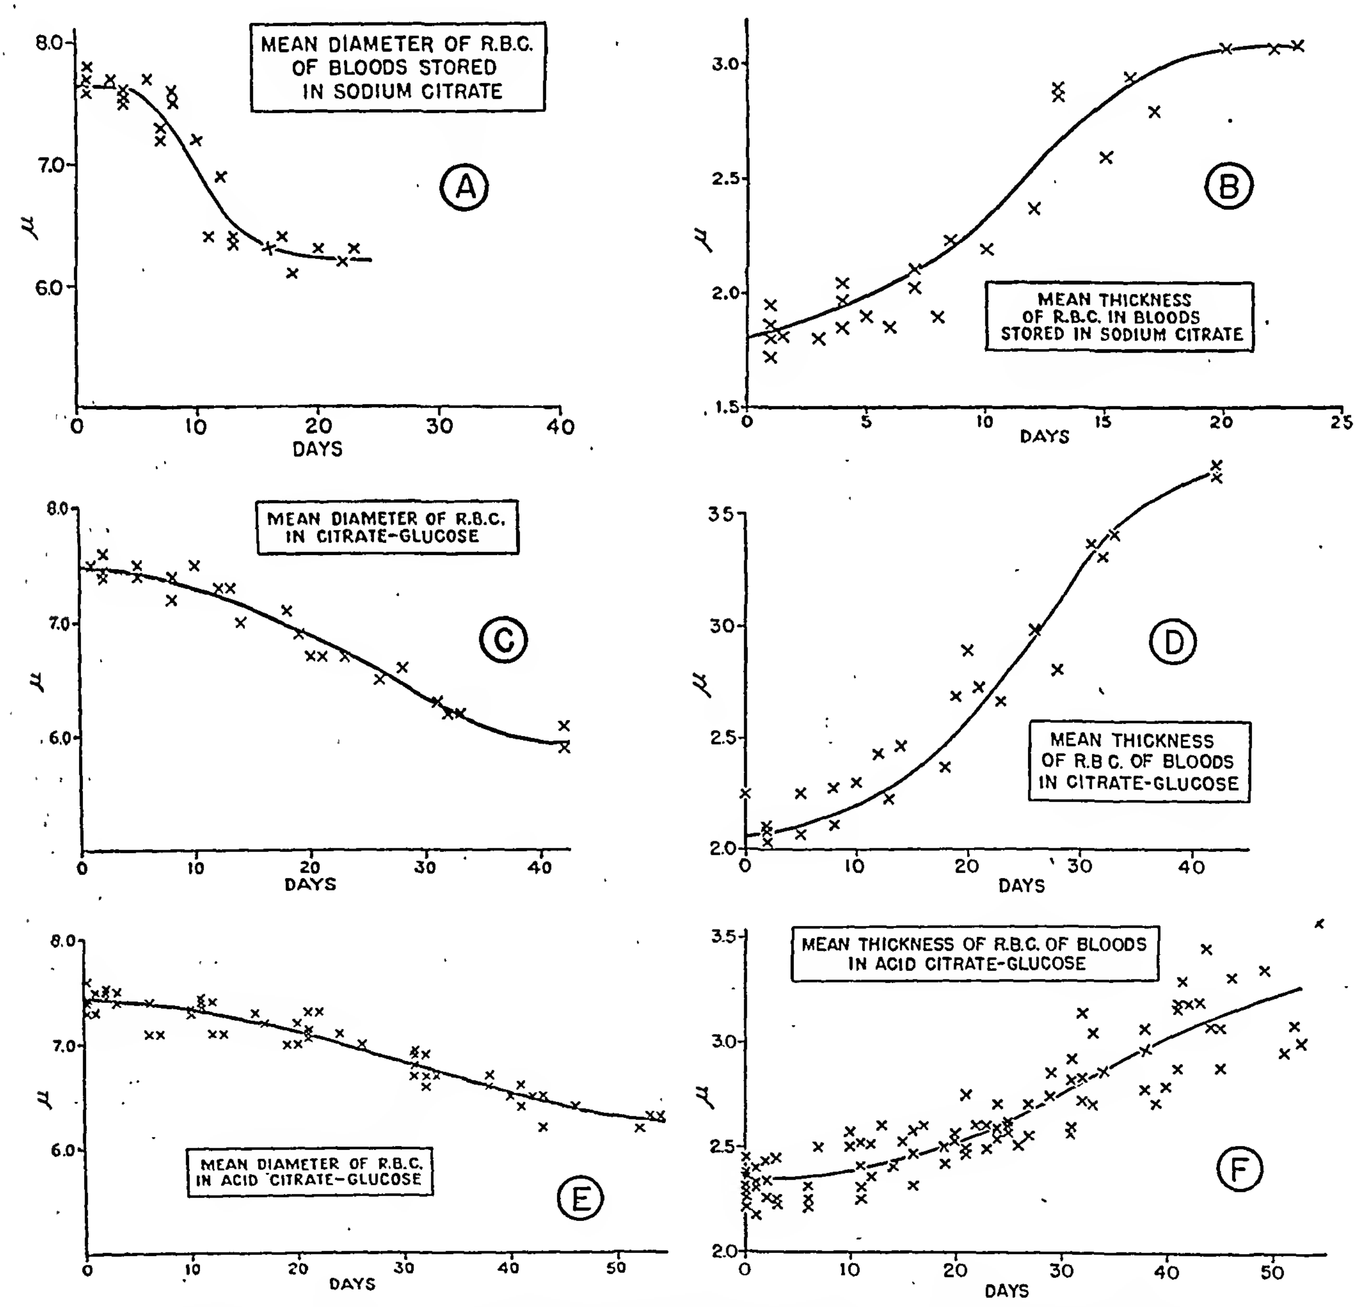

FIG. 1. DIMENSIONAL CHANGES OF ERYTHROCYTES OF BLOODS STORED IN CITRATE, CITRATE-GLUCOSE, AND ACID CITRATE-GLUCOSE SOLUTIONS

cells have been described previously (34). The chemical methods generally used excepting those for the determination of lactic acid and sugar have also been reported (35). The blood sugar was determined by the method of Nelson (36), and lactic acid by a slightly modified aeration-titration method of Friedemann *et al* (37). Reference to special methods is made in following sections, where results obtained by their use are discussed.

DIMENSIONAL CHANGES

Changes of the diameter of the cells and their thickness, calculated from the diameter and volume on the assumption of a disc-shape (34), are presented in Figure 1. (See also columns 1 and 2 of Tables III to V.) It may be seen that in all instances the diameter decreased while the thickness increased. This process is illustrated by the changes in the diameter to thickness ratio which fell from values as high as 4.1 to 2.0 during storage. The mean corpuscular volume of the cells (see column 3 of Tables III to V) rose by about 10 per cent during storage from values close to the normal in both neutral media while it did not change significantly in acid citrate-glucose solution beyond the initial rise to 115 per cent of normal. The mean surface area of the red cells (see column 4 of Tables III to V), also calculated on the assumption of a disc-shape, decreased.

* Blood sample in heparin.

A comparison of the 3 preservatives with regard to the dimensions of the erythrocytes indicates that at the outset the cells of citrated blood were slightly shrunken and flatter, those of blood in acid citrate-glucose somewhat swollen and rounder, and those in citrate-glucose of about the same shape and size as were the cells of heparinized samples. During storage the values for diameter and thickness increasingly approached each other with resulting increased "roundness" of the cells. The pattern of change, with its characteristic sigmoid-shaped time curve, was essentially the same in all preservatives as was the final form attained by the cells. The behavior of the red cells in the 3 preservatives differed primarily in the length of time required for the dimensional alterations to run their course. For instance, while the cells in citrate required 10 days on the average to reach a diameter of less than 6.6 and a thickness of more than 2.8 micra, cells in citrate-glucose assumed a comparable shape in about 25 days and those in acid citrate-glucose, in about 35 days. The differences in the rates of dimensional change are illustrated more clearly in Figure 2, in which

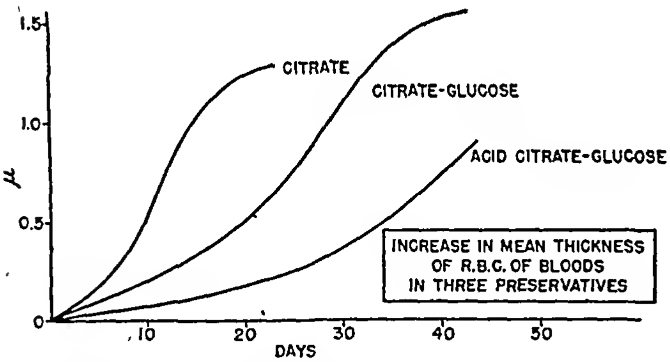

FIG. 2. AVERAGE INCREASE IN MEAN THICKNESS OF ERYTHROCYTES STORED IN 3 PRESERVATIVE SOLUTIONS

the 3 preservatives are compared with respect to the average increase in thickness of the erythrocytes above the initial value. A similar order is oberved in the changes in the calculated surface area.

The calculated decrease in the mean surface area of the cells during storage may be explained as follows: if the assumption is accepted that the mean surface area of a given cell population is constant, as suggested by several observers, the calculated decrease of the area might be apparent only; the hypothesis may be then advanced that an interrelation exists between the calculated change in surface area and the microscopically visible crenation; going one step further, one may assume that the extent of the calculated alteration in the surface area is a reflection, perhaps even a quantitative measure, of the degree of crenation of the erythrocytes.

The alterations in the dimensions of the red cell during storage may be interpreted as manifestations of increasing deterioration of the cell form, resulting in increasing roundness of the cell, or more exactly, in closer approximation of all cell diameters. In this process the cell is changed in form from a biconcave disc to the shape of a wrinkled bag. The "S"-shaped pattern of change with time in the dimensions of the cell, characteristic of phenomena of biological growth and decay, would indicate a relationship between the dimensional and functional state of the cell.

The alterations in the corpuscular volume of the cells, initially and during storage, will be discussed in detail in the following section. They appear to be determined primarily by changes in the osmotic relationships and by shifts of the pH in cells and plasma. Here, it may be pointed out that the disproportion between the increasing approximation of all cell diameters and the change of the cellular volume, seems at least partly to account for the crenation of stored erythrocytes.

OSMOTIC CHANGES

In Figures 3, 4 and 5 are presented data on the percentage of erythrocytes hemolyzed in varying concentrations of sodium chloride. The data for hemolysis in 0.9 per cent sodium chloride solution, while not a direct measure of true "spontaneous" hemolysis, *i.e.*, of the amount of hemoglobin released in the supernatant plasma, are comparable to the amounts measured in the plasma after mixing and centrifugation of stored blood. The hemolysis curves are presented as plots of percentage of cells hemolyzed in different concentrations of sodium chloride at any given time and as time curves for any given concentration of sodium chloride. Also included in the presentation are combined data on several bloods in 0.6 per cent sodium chloride solution, chosen as representative of the osmotic behavior of the erythrocytes.

In comparing the 3 preservatives with respect

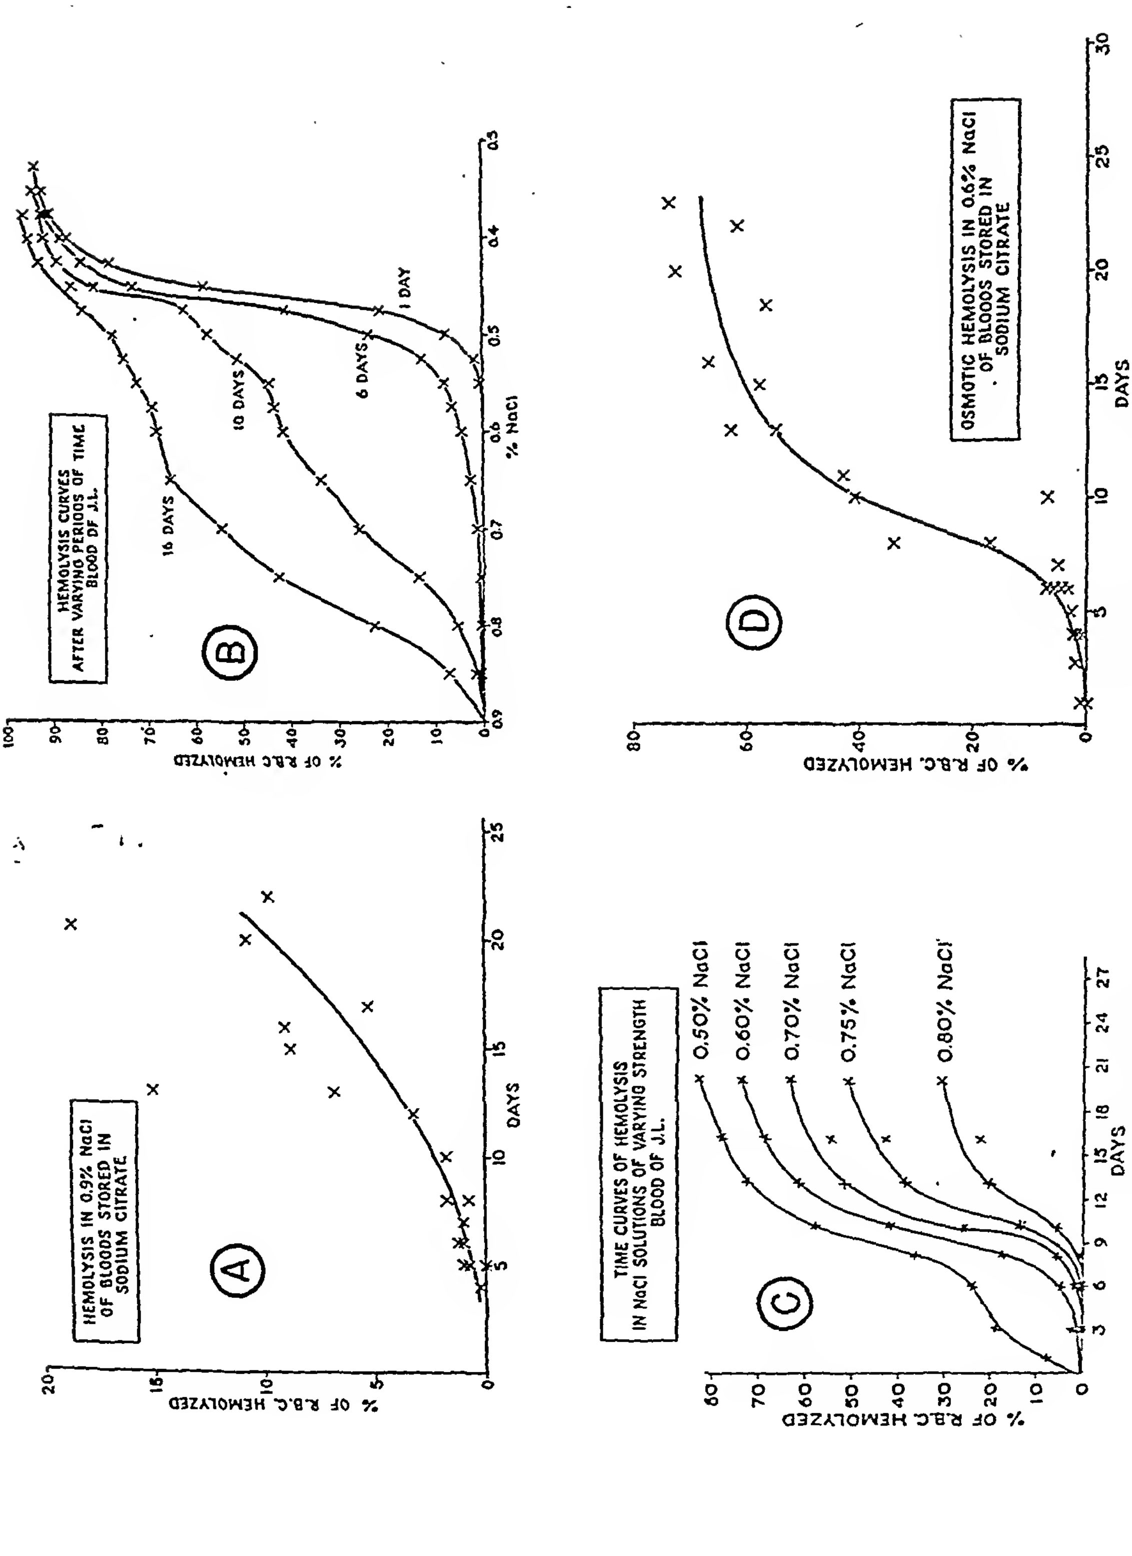

Fig. 3. Osmotic Hemolysis of Erythrocytes of Bloods Stored in Sodium Citrate Solution

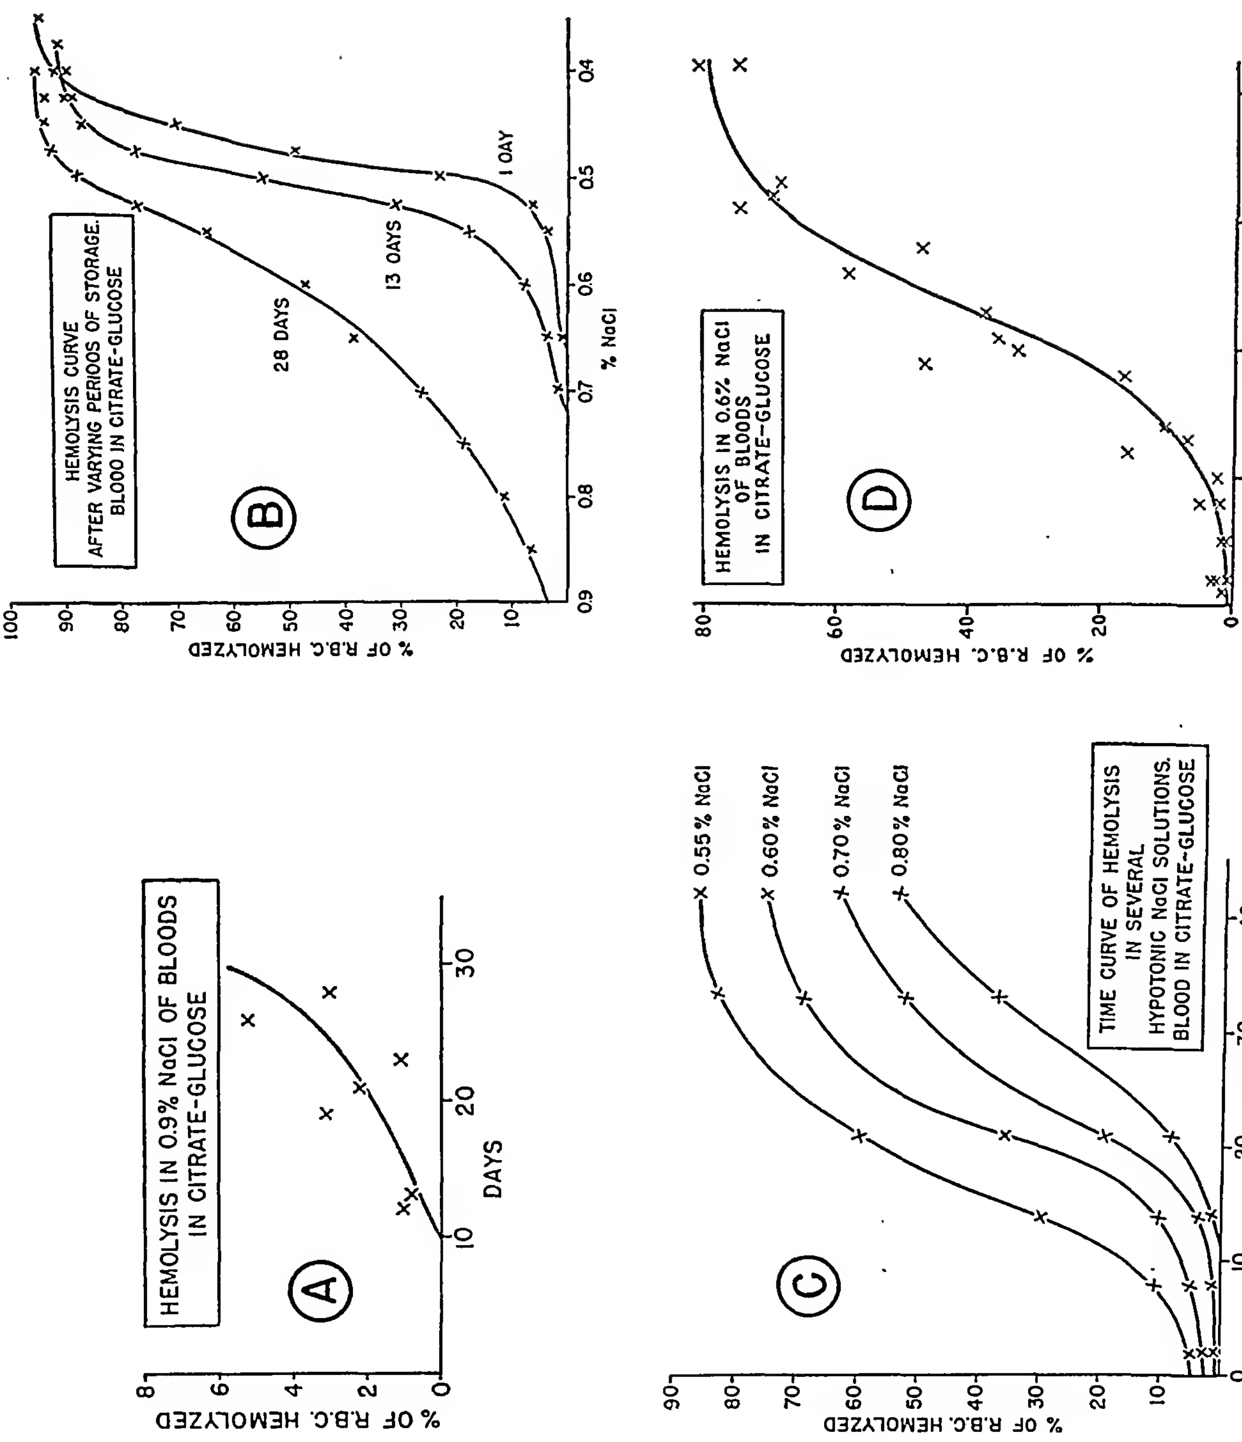

FIG. 4. OSMOTIC HEMOLYSIS OF ERYTHROCYTES OF BLOODS STORED IN NEUTRAL CITRATE-GLUCOSE SOLUTIONS

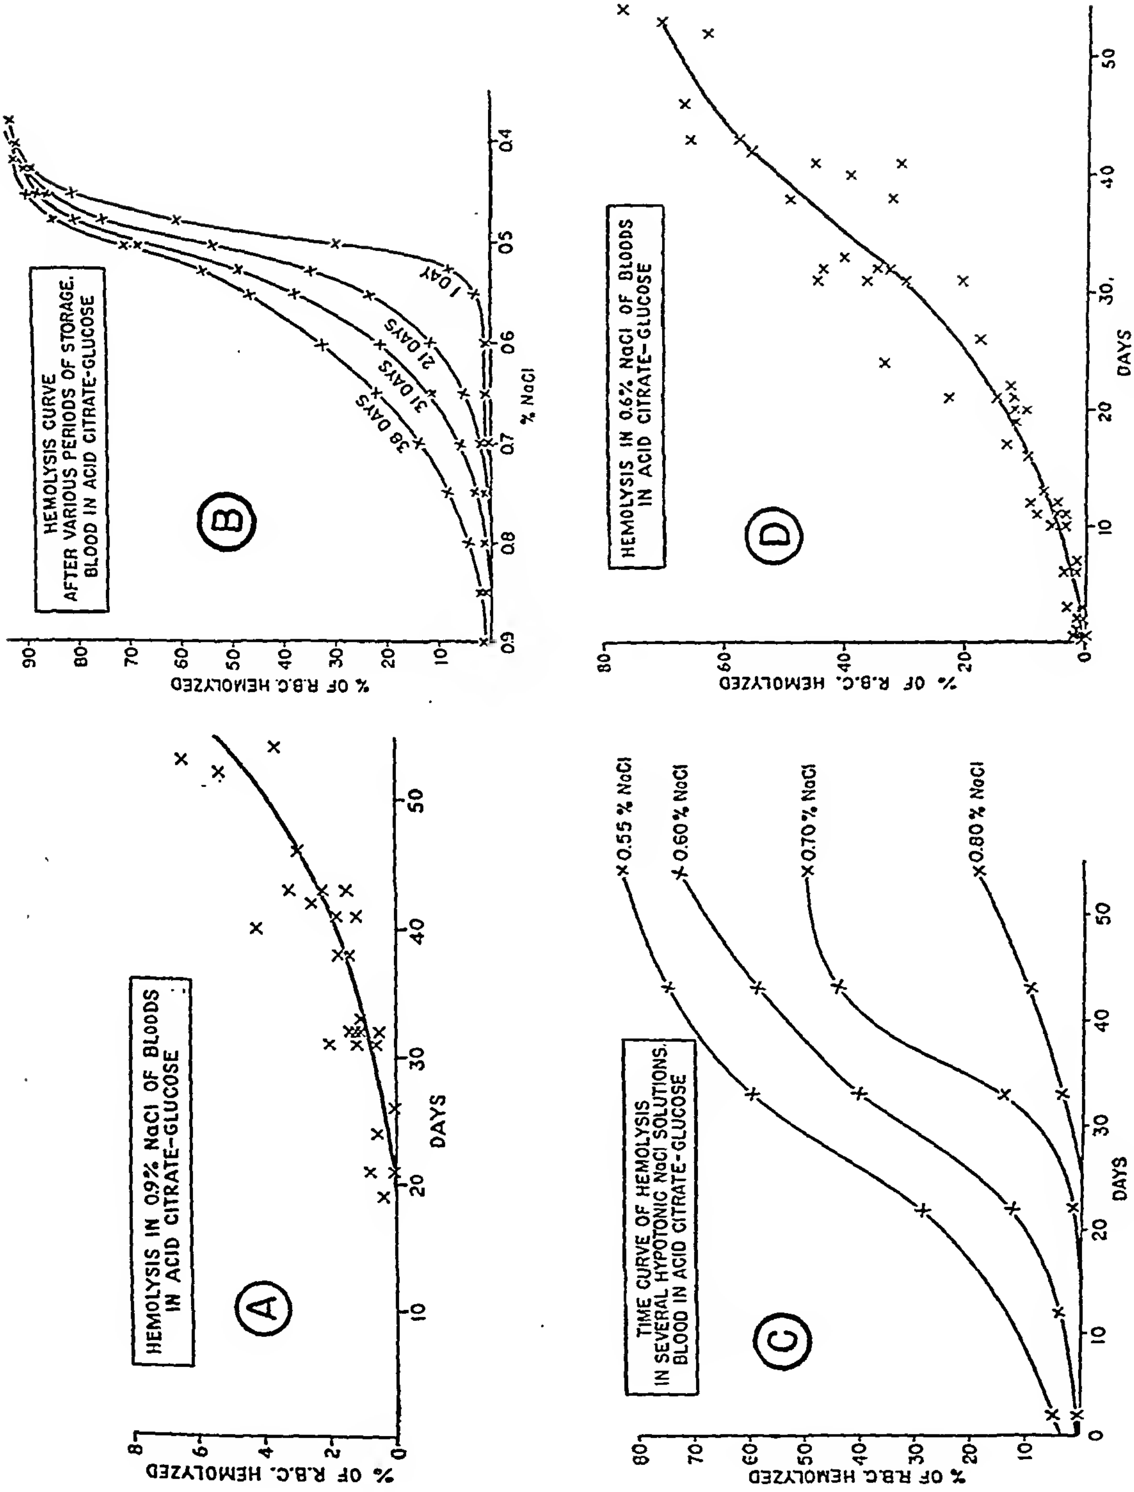

Fig. 5. Osmotic Hemolysis of Erythrocytes of Bloods Stored in Acid Citrate-Glucose Solution

to hemolysis in 0.9 per cent NaCl solution, it is evident that significant degrees of hemolysis were observed earliest and that hemolysis increased at the most rapid rate in simple citrate solution, while it was latest and slowest to increase in acid citrate-glucose.

From an inspection of the hemolysis curves it is apparent that, from being closely similar for all 3 preservatives at the outset, they changed during prolonged storage at different rates. The earliest and most rapid change occurred in the citrate and the slowest, in the acid citrate-glucose solution. An examination of the time curves of hemolysis in different hypotonic salt solutions, which lend themselves better for comparison, indicates that the 3 preservatives arrange themselves in the same order with respect to osmotic hemolysis as they did with regard to dimensional changes and hemolysis in 0.9 per cent NaCl solution.

It should be pointed out that the usual qualitative way of measuring fragility—noting only the points of beginning and of completed hemolysis—would have resulted in a highly misleading picture of the changes occurring, owing to the fact that a small proportion of the cells showed greatly increased fragility after a few days of storage, thus shifting the point of beginning hemolysis to a considerable extent, while the bulk of the erythrocytes was affected at a much later date. This consideration is of particular importance in the study of bloods collected in glucose-containing preservative solutions, where a minute fraction, less than 1.0 per cent, of the cells exhibited greatly increased fragility immediately following the collection of the blood, causing a shift in the point of beginning hemolysis to NaCl concentrations of 0.7 per cent or higher.

The data on hemolysis on 0.9 per cent NaCl solution presented here are comparable to those reported by others on "spontaneous" hemolysis (5, 7). With respect to hemolysis in hypotonic salt solutions, a pattern of change similar to that described here was observed by those workers who followed the percentage hemolysis of erythrocytes in a given salt solution during storage (5, 17, 30). However, different results were reported by those authors who used *median corpuscular fragility* (38), that is, the tonicity of a salt solution in which 50 per cent of erythrocytes are lysed, as a measure of the osmotic behavior of erythrocytes. This index is unsatisfactory because of the fact that great differences in the percentage of erythrocytes hemolyzed result from small variations in salt concentration. The *median corpuscular fragility* is susceptible to the influence of changes in temperature and pH and is affected by a number of minor variations of experimental technique (39). Workers who used this test observed marked alteration initially in bloods stored in various glucose-containing preservatives but noted also that this index changes more gradually with time in bloods preserved in acid than in neutral mixtures (4).

From a consideration of the data here presented one may exclude the hypothesis that hemolysis in 0.9 per cent NaCl solution, or so-called "spontaneous" hemolysis, can be due to osmotic factors. During storage the cells swell only by 10 per cent, far below their critical volume; and there is no relation apparent between the extent of the increase in volume and the degree of hemolysis. Other circumstances, such as lytic factors in the plasma, may account for the hemolysis of stored erythrocytes in nearly-isotonic media. The fact that spontaneous hemolysis increased with the period of storage may be explained on the assumption that the presumed lytic factors affected deteriorated cells only. If such were the case, the degree of spontaneous hemolysis would represent a measure of the degenerative processes taking place in the cells, affecting perhaps primarily the cell membrane.

Critical volume of hemolysis: Additional information concerning the process of osmotic hemolysis can be gathered from a comparison of expected and observed maximal (critical) volumes of the cells. The calculation of this cell characteristic is based on 2 assumptions: (*1*) that the cell membrane cannot be stretched, so that the mean surface area is constant for a given cell population, and (*2*) that the cells are capable of reaching the shape of a perfect sphere. Granted these assumptions, a cell could reach a maximal volume equal to that of a sphere possessing the same mean surface area. This point, the critical volume, would coincide with the beginning of hemolysis. Available data generally are in good agreement with this theory.

In column 5 of Tables III to V are tabulated for citrated blood the maximal volumes after various periods of storage, calculated on the basis of the

corresponding values for the surface area. It can be seen that during storage both observed and calculated maximal volumes, while agreeing reasonably well with each other, decreased from the initial values.

The tonicity of the salt solution at which maximum swelling occurred is tabulated in column 7 of Tables III to V. With increasing time of storage, maximal swelling took place at increasingly high concentrations of NaCl solution. The zone of maximal swelling which may be defined within narrow limits in fresh blood, became less clearly delimited and broader. On examining the data on the osmometric behavior as well as on the maximal volumes of the cells after extended periods of storage it should be remembered that they are not representative of the state of the cell population as a whole since they are descriptive only of cells remaining unhemolyzed, which by then may constitute half or less of the total cell population. In a comparison with respect to change in maximal volume of the erythrocytes, the 3 preservatives range themselves in the same order and at closely similar intervals, as they did in the preceding comparisons.

Two interpretations of the changes in the maximal volume during storage and of the coincidence of the calculated and observed figures may be offered: (*1*), that the surface area actually decreased during storage, with corresponding actual change in the maximal volume attainable by the cells and (*2*), that the apparent decrease of the surface area parallels in extent only the degree of crenation of the erythrocytes; in that case, the expected maximal volume should have remained the same throughout the storage period. The coincidence of the observed maximal volumes with the expected ones calculated on the basis of the apparent decrease of the surface area might be explained as a reflection of the loss of elasticity of the cell membrane, perhaps of its inability to unfold completely to an uncrenated form.

A comparison of hemolysis and volume change of the erythrocytes in hypotonic salt solutions with their maximal critical volumes suggests that during storage the erythrocytes became hemolyzed at volumes increasingly far below their calculated critical volumes. This behavior may signify that the cells, possibly owing to progressive deterioration of the elastic properties of the cell membrane, hemolyze before attaining the spherical shape.

In general, the osmotic properties of the erythrocytes suggest the conclusion that the functional state of the cell, perhaps more specifically that of the cell membrane, during storage becomes the limiting factor determining its behavior rather than the osmotic relationships between the cell and its surrounding medium.

Corpuscular volume: In the following, changes in the corpuscular volume of erythrocytes during storage will be considered from the standpoint of the osmotic relationships obtaining in blood. The discussion will deal with this problem under 2 headings: (*1*) the initial changes, calculated and observed, produced by the addition of preservatives and (*2*) the changes occurring during storage. In considering the first point, it may be useful to list the osmotic properties of the preservative solutions employed and their calculated effect on the electrolyte and osmotic concentration of blood. As may be seen from Table VI, the solutions varied considerably among themselves with respect to their composition: simple citrate preservative is a hypertonic solution with respect to total solutes as well as electrolytes, while citrate-glucose, although osmotically more concentrated, is actually

TABLE VI

Osmolarity of preservative solutions and resulting changes in the osmotic and electrolyte concentration of blood

Solution	Citrate	Citrate-glucose	Acid citrate-glucose
Sodium citrate, *mM. per liter*	109	73	45
Sodium citrate, *m. osm. per liter*	436	292	181
Citric acid, *m. osm. per liter*			22
Glucose, *m. osm. per liter*		278	167
Total osmolarity of solution, *m. osm. per liter*	436	570	370
Total osmolarity of solution, *per cent of initial blood tonicity*	141	184	119
Effective tonicity,* *m. osm. per liter*	436	292	203
Effective tonicity, *per cent of blood tonicity*	141	94	66
Osmolarity of blood after mixing,† *m. osm. per liter*	324	351	324
Osmolarity of blood after mixing, *per cent of initial*	104	113	104
Electrolyte concentration of blood after mixing, *per cent of initial*	104	99	92

* As effective tonicity is designated, this is the osmotic concentration of substances which permeate the cell-membrane very slowly, if at all. In this instance its value was calculated on the assumption that the electrolytes, but not glucose, conform to this condition.

† Calculated on the basis of an initial concentration of 310 milliosmols per liter of water in blood, and of a water content of 0.80 gram per gram of blood.

almost isotonic with blood in terms of effective tonicity, owing to the permeability of the cellular membrane to glucose. Acid citrate-glucose solution, which also contains a higher concentration of solutes than blood, is hypotonic with respect to its electrolyte content. The changes in the osmotic and electrolyte concentration of blood, listed in the same table, were calculated on the basis of an assumed initial water content of 0.80 gram per gram of blood, and an osmolarity of 310 milliosmols per liter of water in blood. In the first 2 columns of Table VII are listed observations on the corpuscular volume and on the cellular concentration of hemoglobin, expressed as percentage of simultaneously determined values on heparinized blood samples. It may be seen that the initial values for the corpuscular volume and the hemoglobin concentration of erythrocytes in both neutral preservatives agreed reasonably well with the predicted values, while the cells in the acid preservative were considerably more swollen. This difference is largely accounted for in terms of the Donnan theory by the additional effect of lowering of pH on the corpuscular volume of the cells. By the use of equations descriptive of the distribution of water between cells and plasma (40), acidification *per se* may be calculated to produce an increase in the corpuscular volume of erythrocytes of about 6 per cent.[2] While many of the values adopted for the calculation are approximations and while several factors have been neglected, it may be justifiably assumed that the variable of major importance is the ionic equivalency of hemoglobin which is determined by the value of cell pH. The cumulative effects of the changes in osmolarity and pH of blood in acid citrate-glucose solution would result in an increase of the corpuscular volume of erythrocytes of about 14 per cent, a value in good agreement with the observed one.

TABLE VII

Change in corpuscular volume during storage

The results represent the mean value, together with the standard error of the mean.

Solution	Storage period	Cells in own plasma: Corpuscular volume	Cells in own plasma: Corpuscular hemoglobin concentration	Volume of packed cells in 0.9 per cent NaCl
	days	*per cent of "normal"**	*per cent of "normal"**	*per cent of volume in plasma*
Citrate	0	97.6±0.6	104.0±0.4	111.7±1.4
	20–30	104.3±0.9	95.9±0.9	122.1±1.5
	Per cent change from initial value	+6.9±0.9	−7.8±0.9	+9.4±1.5
Citrate-glucose	0	99.3±1.2	101.2±0.5	111.0±1.2
	20–30	106.0±1.0	93.6±0.6	117.4±1.0
	Per cent change from initial value	+6.7±1.0	−7.5±0.6	+5.8±1.0

	20–40	113.0±0.3	89.3±0.7	108.5±0.4
	Per cent change from initial value	0.0±0.3	0.0±0.3	+8.5±0.4

* The values in heparinized blood samples have been designated as "normal."

[2] The theoretical changes in the water content of the plasma may be calculated by means of equations 23 and 24 of Van Slyke, Wu and McLean (40).

$$(23)\quad (H_2O)_s = (H_2O)_b \times \frac{2(B)_s - (BP)_s}{2(B)_b - (BP)_s - (BP)_c + (Hb)}$$

$$(24)\quad (H_2O)_c = (H_2O)_b \times \frac{2(B)_c - (BP)_c + (Hb)}{2(B)_b - (BP)_s - (BP)_c + (Hb)}$$

in which the parentheses denote units of substance per unit of whole blood, and the subscripts, s, c, b refer to plasma, cells, and whole blood, respectively. B, P, and Hb refer to the sum of cations, the non-diffusible anions, and the osmolarity of hemoglobin, respectively. The following assumptions and substitutions were used in applying this equation: It was assumed that all factors except for $(BP)_c$, by which the equivalency of the non-diffusible anions in the red cells is designated, did not change on acidification. A numerical value of 0.84 gram per ml. was assigned to $(H_2O)_b$, the water content of whole blood. An initial cell volume of 36 per cent was assumed. To $(B)_b$, the total cations of whole blood, a value of 138 meq. per liter was assigned, and to $(B)_s$ the cations of serum, a value of 93 meq. per liter. To $(BP)_s$, the ionic equivalency of the serum proteins, a value of 10 was given, on the basis of an assumed protein concentration of 7 grams per 100 ml. of plasma. For the hemoglobin portion of $(BP)_c$, an initial value of 16 was calculated on the basis of an assumed hemoglobin concentration of 5 mM. per liter, a cell pH of 7.20, and an iso-ionic point of reduced hemoglobin of 6.81 at 38° C. For the buffering power the value of Adair (41), 9.2 meq. per mol. of hemoglobin was adopted. The ionic equivalency of hemoglobin after acidification of the blood to pH values between 6.9 and 7.0 in the plasma was taken as zero, on the assumption of a cell pH at the iso-ionic point of hemoglobin. Constant values of 14 and 9, respectively, were given to the ionic equivalency of the organic phosphates and the osmolarity of the non-diffusible anions in the cells. Given these assumptions, a value of 0.603 gram of plasma water initially and of 0.566 after acidification was calculated. This transfer of water from the plasma to the cells would result in an increase of 6.0 per cent of the corpuscular volume of the cells.

During storage the corpuscular volume increased and the corpuscular hemoglobin concentration correspondingly decreased in bloods stored in the neutral solutions while these indices remained unchanged in bloods collected in the acid medium in which the cells from the outset had assumed an increased volume. It would appear that, in part, the change of the corpuscular volume in the neutral media during storage was due to the lowering of pH with a consequent shift in the distribution of water between cells and plasma, as predicted by the Donnan theory. However, it is evident that other factors are also involved, since the pH in the initially acidified blood continued to decrease without any further change in the corpuscular volume. This behavior will be discussed more fully in a later section dealing with the changes of cations.

Owing to the fact that during storage cations as well as anions permeate the cell membrane, the corpuscular volume of erythrocytes in their own plasma cannot be taken as an indication of alterations occurring in the total osmotic concentration of blood. In this connection it is of interest to compare the volume assumed by erythrocytes of stored blood suspended in 0.9 per cent sodium chloride solution with that observed in their own plasma. From such a comparison a rough indication of the osmotic content of erythrocytes may be expected on condition that in the brief periods of test the cations diffuse only slowly. In column 3 of Table VII are recorded data on the corpuscular volume of erythrocytes of stored blood suspended in 0.9 per cent sodium chloride, expressed as percentage of the simultaneously determined volume in their own plasma. It is apparent that even initially the volume of the erythrocytes in the neutral preservatives, but not in the acid one, exceeded the value measured in their own plasma. After prolonged periods of storage the difference between the 2 measurements increased in all 3 preservatives. The variable initial behavior of erythrocytes in 0.9 per cent sodium chloride does not appear explicable by known osmotic factors.

The explanation nearest at hand for the uniformly increased difference between the volume of erythrocytes in their own plasma and that in 0.9 per cent sodium chloride solution during storage appears to be that, with time, blood becomes increasingly hypertonic with respect to 0.9 per cent sodium chloride solution owing to the breakdown of larger molecules into smaller ones. Three processes occurring during storage which may influence the osmolarity of blood may be cited: (*1*) the accumulation of lactic acid, (*2*) the breakdown of organic phosphates and (*3*) decomposition of glutathione. These processes, detailed consideration of which would occupy too much space, may roughly be estimated to result in an increase of the osmolarity of blood by 5 per cent. This estimate falls below the actually observed change in the corpuscular volume in 0.9 per cent sodium chloride solution during storage, particularly so, when it is considered that some outward diffusion of solutes must take place during the brief exposures to 0.9 per cent sodium chloride solution.

CHEMICAL CHANGES

Plasma pH

The determination of pH was carried out at 37.5° C.; the values recorded in Figure 6 are therefore directly comparable to those customarily measured in biological studies. Under the experimental conditions, where loss of CO_2 owing to exposure to air could not be avoided, the results are of relative value only. The pattern and extent of the changes in pH were obviously related to the rate and amount of lactic acid production during storage, the cessation of the downward shift of pH in citrated blood coinciding with the disappearance of glucose, while in the glucose-enriched media exhaustion of the glycolytic power of the erythrocytes was the limiting factor.

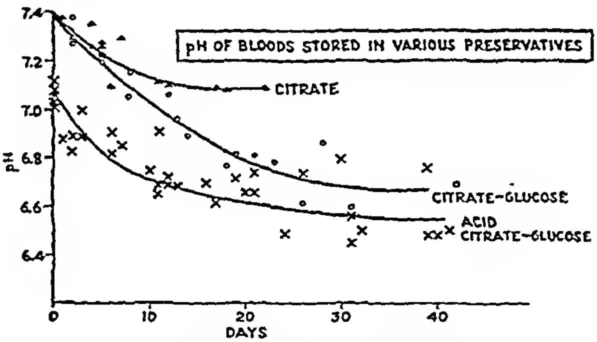

FIG. 6. pH CHANGES DURING STORAGE OF BLOODS STORED IN 3 PRESERVATIVE SOLUTIONS

In general, the pH change during storage in a given blood is dependent on the amount of lactic acid accumulating, on the one hand, and on the type and quantity of buffers present, on the other.

As lactic acid accumulates, CO_2 is lost from the blood in increasing measure, reaching levels as low as 6 meq. per liter after 10 days of storage in glucose-containing media. Among the buffers, hemoglobin is the most important, with phosphates and serum protein following in order. The effect of citrate ion on the ionic balance deserves some comment. The effect of trisodium-citrate on the buffering of the blood may be neglected under the initial conditions of storage, in view of the fact that the pK′ even of the third acid group of citric acid at 5.7 is too far removed from the normal pH of the blood to be of importance. The presence of citric acid in acid citrate-glucose mixture serves more to poise the blood at low pH values from the beginning than to change its buffering qualities, while the addition of tri-sodium citrate in this solution has a negligible effect on either pH or buffering. The great retardation in the rate of fall of pH during storage can be ascribed to 2 factors: (*1*) a decreased rate of glycolysis and with it of lactic acid accumulation and (*2*) the fact that the buffering power of the blood increases as it becomes more acid and is near a maximum at about pH 6.6. Phosphates, present in a concentration of 15 mM. per liter of erythrocytes at this pH, exert their maximum buffering effect, and hemoglobin, close to its iso-ionic point, begins to function as a cation. With lowering of pH the citrate buffering also increases in importance.

Blood sugar, lactic acid, and glycolysis

The sugar concentration of citrated blood, shown in Figure 7A, diminished swiftly, reaching levels of about 10 mgm. per 100 ml. on the eighth day of storage, such levels presumably representing residual nonfermentable reducing substances. The curve of the lactic acid accumulation, portrayed in the same figure, complements that of glucose disappearance. Together the 2 curves demonstrate within the limits of the methods used that glucose was entirely converted into lactic acid, which, once formed, remained unchanged during long periods of storage. In the glucose-enriched media, the glucose decreased by about 200 mgm. from an initial value of about 600 mgm. per 100 ml., the change occurring at a more rapid rate and terminating sooner in neutral, than in acid citrate-glucose. The curves of lactic acid accumulation (Figures 7C and 7E) presenting a complementary picture, with the rate and the final levels higher in neutral, than in acid, citrate-glucose solution.

As an over-all index of their metabolic condition, the glycolytic power of erythrocytes was tested by incubating blood samples for 90 minutes at 37° and measuring the amounts of lactic acid produced and glucose removed during such periods. For the study of the glycolytic faculty of the erythrocytes of citrated blood, which after a few days' storage is depleted of glucose, glucose solution was added before incubation. Inasmuch as no attempt was made to control the pH closely and since the rate of glycolysis is well known to be dependent upon the pH, being much greater at higher pH values, the results of the test have only limited quantitative significance. Individual measurements of rates of 10 mgm. or less per hour are of doubtful significance and attain importance only when evaluated statistically owing to limitations in the accuracy of the methods used. As shown in Figures 7B, 7D, and 7F the glycolytic activity of the erythrocytes ceased earliest in simple citrate and latest in ACD solution. It may also be seen that the erythrocytes had a higher initial glycolysis rate in the 2 neutral media than in the acid one.

The significance of glycolysis in the functioning of erythrocytes lies in the fact that glycolysis is the most important energy-yielding process occurring in the cells. Their oxygen consumption normally is minute, accounting for less than 10 per cent of the energy yielded by glycolysis. The weakness of the aerobic metabolism of erythrocytes is further illustrated by the virtual absence of the Pasteur effect, as indicated by the fact that glycolysis proceeds at essentially the same rate in oxygen as under anaerobic conditions (42). Before accepting the significance of the glycolytic process in the functioning of erythrocytes, one may consider the question of their metabolic energy requirements. These cells, after maturation from the reticulocyte stage, do not appear to undergo further development nor do they multiply. Their most impressive attribute is the biconcave form, which is maintained under a variety of conditions throughout their life. There has been considerable speculation regarding the mechanism for the maintenance of the characteristic form of erythrocytes (43). Generally 2 basic hypotheses have been advanced: (*1*) the existence of a rigid structure and

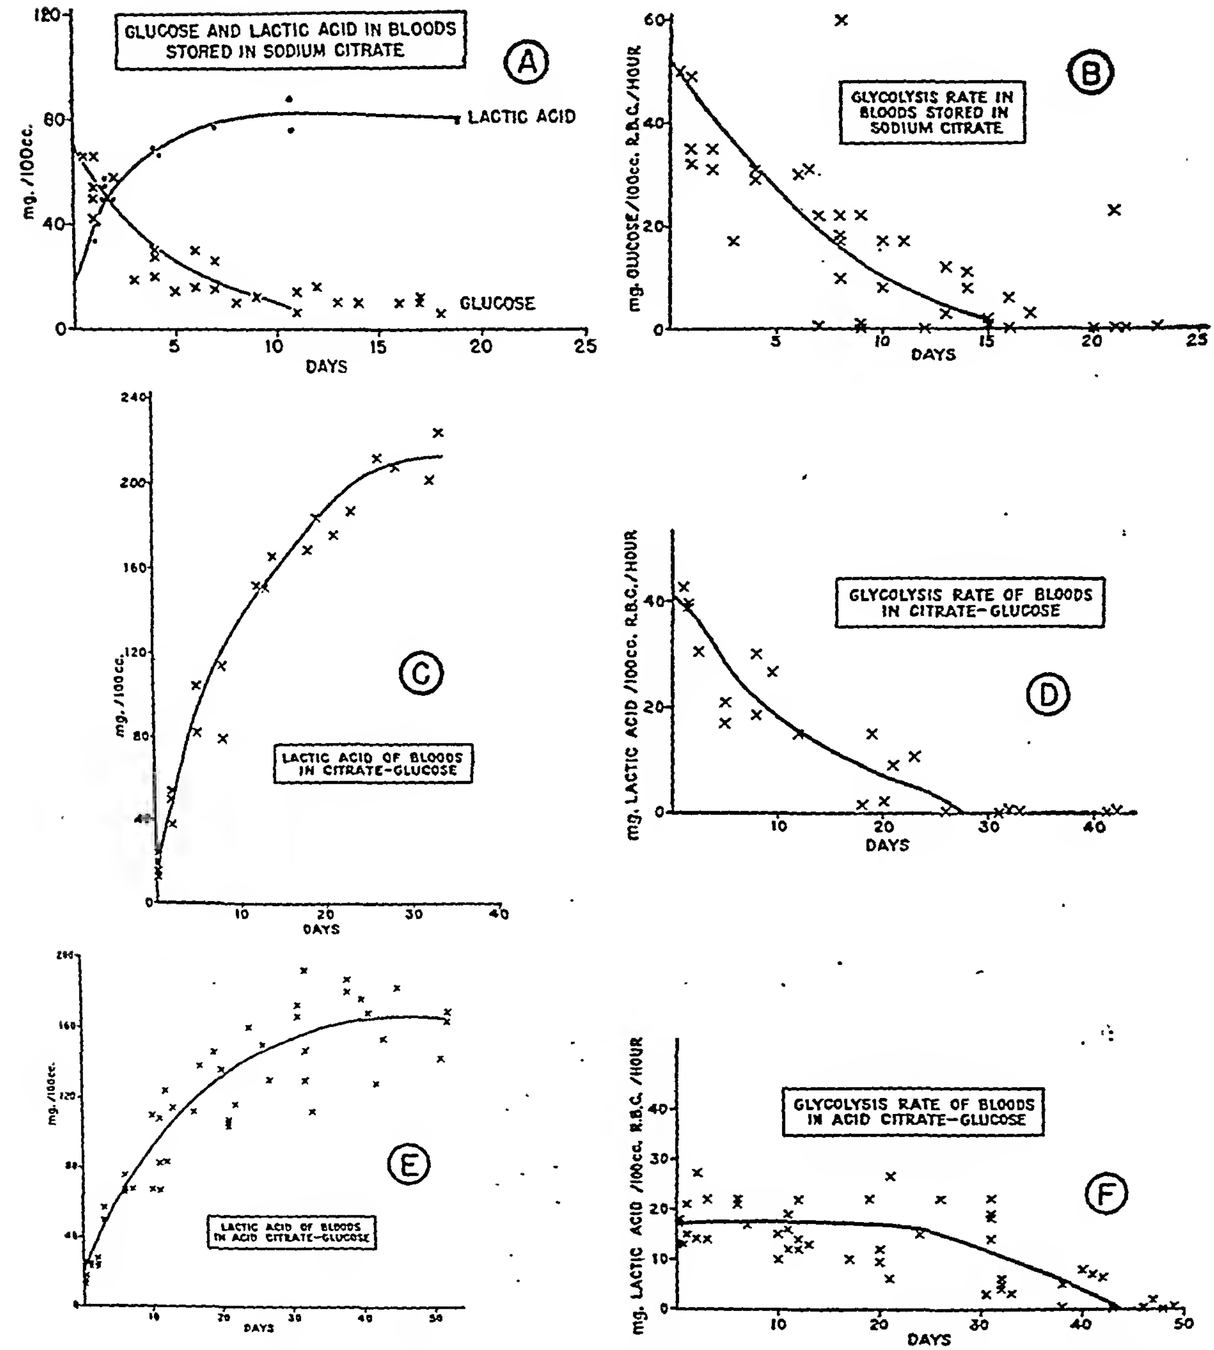

FIG. 7. CHANGES IN GLUCOSE, LACTIC ACID AND GLYCOLYSIS RATE OF BLOODS STORED IN 3 PRESERVATIVE SOLUTIONS

(2) a dynamic balance of forces resulting in constancy of the cellular shape. If, under most conditions, the erythrocytes do not possess a rigid structure, as is indicated by considerable evidence, the conclusion is inescapable that continuous expenditure of energy is required for the preservation of the biconcave form. An attractive hypothesis would then be that in part the function of the glycolytic process is to yield the energy required for the maintenance of the cellular form.[3] Ac-

[3] Assuming a surface tension of 60 dynes per cm., the energy required by a single cell would be in the order of

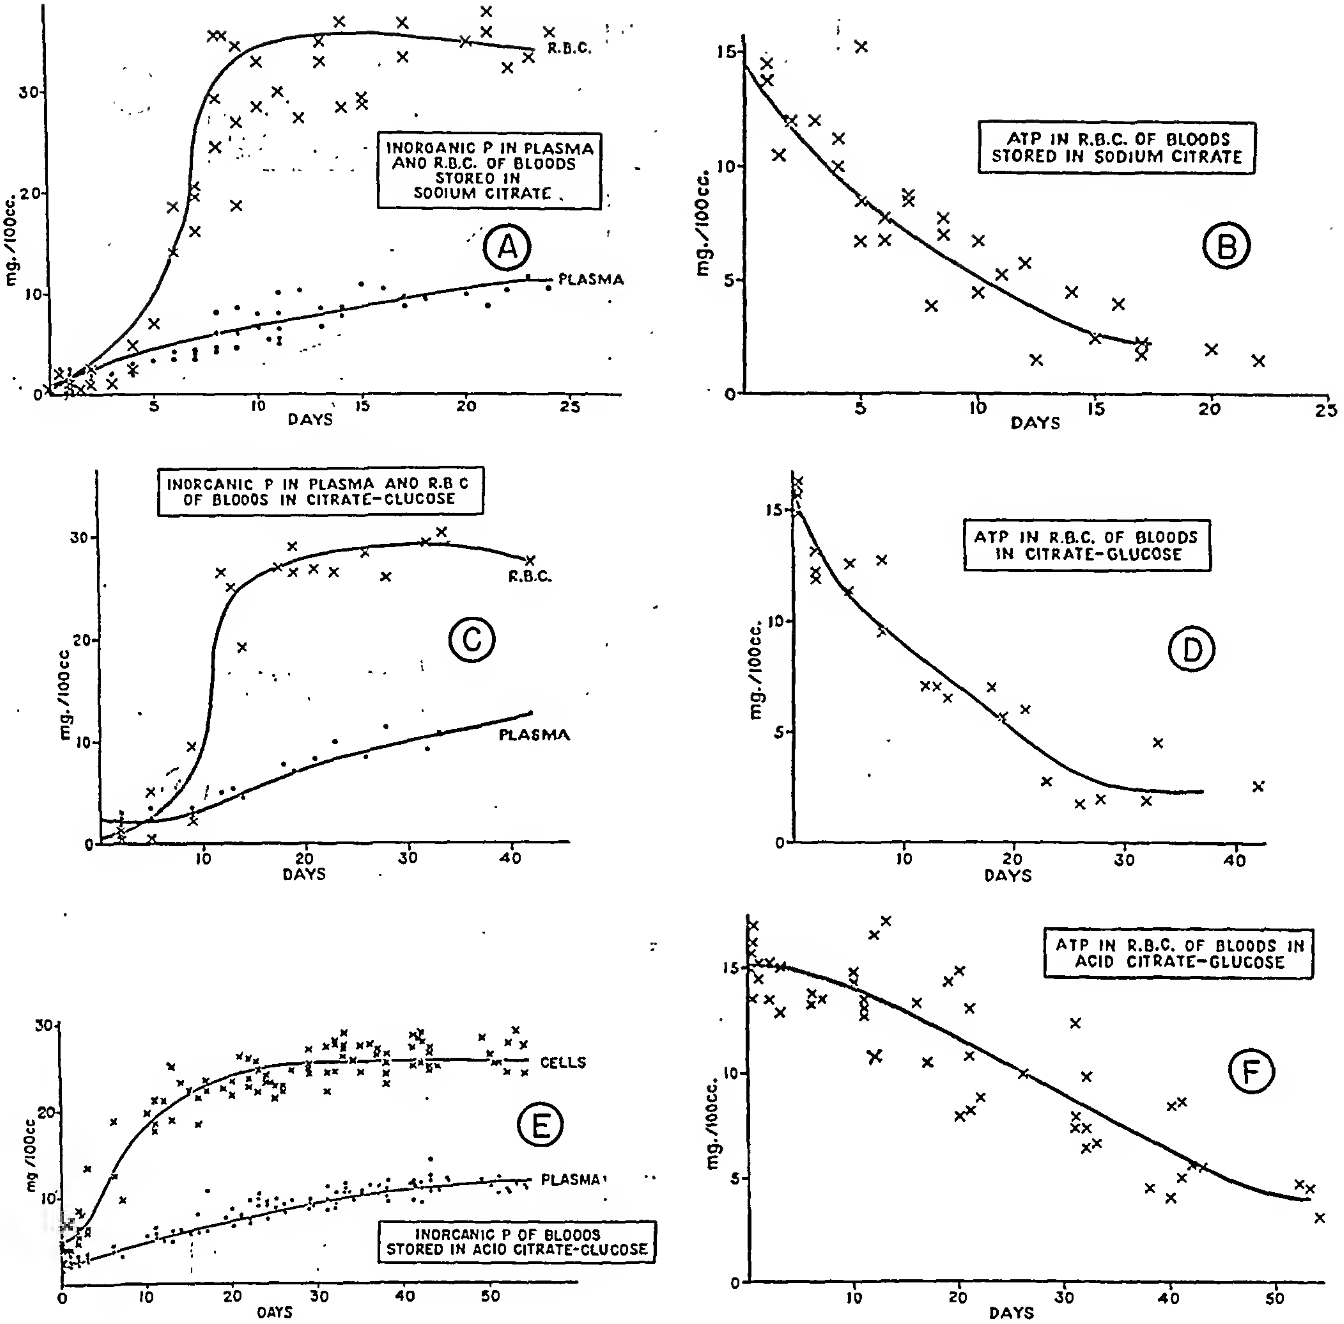

FIG. 8. CHANGES IN THE INORGANIC PHOSPHORUS DISTRIBUTION AND THE ADENOSINE TRIPHOSPHATE CONTENT OF RED CELLS DURING STORAGE OF BLOOD IN 3 PRESERVATIVE SOLUTIONS

cepting this premise, the similarity of patterns of dimensional and chemical changes and their close correspondence would reflect a causal relationship.

10^{-5} erg. Assuming a corpuscular volume of 90 micra^3, 100 ml. of cells would contain about 10^{12} erythrocytes, with an energy requirement of 10^7 ergs, that is about 0.25 cal. This would correspond to the energy yielded by glycolysis of about 2 mgm. of glucose per 100 ml. of cells. If the surface tension of the cell and plasma is less, as is indicated by some studies, the energy requirement would be correspondingly decreased.

Acid-soluble phosphorus compounds

Inorganic phosphorus in cells and plasma: The inorganic phosphorus in the red cells is shown in Figures 8A, 8C, and 8E. In the neutral media, it rose rapidly following a period of delay while in the acid medium, it rose from the start but at a lower rate. The inorganic phosphorus of the plasma in all media rose at an approximately linear rate.

Adenosine triphosphate: The fate of adenosine

triphosphate (ATP) during storage was of particular interest since this compound is an important co-enzyme of glycolysis. Data for this compound, calculated from the values for the easily-hydrolyzable phosphorus, are presented in Figures 8B, 8D, and 8F. It may be seen that it decreased most slowly in the blood stored in ACD solution.

Adenosine triphosphate was determined more specifically in several bloods as the easily-hydrolyzable phosphorus in the mercury precipitate of the trichloracetic acid filtrate. The results, not presented here in detail, indicated for citrated blood an initial concentration of about 12 mgm. per 100 ml. of cells diminishing to values below 2 mgm. after about 10 days of storage. The adenosine triphosphate changes in the glucose-enriched media bore the same relation to those in citrated blood as were given by the cruder method described previously. Studies were also carried out on the fate of the other components of the adenosine triphosphate molecule during storage besides that of the 2 easily hydrolyzable phosphate groups. Adenine, hypoxanthine, and purine nitrogen were determined in the whole blood and in fractions comprising nucleotides on the one hand and nucleosides plus free purines on the other. By following the pentose content of the mercury precipitate of the trichloroacetic acid extract, which contains all the nucleotide and a considerable proportion of the nucleoside, a rough measure of pentose combined with purine was obtained. The results, to be presented in detail elsewhere, indicated that the several parts of the adenosine triphosphate molecule underwent changes during storage according to differing patterns and at varying rates. The most rapid, and for the glycolytic process most critical change, was the loss of the 2 easily hydrolyzable phosphate groups. As a consequence, free adenylic acid accumulated. Adenine was deaminated to hypoxanthine, the conversion reaching as much as 80 per cent. The deamination seemed to be accompanied in each case by the loss of the third phosphate group, leading to the accumulation of hypoxanthine riboside after prolonged periods of storage.

Organic acid-soluble phosphorus: The changes in the organic acid-soluble phosphorus of the cells, which consists for the most part of a mixture of adenosine triphosphate and diphosphoglyceric acid, mirrored to a large extent those of inorganic phos-

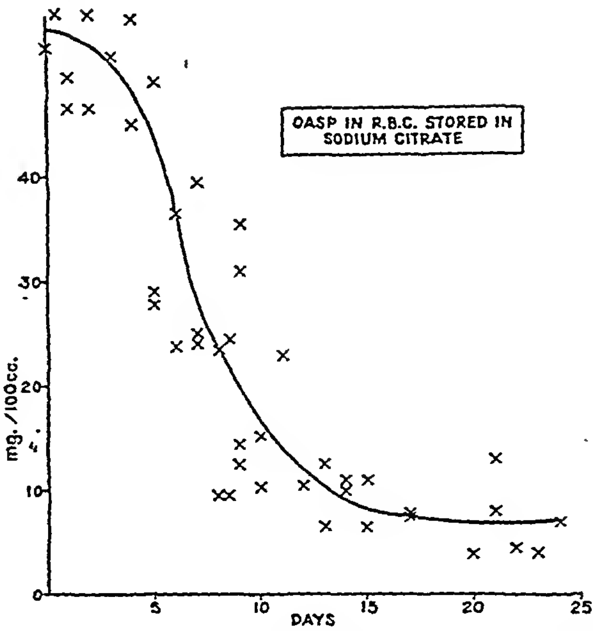

Fig. 9. Organic Acid Soluble Phosphorus in Blood
Stored in Sodium Citrate

phorus as shown for citrated blood in Figure 9

The total acid-soluble phosphorus content of all bloods remained unchanged even after the most extended storage periods (70 days), indicating that the phospholipids, which in mammalian bloods almost entirely account for the acid-insoluble phosphorus fraction, were not hydrolyzed under such conditions.

A discussion of the changes in the phosphorus distribution of blood during storage necessitates a sketchy review of the changes occurring during glycolysis at 37° C., and a brief consideration of the role of the phosphorus compounds in the intermediate reactions of the glycolytic process (44). The glycolytic system of the erythrocytes is distinguished by great sensitivity to changes of pH, the over-all rate of glycolysis increasing with elevation of pH. If glycolysis is allowed to proceed at pH values above 7.3, the inorganic phosphorus, following a brief period during which the level may decrease, steadily increases, at the expense primarily of adenosine triphosphate and later also of diphosphoglyceric acid. During incubation at pH values below 7.3, the inorganic phosphorus rises from the start at a rapid rate, while the adenosine triphosphate is maintained at a high level and the diphosphoglyceric acid diminishes swiftly (45). The resemblance beween the changes occurring

at 37° C. and those taking place in bloods during storage at low temperatures is obvious: In bloods collected in neutral media, a short period of unchanged or decreased levels of inorganic phosphorus is followed by a breakdown of both adenosine triphosphate and diphosphoglyceric acid, as judged by the data described earlier; in bloods stored in acid citrate-glucose, an immediate rise of the inorganic phosphorus goes hand in hand with the maintenance of high levels of adenosine triphosphate for considerable periods of time. Decreasing values of the total organic acid-soluble phosphorus were, by inference, accounted for by changes in the diphosphoglyceric acid.

In the light of modern concepts of the glycolytic process (45, 46, 47) the changes in the glycolytic rate and in the distribution of phosphorus compounds at varying pH values may be interpreted as follows: At elevated pH values glycolysis proceeds at a rapid rate, while the level of adenosine triphosphate tends to decrease; this indicates that under such circumstances the rate of esterification of glucose by adenosine triphosphate proceeds at a more rapid rate than does the rephosphorylation of adenylic acid. In acidified blood, where the glycolytic rate may be only one-third as great as normal the adenosine triphosphate is maintained at a higher level, indicating that rephosphorylation of adenylic acid keeps pace with the esterification of glucose. This balance is in part ascribable to the decreased over-all rate of turnover; in addition, under such circumstances diphosphoglyceric acid in decomposing furnishes an additional source of phosphorus for the re-synthesis of adenosine triphosphate. Since adenosine triphosphate appears less susceptible to irreversible deaminating attack than adenylic acid, circumstances leading to minimum concentrations of adenylic acid, such as prevail in acidified blood, tend to slow the rate of breakdown of the essential nucleotides.

From inspection of the data it becomes evident that the glycolytic power of the erythrocytes was still present to some extent at a time when most of the organic acid-soluble phosphorus had decomposed. The lack of correlation between the 2 indices suggests that only a small component of the organic acid-soluble phosphorus, perhaps the adenosine triphosphate, or a portion thereof, constitutes the limiting factor in the glycolytic process.

On the basis of the data presented one may venture the hypothesis that the maintenance of the functional state of the cell and of its various characteristics, dimensional, osmotic, and chemical, is dependent upon the glycolytic process which in turn is dependent on the intact functioning of the enzyme system concerned with it; adenosine triphosphate, or a compound determining its concentration, is of critical importance for the preservation of the glycolytic power of the erythrocytes. It may be surmised that only cells which by virtue of a functioning enzyme structure have the ability to recover their normal physical and chemical structure survive *in vivo*.

Potassium and sodium

The changes in the potassium content of serum and cells are portrayed in Figures 10A, 10C, and 10E. It can be seen that the potassium content of plasma of citrated blood increased in the beginning at the rate of about 2.0 meq. per liter per day and more slowly after longer periods, reaching a value halfway towards diffusion equilibrium in about 8 days. Half-diffusion-equilibrium values were reached after 12 days in citrate-glucose and after about 23 days in acid citrate-glucose. The changes of potassium in the cells in each case mirrored faithfully those occurring in plasma.

The sodium in plasma and cells, as shown in Figures 10B, D, and F, underwent in all solutions a change reciprocal to that of the potassium, but at a slower rate. A comparison of the 3 preservatives with regard to sodium leads to essentially the same conclusion as described above for potassium.

It is of interest to examine to what extent the exchange of potassium and sodium between cells and plasma follows the law of simple diffusion, particularly so, in view of the possibility that the normally existing inequality of the ionic concentrations between cells and plasma is maintained by metabolic processes. It would appear that the processes of ionic exchange, except for the first few days, may be described on the assumption of simple diffusion, with rates decreasing in order in citrate, neutral, and acid citrate-glucose solutions.

The changes in the ionic composition of blood during storage have obvious implications with regard to the general theory of permeability of the erythrocyte membrane. On the one hand, it appears that sodium and potassium exchange across the cellular membrane during storage (as indeed

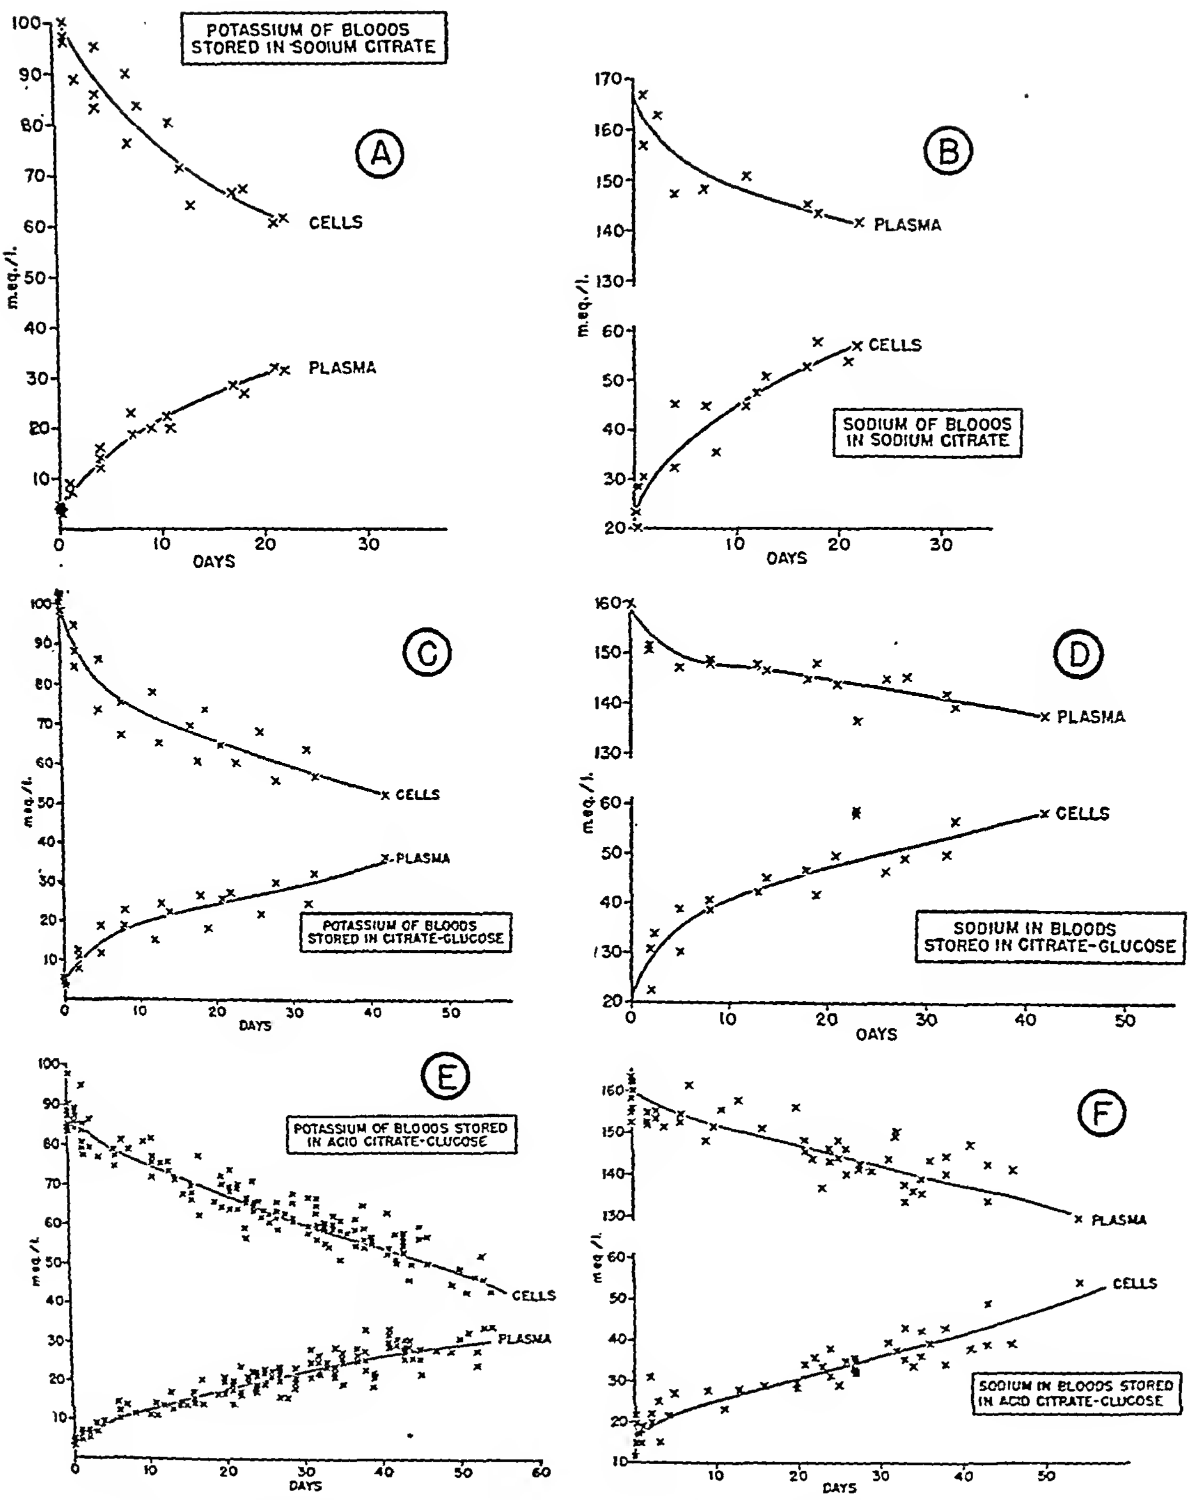

Fig. 10. Changes in Distribution of Potassium and Sodium between Plasma and Cells of Bloods Stored in 3 Preservative Solutions

in vivo, as shown by the radioactive tracer technique [48 to 50]); on the other hand, there exists considerable evidence which indicates that the exchange of water and anions between cells and plasma may be described by the Donnan theory on the postulate of non-permeability of the erythrocyte membrane to cations (40, 51, 52). In order to conciliate this apparent contradiction, it has been proposed that the cations exchange across the cellular membrane not by way of simple diffusion, but rather by means of a metabolic process. Such a hypothesis would also account for the unequal distribution of potassium and sodium between cells and plasma. The decrease of cellular potassium during storage may then be thought to be due to unfavorable conditions for the specific metabolic process concerned with the transfer of potassium so that the normally existing steady state is no longer maintained. According to another explanation which is not necessarily in conflict with the one just mentioned, the non-diffusibility of the cations may be due to some form of binding of the cations. However, existing data indicate that at least 90 per cent of the cell water is "free," that is, osmotically active, and that the degree of osmotic activity of cations in the cells does not differ markedly from that in the plasma. It is still conceivable that there exists within the cells a restraining influence which, while preventing the free outward diffusion of cations, interferes little with their osmotic activity. This hypothesis gains interest in line with observations to be presented in the following paragraphs.

In view of the intimate connection between the electrolyte concentration and the water content of the cells, it is of interest to examine the changes during storage in the total concentration of cations. In Table VIII are presented the mean values for the sum of sodium and potassium, taken to represent the total cations, observed on blood in acid citrate-glucose solution initially and after periods of storage of 20 to 40 days. The concentrations in cells and plasma are recorded in meq. per liter of each, and per kgm. of water. On either basis, it it evident that the cells in acid citrate-glucose solution actually lost cations during storage. This loss apparently occurred in a manner that left the water distribution, and with it the cellular volume, unchanged. The amount of cation transferred from cells to plasma agrees well with the value calculated from the ionic equivalency of hemoglobin when the water content of the cells remains constant. This is also shown in the table. The behavior of the erythrocytes suggests that their corpuscular volume in acidified blood is maintained by a graded transfer of cation in apparent proportionality to the increased ionization of hemoglobin as a cation. To explain the unexpected behavior the following hypothesis may be tentatively adduced: assuming that the apparent non-diffusibility of cations across the cellular membrane is caused by some restricting interaction, perhaps a molecular force existing between the cations and other components within the cell, one may reason

TABLE VIII

Distribution of cations between cells and plasma during storage of blood in acid citrate-glucose solution

The results are expressed as the mean, together with the standard error of the mean.

	*p****	0.001	<0.05	
	Calculated value** *meq. per liter*	−12	+7	

* A constant value of 0.743 gram per ml. was calculated for the cell water by means of the formula

$$H_2O_c = 94.53 - 0.704\ Hb_c$$

where Hb_c indicates the concentration of hemoglobin in gram per 100 ml. of cells, on the basis of a measured hemoglobin concentration of 30.0 grams per 100 ml. The plasma water was assumed to be 0.95 gram per ml.

** These values were calculated by means of equations and assumptions described earlier, on the basic premise that the water distribution between cells and plasma remained constant during storage and that the only variable was the ionic equivalency of hemoglobin, for which the values given by Adair (41) were used. For the calculation of the initial values of cell and plasma water it was assumed that the blood in the beginning was at a pH close to the iso-ionic point of hemoglobin. As may be seen, the values calculated on this rough approximation were in fairly good agreement with the observed values. Given an acidification to a pH in the plasma of 6.50 during storage, the changes in the distribution of cations in plasma and cells were calculated with the same values for the serum and cell water as assumed initially.

*** p = the percentage chance that a deviation as great or greater than that observed would arise by chance alone; any value of p 0.05 or less is usually accepted as indicating a significant difference.

that the hemoglobin cation competes with the monovalent cations, displacing them from positions previously occupied, perhaps by virtue of its greater size. The displaced monovalent cations, no longer restrained, would then freely leave the erythrocyte. Since diffusible anions would enter the cell in direct proportion to the cationic ionization of hemoglobin and an equal proportion of cations becoming diffusible would leave the cell constant osmolarity and therefore constant water content would be maintained. According to this hypothesis, therefore, erythrocytes would tend to maintain constant volume below the iso-ionic point of hemoglobin, by means of loss of cations in direct proportion to the ionization of hemoglobin as a cation.

STATISTICAL COMPARISON OF 5 INDICES OF BLOOD PRESERVATION

In Table IX are presented data based on 96 blood samples on the degree of association among the 5 indices of blood stored in 3 preservative solutions. The table contains values for the regression equations and correlation coefficients between percentage hemolysis in 0.6 per cent NaCl solution, which (as the most precise measurement) was chosen as the basis of comparison on the one hand and the 4 other indices on the other. It may be seen that for each of the preservative solutions close association existed between the alterations of hemolysis in 0.6 per cent NaCl solution and the changes of any of the 4 other indices, the only exception being glycolysis of blood in simple citrate, the values for which were rather variable. An inspection of the data indicates that the absolute values of the regression coefficients were of similar magnitude in all 3 preservatives. Similarity in the relative rates of change of all 5 indices in the 3 preservatives is indicated by the highly significant values for the regression and correlation coefficients for the pooled values. In Table X are recorded for the purpose of close comparison the differences among the several regression coefficients for the 3 preservative solutions. It may be seen that except for 2 values, the differences between the several regression coefficients were of small magnitude. When the individual regression coefficients in each of the 3 preservative solutions were compared with the pooled estimate, no statistically significant difference was apparent in any instance.

The similarity of the regression functions with change in hemolysis for the dimensional, metabolic, and chemical characteristics of the red cell in the 3 solutions of widely differing preservative qualities indicates that the several indices displayed similar relationships among each other despite great variations, up to 4-fold, in the rate of change with time. The data as a whole represent indirect evidence of close interdependence of physical, osmotic, and chemical properties of the red cell.

DISCUSSION

From a review of the composite findings presented, it appears that a number of apparently unrelated properties of the erythrocyte undergo

* p = percentage chance that a deviation as great or greater than that observed would arise by chance alone; any value of p 0.05 or less is usually accepted as indicating a significant difference. The bold-faced figures indicate significant differences.

changes in a characteristic manner during storage. These alterations follow a similar pattern in each of the 3 preservatives studied. A brief listing of the cellular characteristics which changed in a critical and characteristic manner during storage may be useful at this point. They were: (*1*) hemolysis in several concentrations of NaCl solution from 0.9 per cent down, (*2*) dimensional changes of the erythrocyte, *i.e.*, in diameter, thickness, and surface area, (*3*) glycolyzing power, (*4*) adenosine triphosphate content, and (*5*) change in the distribution of potassium. Not all physical or chemical properties of the cell followed this pattern; for instance, the corpuscular volume appears to be determined by the osmotic and ionic relationships existing between cells and serum rather than by the functional state of the cell. The liberation of inorganic phosphorus and alterations of the glutathione content belong also in the group of cellular properties, which did not change in a manner which can be correlated with the preservation of the red cell. Such differences in behavior suggest that, while some of the cellular properties are intimately related to the metabolic activity of the cell and reflect its functional state, others do not bear such a relationship. To some extent, the division may be artificial and dependent on the scale and method of measurement adopted. This is illustrated by the conflicting experiences with the use of osmotic hemolysis as an index of blood preservation.

Comparison of in vitro *and* in vivo *tests*

The practical importance of *in vitro* data hinges on their close correlation to the *in vivo* survival of erythrocytes. In order to compare the results reported here with the *in vivo* behavior of stored blood, the data on the percentage survival of erythrocytes 7 days after transfusion obtained (6) by a differential agglutination method have been charted in Figure 11. The preservatives tested by

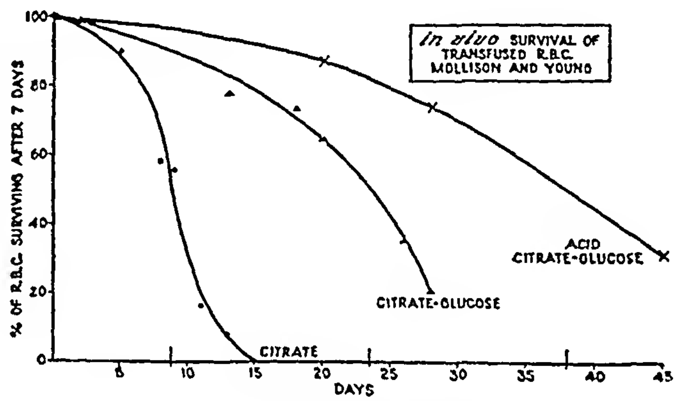

FIG. 11. *In vivo* SURVIVAL OF ERYTHROCYTES OF BLOODS STORED IN 3 PRESERVATIVE SOLUTIONS ACCORDING TO DATA OF MOLLISON AND YOUNG (6)

the British workers, except for the use of a higher concentration of citrate in the neutral media, were closely comparable to those studied here. Similar results have been obtained by the use of radioactive iron for the direct measurement of the survival of the erythrocytes (Gibson, Ross). The close correspondence between *in vitro* and *in vivo* results indicates the practical usefulness of *in vitro* methods and supports the initial hypothesis of close interrelation between many properties of the red cell.

The principal applications of *in vitro* methods appear to be two: first, as preliminary procedures for the screening of preservative solutions before they are submitted to definitive testing by established *in vivo* methods. Their rapidity, sensitivity and accuracy, make them well suited for this purpose. As to accuracy, one advantage lies in the fact that only the variability of the donor comes into play, whereas *in vivo* testing is affected by the cumulative variabilities of donor and recipient.

Second, *in vitro* methods have their widest field of use in the investigation of the mechanism of deteriorative processes of the cell and constitute therefore the basis for rational elaboration of improved preservative techniques. For instance, they already appear to furnish some understanding of the apparent advantage of the addition of glucose and of acid to blood. Their failure under certain conditions to reflect the functional state of the cell is perhaps more an index of the deficiencies of our understanding than a general argument against their validity. The employment of a series of indices for the description of the preservation of the red cell should help to guard against the danger of reliance on any single index, which under certain experimental conditions may prove to be a fallacious guide.

Practical considerations

While the length of preservation appears of paramount importance in the selection of preservative solutions, other factors merit attention in the consideration of the practical usefulness of any preservative. Among these may be mentioned: (*1*) ease of sterilization of the preservative solution, (*2*) extent of dilution of the blood, (*3*) suitability for the subsequent preparation of fluid or dried plasma, and (*4*) possible deleterious effects of ingredients of the preservative solutions proposed. For instance, with respect to the first point, neutral citrate-glucose solution, which requires a special technique to prevent caramelization of glucose, is at a disadvantage compared with simple citrate solution. ACD solution on the other hand may be sterilized as simply as citrate solution alone. In view of the superiority of this solution with respect to the longevity of red cells, the subsequent discussion will be limited to consideration of its merits and demerits. Its use entails a dilution of blood to the extent of 25 per cent, so that the concentration of protein in the plasma is reduced to about 5.1 grams per 100 ml., assuming an initial concentration of 7 grams per 100 ml. and taking into account the swelling of the erythrocytes. The protein concentration of plasma of blood in simple citrate, calculated on the same assumption, is about 5.8 grams per 100 ml. With respect to the preparation of dried plasma, some increase in drying time may be expected owing to the presence of glucose in acid citrate-glucose solution. The possibility of deleterious effects of the acidification of blood may be dismissed on theoretical grounds as well as on the basis of practical experience. Injection of an organic acid, which is easily metabolized in the body with the production of CO_2, in amounts such as are added to blood, may be confidently expected not to produce an appreciable effect on the ionic equilibrium of the blood of the recipient. Direct experiments on this point have been carried out (6). A comparable condition exists in any stored blood, where the amounts of lactic acid accumulated are about as much as the amounts of citric acid added. In summary one may therefore say that, while acid citrate-glucose solution produces a somewhat more dilute plasma and may give rise to minor difficulties in the production of dried plasma, its greatly superior preservative qualities make it the preservative solution of choice.

SUMMARY

On the basic premise that the erythrocyte represents a functional unit, with closely interdependent physical and chemical properties, which in turn are related to its viability, a study of dimensional, osmotic, and chemical changes of blood stored in 3 preservative solutions was undertaken. The preservatives studied were: (*1*) simple citrate solution, (*2*) a neutral, and (*3*) an acid citrate-glucose (ACD) solution. The results of this investigation may be summarized as follows:

(*1*) During storage red cells undergo a change in their dimensions in a characteristic and critical manner; their thickness increases, their diameter decreases, and their apparent surface area is reduced. These alterations are interpreted as manifestations of progressive deterioration of the cell. They progress most rapidly in blood in simple citrate, and most slowly in blood in acid citrate-glucose solution. Changes in the corpuscular volume appear to be determined by physico-chemical relationships and not to be related to the functional state of the cell.

(*2*) Osmotic hemolysis of erythrocytes becomes similarly altered in a progressive manner during storage, at a rapid rate in simple citrate and most slowly in acid citrate-glucose solution.

(*3*) The plasma pH decreases to a value of 7.1

in simple citrate solution, and to a value below 6.6 in the glucose-enriched media in direct relation to the amount of lactic acid accumulated.

(*4*) The ability of the red cells to glycolyze is lost first in simple citrate solution and is preserved longest in acid citrate-glucose solution.

(*5*) The inorganic phosphorus increases sharply in the red cells, with corresponding decrease of the organic acid-soluble phosphorus, but changes in a more gradual manner in the plasma. Adenosine triphosphate, a co-enzyme of blood glycolysis, is preserved considerably longer in blood in ACD solution than in the 2 neutral media. Maintenance of adenosine triphosphate appears of importance for the preservation of the metabolic function of erythrocytes.

(*6*) Decreases of potassium and increases of sodium in erythrocytes reported by others have been confirmed. During storage the total cation content of erythrocytes decreases. This fact and the constancy of the corpuscular volume of erythrocytes in ACD solution during storage are interpreted as indicating loss of cations on the acid side of the iso-ionic point of hemoglobin, in direct proportion to the dissociation of hemoglobin as a cation, with the osmolarity of the cells remaining constant.

Judged by various indices the state of erythrocytes of citrated blood after 8 days is approximately equivalent to their state in neutral citrate-glucose after 18 days and in ACD solution after 33 days.

It would appear that *in vitro* testing has its place in the study of preservation of erythrocytes (*1*) as a useful preliminary procedure for the screening of preservative solutions before these submitted to definitive testing by direct measurement of their survival *in vivo*, and (*2*) as a useful tool in the development of improved methods of blood preservation on a rational basis.

ACD solution is recommended for practical use.

ACKNOWLEDGMENT

I should like to thank primarily Dr. G. M. Guest for his interest and encouragement; discussion with him provided the initial stimulus for this investigation. I am greatly indebted to Dr. P. Hoxworth, Director of the Blood Bank of the Cincinnati General Hospital, for his help in obtaining blood samples and generously providing the facilities of the blood bank, and to Mrs. E. W. Brown for her advice in the statistical planning and her aid in the statistical analysis of the data. I am grateful to Mrs. M. G. Moore, Mrs. B. Hobson, Mrs. M. S. Mellette, and Miss E. Foy for technical assistance and to Mrs. D. Vergon and Miss A. Hobson for help in the preparation of the manuscript.

DIMENSIONAL, OSMOTIC, AND CHEMICAL CHANGES OF ERYTHROCYTES IN STORED BLOOD. II. EVALUATION OF SEVERAL ACID AND NEUTRAL PRESERVATION MIXTURES. EFFECT OF STORAGE AT 25° C. IN ALSEVER'S SOLUTION [1]

By S. RAPOPORT

WITH THE TECHNICAL ASSISTANCE OF MARY WING

(From the Children's Hospital Research Foundation and the Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati)

(Received for publication August 31, 1946)

In this communication are summarized several phases of a program aimed at assessing the value of *in vitro* methods for gauging and improving preservative techniques (1). A series of experiments is reported on the effect on the preservation of erythrocytes of variations in the extent of dilution and acidification from the original acid citrate-glucose (ACD-I) solution (2, 3). The experiments yielded only negative results. They are reported as a record for other workers in the field and because they bear on the theory of permeability of the red cell. A second phase deals with a comparison between ACD-I and Alsever's solution (4) with respect to the preservation of red cells, undertaken because of the extensive use of Alsever's solution by the United States Army in the European Theater of Operations. Because it was claimed that blood can be stored satisfactorily without refrigeration in Alsever's solution (5) an experiment on the effect of storage at 25° C. on the preservation of red cells was also included. Finally, a few data are reported on the *in vitro* changes of blood stored in De Gowin's (6) and McGill II (7) solution. These neutral solutions entail dilution of blood to the extent of 150 and 50 per cent, respectively.

Since many of the changes observed in this study are similar to those reported in the preceding communication, the report for the most part is limited to 5 indices: (*1*) hemolysis in 0.6 per cent NaCl solution, (*2*) increase of thickness, (*3*) changes in adenosine triphosphate content, (*4*) glycolysis rate and (*5*) potassium concentration of cells. In addition, calculations and data on the osmotic characteristics of the preservatives studied and the changes in corpuscular volume of erythrocytes are presented.

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Children's Hospital of Cincinnati.

METHODS AND MATERIALS

The technique of collecting and distributing the blood samples and the analytical methods used have been described previously (1).

TABLE I

Composition of acid citrate-glucose mixtures for the preservation of whole blood

Mixture	Na citrate*	Citric ac.*	Glucose*	Citr. ac. / Na citr.	pH	Vol. added to 100 ml. blood	Plasma pH
	grams per 100 ml.	*grams per 100 ml.*	*grams per 100 ml.*	*Molar ratio*		*ml.*

ACD-IF	1.33	0.60**	3.00	0.49		25	7.05

* Tri-sodium citrate $\cdot 2H_2O$, citric acid $\cdot H_2O$, glucose anhydrous.
** Lactic acid.

In Table I is shown the composition of the various ACD solutions studied. It may be seen that they covered a range of dilution of blood from 10 to 25 per cent, which is the most useful range and of pH from 7.0 to 6.8. In solution ACD-IF, citric acid was replaced by an equivalent amount of lactic acid with a view to exploring the possibility that accumulation of lactic acid may represent the limiting factor in the preservation of red cells. The composition of De Gowin's and McGill II solutions has been given in the literature (4, 6, 7) and is therefore omitted. A few words of comment with regard to Alsever's solution may be in order: This solution as originally described had the composition: sodium citrate 0.57,

sodium chloride 0.42, dextrose 1.87 grams per 100 ml. to be added in equal volume to blood. During the war the Baxter company modified it as follows: sodium citrate 0.80, sodium chloride 0.42, dextrose 2.05 grams per 100 ml., with the addition of 0.0075 gram of citric acid, resulting in a pH of the mixture of 6.8. This modification, designated simply as Alsever's solution in the following discussion, was the one studied in this laboratory. Later the same company modified the solution still further by adding sufficient citric acid to bring the pH to 6.0.

RESULTS

In Figure 1 is shown a comparison of McGill II and De Gowin's solution and of several variants of ACD–I solution with ACD–I mixture, portrayed graphically by plotting the values of each of the simultaneously determined indices in the solution under test against the corresponding values of the same blood in ACD–I solution. In the case of equal performance the plot will lie on a straight line equidistant from abscissa and ordinate, *i.e.*, the diagonal. Such lines are drawn in each of the graphs. For the properties of the red cell which show a tendency to increase in numerical value during storage, such as thickness, hemolysis, and potassium content of plasma, an arrow-point directed away from the origin is provided, while for those properties which tend to decrease during storage, such as the adenosine triphosphate and potassium content of cells and their glycolysis rate, the arrow is pointed toward the origin of the diagonal. The data on bloods stored in solutions inferior in preservative quality to ACD–I mixture would tend to be above the diagonal for cell characteristics which tend to increase in numerical value during storage and below it for those which tend to decrease. It may be seen that erythrocytes in McGill II solution were inferior in preservation to those in ACD–I solution with respect to hemolysis in 0.6 per cent NaCl solution, thickness, adenosine triphosphate and potassium content. With respect to glycolysis the data require additional interpretation. Erythrocytes in McGill II solution, as in other neutral mixtures, initially glycolyze at a rate greater than those in ACD–I solution, but their glycolyzing power is exhausted sooner. The values for McGill II solution lying above the diagonal line refer to blood samples after only short periods of storage, while those below the line refer to bloods stored for longer periods of time, when their glycolyzing power was exhausted, while it still persisted in a parallel blood sample in ACD–I solution. The data on the potassium content of the plasma appear to be at variance with the other indices but it should be remembered that blood stored in McGill II solution is diluted to the extent of 50 per cent, entailing an almost 2-fold dilution of the plasma. Data on hemolysis of red cells in De Gowin's solution are omitted from presentation since the osmotic behavior of erythrocytes in this solution differs markedly from that in the other solutions tested. Values for other properties of erythrocytes in this solution are also somewhat difficult to interpret because of the great increase in their cellular volume. Those charted have been corrected for the increase in volume. It appears that the cells in De Gowin's solution increased progressively in thickness during storage and that their adenosine triphosphate content and glycolyzing power became exhausted earlier than in parallel blood samples stored in ACD–I solution. The potassium content of the cells decreased at a rapid rate, probably because of the low content of electrolyte of the solution, while the potassium content of the plasma, which represents a 3.5-fold dilution of the original, was lower than in all other solutions. Solution ACD–IA, the most concentrated modification of ACD–I mixture, appears also somewhat inferior to ACD–I solution in its performance, as judged by hemolysis, thickness, and glycolysis rate. Other indices did not show significant differences. The comparatively good preservation of blood in solution IF, which contains lactic acid in amounts equal to those accumulated during extended periods of storage, although inferior to ACD–I, suggests that lactic acid *per se* is not an important deteriorative factor. None of the other solutions tested appeared significantly different in preservative quality from ACD–I solution.

In Figure 2 are shown the changes of red cells during storage at 4° and 25° C. in Alsever's solution and at 4° C. in ACD–I mixture. It may be seen that erythrocytes of blood in Alsever's solution were similar in their preservation to those in ACD solution until about the fourteenth day when both were kept at 4° C. Beyond this time they deteriorated at an increasingly rapid rate. The effects of storage of 25° C. are apparent in regard to all indices studied, storage for 2 days at this temperature being approximately equivalent to 2 weeks storage at 4° C. It may be mentioned

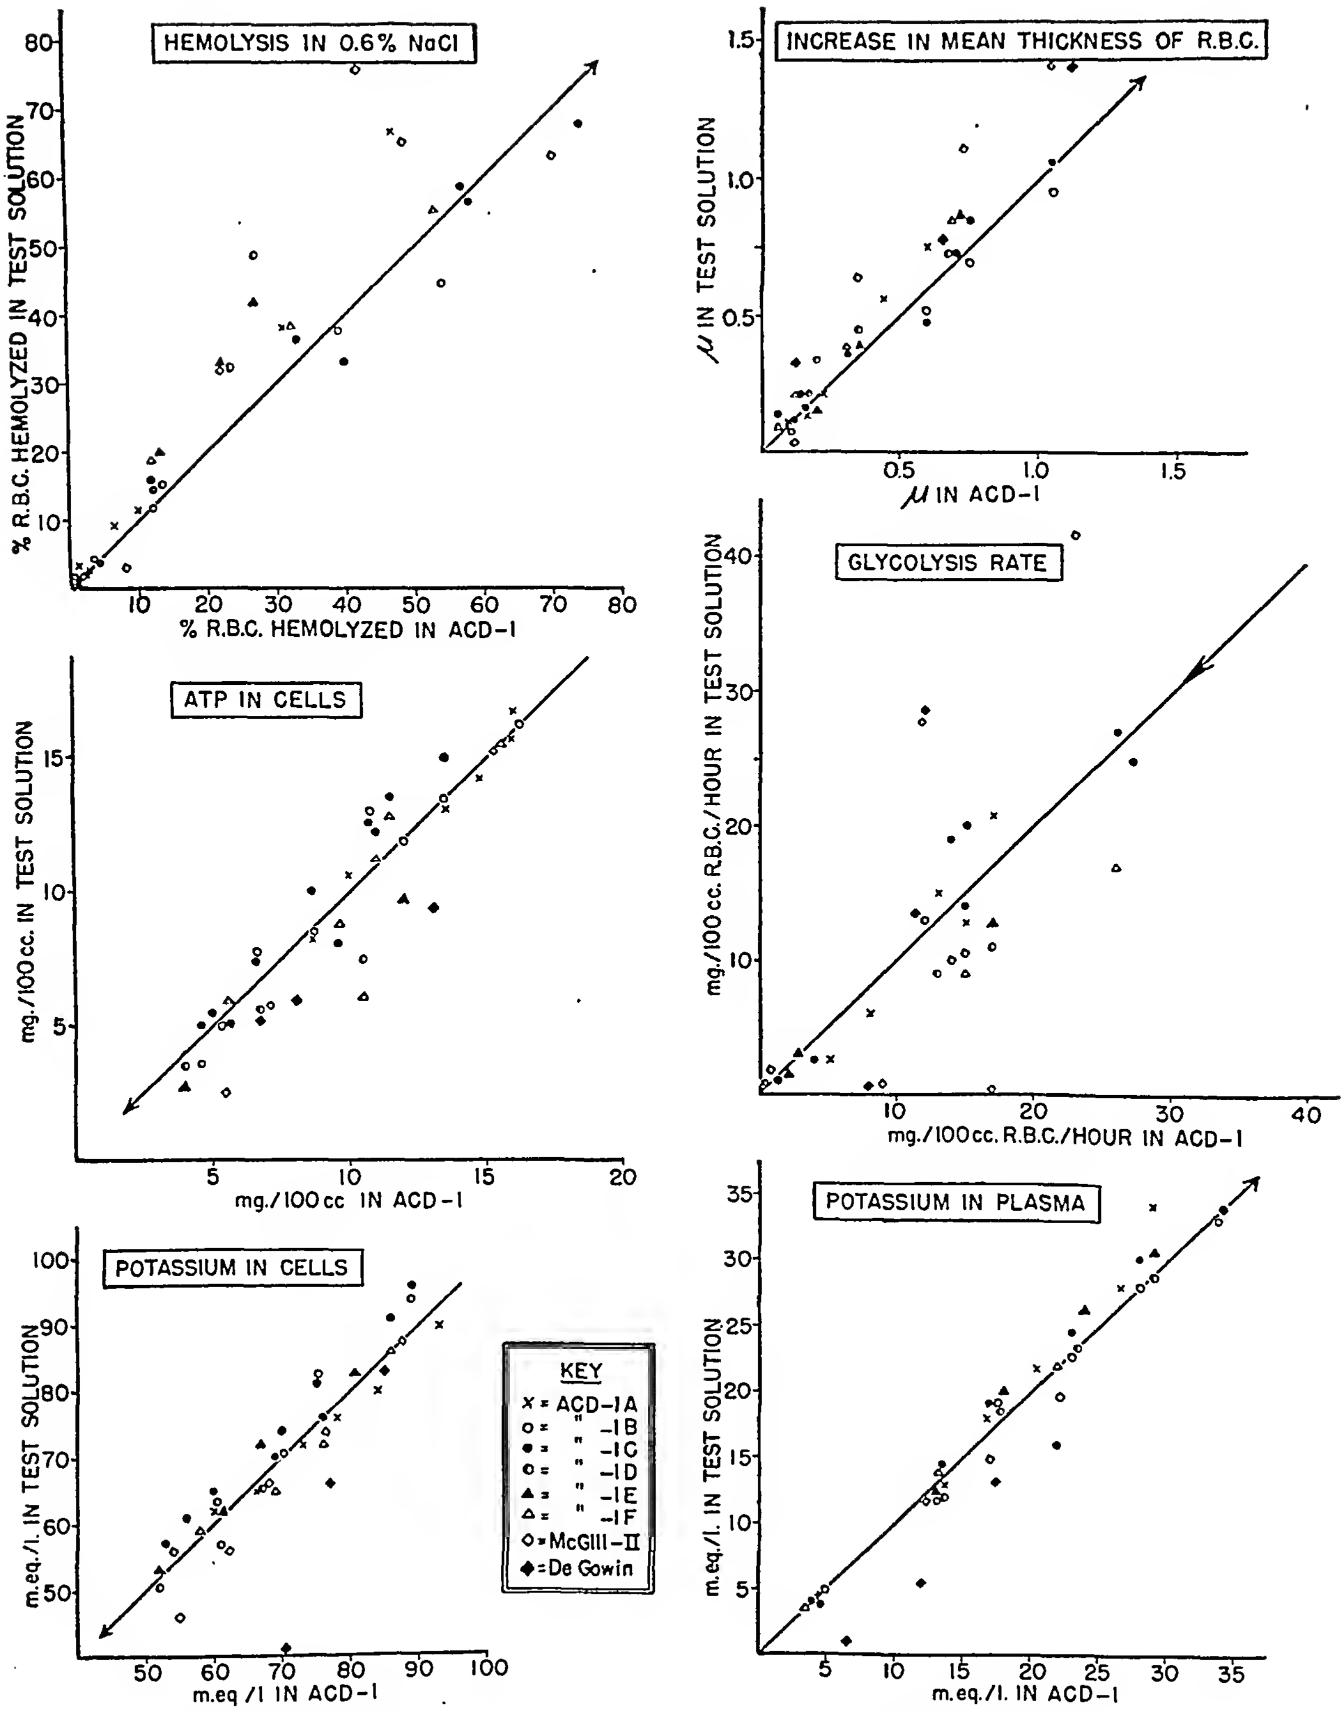

Fig. 1. Comparison of Several Acid and Neutral Citrate-Glucose Solutions with ACD-I Solution.

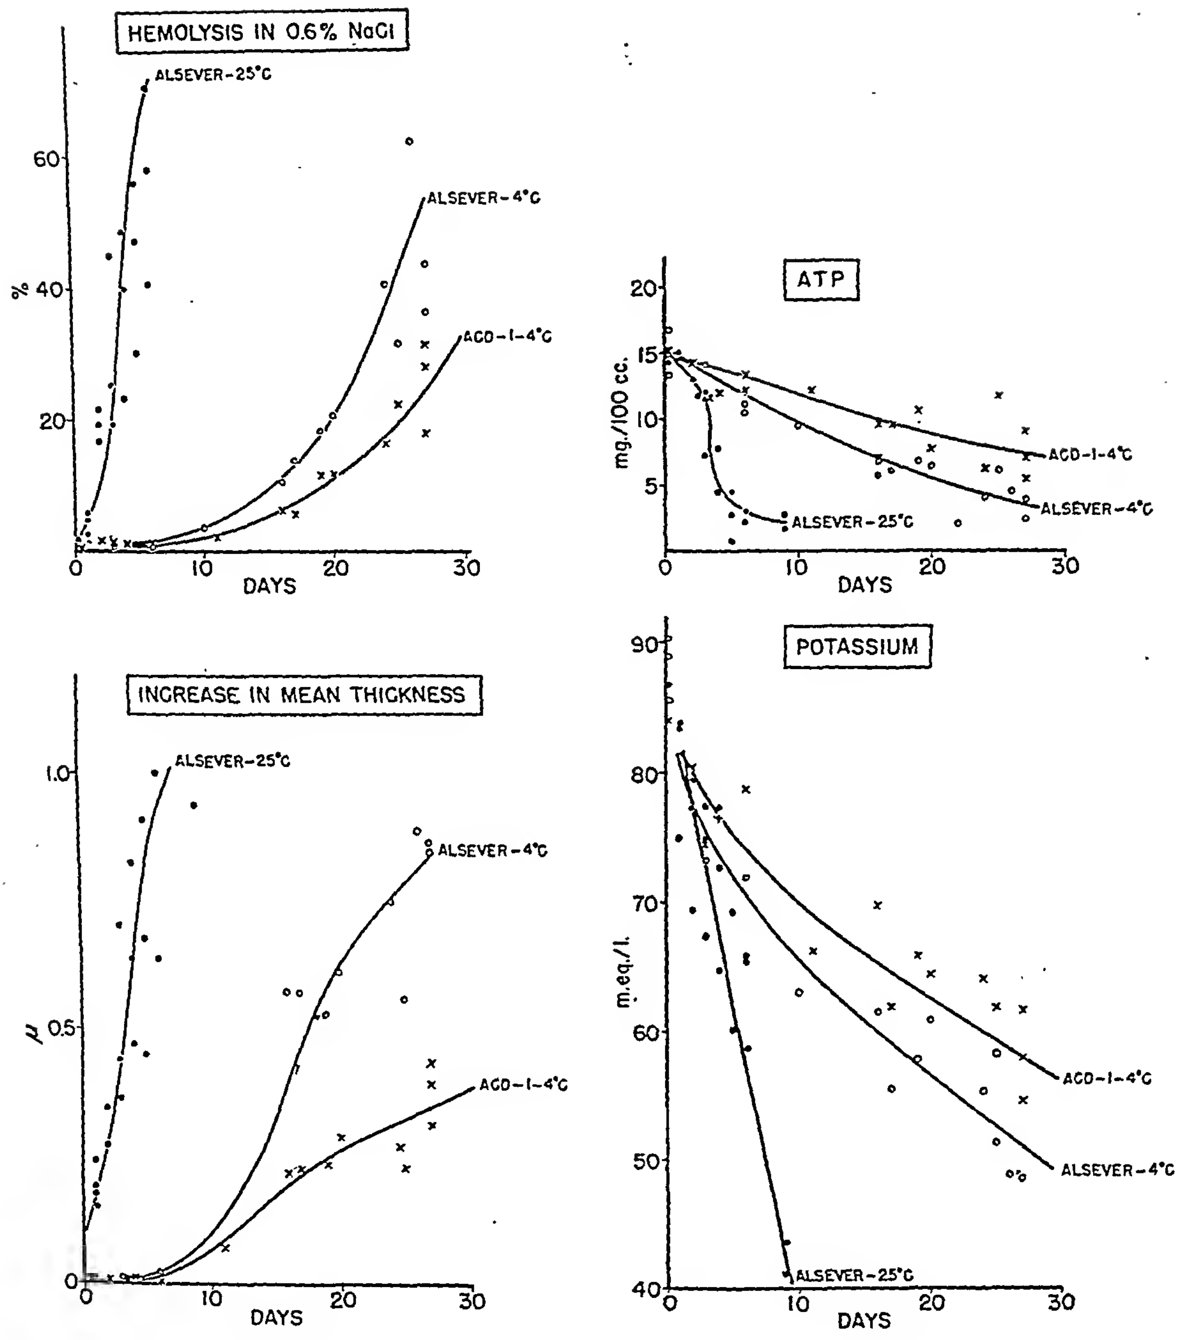

FIG. 2. CHANGES IN CELLULAR INDICES IN ALSEVER SOLUTION AT 4° AND 25° C. AND IN ACD-I SOLUTION AT 4° C.

here that even after storage periods of 10 days at room temperature spontaneous hemolysis was of small degree, indicating that this measurement is a fallacious index under such circumstances. From the data the conclusion may be drawn that non-refrigeration has a catastrophic effect on the functional state of the cell.

Osmotic characteristics of preservative solutions and corpuscular volume of erythrocytes

In Table II is given a description of the various ACD mixtures and in Table III, of the neutral preservatives from the standpoint of their osmotic and electrolyte composition. In Table IV is pre-

sented a summary of the predicted and observed values of corpuscular volume and hemoglobin concentration of erythrocytes of stored bloods in 5 acid and 3 neutral preservative solutions. As may be seen from the data, agreement between observation and theory was close for all solutions which differed in a minor degree only from the tonicity of blood. The results indicate that osmotic effects and membrane equilibria affect independently and in a strictly additive manner the corpuscular volum of erythroycytes. The constancy of the cell volume during storage in all acidified solutions and the limited increase in the neutral ones are in consonance with the hypothesis, that cations on the acid side of the iso-ionic point of hemoglobin are lost from the cell in proportion to the ionization of hemoglobin.

TABLE II

Osmolarity of various ACD preservative solutions and resulting changes in the osmotic and electrolyte concentration of blood

ACD solution	I	IA	IB	IC	ID	IE
Sodium citrate, *mM. per liter*	45	112	38	68	30	64
Sodium citrate, *m. osm. per liter*	181	450	152	272	120	255
Citric acid, *m. osm. per liter*	22	55	30	37	38	50
Glucose, *m. osm. per liter*	167	418	167	278	167	278
Total osmolarity of solution, *m. osm. per liter*	370	923	349	587	325	583
Total osmolarity of solution, *per cent of initial blood tonicity*	119	298	113	189	105	188
Effective tonicity,* *m. osm. per liter*	203	505	182	309	158	305
Effective tonicity, *per cent of initial blood tonicity*	66	163	59	100	51	98
Osmolarity of blood after mixing,** *m. osm. per liter*	324	378	319	354	314	353
Osmolarity of blood after mixing, *per cent of initial*	104	122	103	114	101	114
Electrolyte concentration of blood after mixing, *per cent of initial*	92	107	90	100	88	100

* Effective tonicity is designated the osmotic concentration of substances which permeate the cell membrane very slowly, if at all. In this instance its value was calculated on the assumption that the electrolytes, but not glucose, conform to this condition.

** Calculated on the basis of an initial concentration of 310 milliosmols per liter of water in blood, and of a water content of 0.80 gram per gram of blood.

TABLE III

Osmolarity of 3 neutral preservative solutions and resulting changes in the osmotic and electrolyte concentration of blood

Solution	Alsever	DeGowin	McGill II
Sodium citrate, *mM. per liter*	27	14.5	44

* The values in heparinized blood samples have been designated as "normal."

SUMMARY

In a study of 6 acid preservative solutions, none was found which exhibited better preservative qualities than ACD–I solution. There was some indication that one of the modifications, which was hypertonic, resulted in inferior preservation of erythrocytes. Lactic acid did not appear to be a deteriorative factor of major importance.

A comparison of Alsever's solution with ACD–I solution indicated that it possessed inferior preservative qualities. The effect of storage of blood at 25° C. in Alsever's solution was a great acceleration of deteriorative processes within the red cell.

A study of the osmotic characteristics of the various preservative solutions and of the corpuscular volume of erythrocytes indicated that addition of Alsever's and McGill II solutions resulted in only minor deviations of the electrolyte concentration of blood from the normal, while the addition of De Gowin's solution produced a decrease of the electrolyte concentration to less than ½ of normal with profound changes in the osmotic behavior of the cells. The observed corpuscular volume of erythrocytes in 5 acid and 2 neutral preservatives was in good agreement with predictions based on consideration of the osmotic and membrane equilibria of the red cell and on the assumption that red cells lose cations below the iso-ionic point of hemoglobin in amounts proportional to its ionization as a cation.

DIMENSIONAL, OSMOTIC, AND CHEMICAL CHANGES OF ERYTHROCYTES IN STORED BLOOD. III. COMPARISON OF 3 DILUTIONS OF ACID CITRATE-GLUCOSE SOLUTION (ACD) [1]

By S. RAPOPORT

WITH THE TECHNICAL ASSISTANCE OF MARY WING

(*From the Children's Hospital Research Foundation and the Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati*)

(Received for publication August 31, 1946)

Previous studies have indicated that acid glucose-citrate solutions provide the best preservation available at the present time (1). The mixture proposed by Loutit and Mollison (2, 3), conventionally called ACD–I in the United States, has been most extensively studied and appears unsurpassed in its preservative qualities. It is added in amounts of 25 ml. per 100 ml. of blood. The study to be reported was undertaken with the aim of defining the minimal amount of acid citrate-glucose diluent compatible with optimal preservation of blood. With this in mind a comparison was instituted among 3 acid citrate-glucose solutions so adjusted as to produce the same degree of acidity and the same citrate concentration as is achieved with ACD mixture, even though they were added in amounts of 15, 20, and 25 ml. per 100 ml. of blood (originally designated ACD–G, H, K). On the basis of previous data which indicated that only about 0.2 gram of glucose were glycolyzed by 100 ml. of blood during the usual storage periods, the glucose content of these solutions was reduced to ½ of that in ACD–I. Since the anticipated differences between the preservatives were small compared with the variability between individual bloods, the experiment was conducted with special attention to randomization of the variables concerned. By its arrangement this study afforded an opportunity to assess the variability among different bloods treated in the same way and to compare it with the variability among several samples of one blood treated in a different way.

EXPERIMENTAL

From each of 6 healthy male volunteers samples of blood were drawn and collected aseptically in 3 different acid citrate-glucose solutions. The samples were then distributed into vials and stored in a previously described manner (1). The 18 blood samples available were tested over a period of 22 days (from the twenty-second through the forty-third day of storage), each blood sample being examined twice during the period.

The analytical methods used have been described previously, except for the procedure for estimating glycolyzing power of blood, which was modified with a view toward simplifying the measurement by determining glucose disappearance instead of lactic acid accumulation and rendering it more sensitive by increasing the pH of the blood sample during incubation.

The solutions used, the composition of which is listed in Table I, were made up on the basis of the following considerations: The concentration of glucose was adjusted so as to give a final constant increment of 0.3 gram per 100 ml. of blood mixed with the preservative solution. The concentration of sodium citrate was calculated in a similar way with the design of keeping the final concentration of citrate ion constant. In order to obtain the same pH value of about 7.0 in all bloods, the concentration of citric acid was varied so as to make the amount added to 100 ml. of blood constant. This adjustment was based on the consideration that the amount of citric acid required to bring a blood to a desired pH value is dependent on the buffering properties of blood, principally of its erythrocytes, but is unrelated to the final volume of dilution.

TABLE I

Composition of preservative solutions

Mixture	Na citrate*	Citric acid*	Glucose*	pH	Volume added to 100 ml. of blood
	grams per 100 ml.	*grams per 100 ml.*	*grams per 100 ml.*		*ml.*
ACD–15 (ACD–G)	1.98	0.78	2.30	4.90	15
ACD–20 (ACD–H)	1.58	0.59	1.80	4.96	20
ACD–25 (ACD–K)	1.33	0.47	1.50	5.03	25

* Tri-sodium citrate $\cdot 2H_2O$, citric acid $\cdot H_2O$, glucose anhydrous.

TABLE II

Osmolarity of preservative solutions and resulting changes in the osmotic and electrolyte concentration of blood

Solution	ACD-15	ACD-20	ACD-25
Sodium citrate, *mM. per liter*	67	54	45
Sodium citrate, *m. osm. per liter*	270	215	180
Citric acid, *m. osm. per liter*	37	28	22
Glucose, *m. osm. per liter*	128	100	83
Total osmolarity of solution, *m. osm. per liter*	435	343	285
Total osmolarity of solution, *per cent of initial blood tonicity*	140	111	92
Effective tonicity,* *m. osm. per liter*	307	243	203
Effective tonicity, *per cent of initial blood tonicity*	99	78	66
Osmolarity of blood after mixing,** *m. osm. per liter*	330	317	304
Osmolarity of blood after mixing, *per cent of initial*	106	102	98
Electrolyte concentration of blood after mixing, *per cent of initial*	100	96	92

* Effective tonicity is designated the osmotic concentration of substances which permeate the cell membrane very slowly, if at all. In this instance its value was calculated on the assumption that the electrolytes, but not glucose, conform to this condition.

** Calculated on the basis of an initial concentration of 310 milliosmols per liter of water in blood, and of a water content of 0.80 gram per gram of blood.

TABLE III

Corpuscular volume and hemoglobin concentration of erythrocytes stored in 3 dilutions of ACD solution

Preservative solution	Corpuscular volume		Corpuscular hemoglobin	
	μ	*per cent of "normal"**	*grams per 100 ml.*	*per cent of "normal"**
Heparin	89.0±1.4		34.0±0.4	
ACD-15	95.3±0.4	107	31.8±0.4	94
ACD-20	97.9±0.8	109	31.3±0.4	92
ACD-25	99.5±0.8	112	30.6±0.2	90

* The values in heparinized blood samples have been designated as "normal."

The osmotic characteristics of the solutions employed are given in Table II. In Table III are summarized data on the initial corpuscular volume and hemoglobin concentration of erythrocytes in the 3 preservatives. The results are in good agreement with the hypothesis previously discussed (1).

During storage the corpuscular volumes remained unchanged at their respective values, despite increasing acidification of the blood, a finding which, if interpreted in a manner similar to that used previously, indicates escape of cations from the red cell in amounts proportional to the degree of ionization of hemoglobin as a cation.

RESULTS

From an inspection of the data in Figures 1 to 4 it is evident that the 3 dilutions of ACD solution differed in no respect from one another. Moreover there was no significant difference in any of the indices between the present series of experiments and those carried out previously with an acid citrate-glucose solution of double content of glucose (ACD-I).

The data on the regression lines of the individuals indicate that the differences between them were many-fold greater than the differences encountered between different samples of blood of 1 individual. Such data signify clearly, on the one hand, the advantages of comparing preservatives on one blood, and, on the other hand, the variability that may be expected when bloods of different individuals are compared. With *in vitro* testing the variability arises from differences among donors alone; it may be surmised that even greater differences will be found by chance alone, when *in vivo* tests are carried out under conditions where the cumulative variations of donor and recipient exert their influence.

DISCUSSION

The data presented clearly indicate that ACD-15 (ACD-G) solution is in no way inferior to the ACD solution originally described. In addition, the new solution has the advantage of entailing less dilution of blood, with the result that the final plasma protein concentration, calculated on the assumption of an initial concentration of 7 grams per 100 ml., is about 5.8 grams per 100 ml., that is, essentially the same as that in plasma of citrated blood. The explanation for the equality of the plasma protein concentrations in the 2 media lies in differences in the volume assumed by the erythrocytes. While the cells in citrate shrink by about 4 per cent, those in ACD-15 solution swell by about 7 per cent. The water shifts in opposite direction tend to cancel the existing difference of 5 per cent in the dilution of blood. A second advantage of ACD-15 solution as compared with the old acid citrate-glucose mixture is the reduced amount of glucose, which should lessen the difficulties in the preparation of dried plasma.

SUMMARY

In a comparison of 3 dilutions of ACD solution it was found that the extent of dilution of blood may be reduced to 15 ml. per 100 ml. without affecting the preservation of red cells; also, that the amount of glucose may be reduced to ½ of that in

the original ACD-solution. A greater variability among bloods of different individuals as compared with different blood samples of one individual has been demonstrated.

DIMENSIONAL, OSMOTIC, AND CHEMICAL CHANGES OF ERYTHROCYTES IN STORED BLOOD. IV. CELLS SEPARATED FROM PLASMA[1]

By S. RAPOPORT

WITH THE TECHNICAL ASSISTANCE OF MARY WING

(From the Children's Hospital Research Foundation and the Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati)

(Received for publication August 31, 1946)

The possibility of utilizing erythrocytes remaining after the removal of plasma has been of increasing interest in the last years with the expanding use of plasma and its derivatives and with better understanding of the clinical use of red cells. Although several reports of the large-scale use of resuspended cells are available (1 to 9), only scant information exists on *in vitro* changes taking place in separated red cells during storage in the packed state or in resuspension. The present study, part of an investigation dealing with *in vitro* changes of stored blood, is concerned with dimensional, osmotic, and chemical changes of separated cells. In view of the fact that the American Red Cross during the war collected blood in simple citrate solution as well as in ACD solution, depending on whether the blood was to be used as such or for the preparation of plasma, both types of cells, those derived from bloods collected in simple citrate solution and those from bloods collected in ACD solution, were studied. The purposes of the study may be defined as follows: (*1*) to establish the validity of *in vitro* testing of separated red cells and (*2*) to delimit, if possible, the optimum conditions of storage and the best type of resuspension fluid for separated cells. In most instances the report will be limited to a presentation of changes of 4 indices of blood preservation: (*1*) hemolysis in 0.6 per cent NaCl solution, (*2*) changes in cellular thickness, (*3*) adenosine triphosphate content, and (*4*) glycolyzing power of erythrocytes. Complete measurements of dimensional changes, including diameter, surface and volume; of the osmotic behavior; and of the phosphorus and cation distributions were performed as described in the first paper of this series (10), but are omitted here for the sake of conciseness. The results of these studies in all instances supplemented and confirmed the data to be reported.

METHODS

Bloods were collected at the Blood Bank of the Cincinnati General Hospital in a manner earlier described (10). They were centrifuged, the plasma separated 24 hours after collection, and the blood cells promptly resuspended in an equal volume of resuspension fluid. After mixing they were distributed into a series of vials and stored at 4° C. until the time of testing. In the experiments on preservation of cells stored in the packed state, the packed cells were left undisturbed until immediately prior to testing, when they were diluted with an equal volume of 0.9 per cent NaCl solution. A series of 16 bloods were collected in the Blood Bank of the American Red Cross in Indianapolis, resuspended in the Lilly Research Laboratories, and shipped to Cincinnati by Railway Express. This series of experiments was undertaken in order to test the preservation of red cells under actual conditions of practice. Since the bloods did not differ significantly from those studied under laboratory conditions, results on them were combined with the other data. A list of the principal resuspension fluids used is given in Table I. The fluids were made up in such a way

TABLE I

Composition of mixtures for the resuspension of blood cells

Mixture	Citric acid		Total citrate	Glucose	Plasma pH
	mgm. per 100 ml. cells	*mM. per 100 ml. cells*	*mM. per 100 ml. diluent*	*grams per 100 ml. final mixture*	
C_2D_2	30	0.14	1.32	0.3	7.04
C_2E_2	60	0.29	1.32	0.3	6.96
C_2F_2	90	0.43	1.32	0.3	6.86
C_2G_2	120	0.57	1.32	0.3	6.79
C_2	0	0	1.32	0.3	
C_2E_2 Globulin 3 per cent*	60	0.29	1.32	0.3	7.04
C_2E_2 Knox gelatin 5 per cent*	60	0.29	1.32	0.3	7.02
C_2E_2 Oxypolygelatin 4 per cent*	60	0.29	1.32	0.3	7.03

The mixtures were made up with 80 ml. of 0.9 per cent NaCl and sufficient water to give a final volume of 100 ml. They were added in equal volume to separated blood cells.

* These products were brought to a pH of 7.0 by additions of NaOH or HCl before they were mixed with the other ingredients of the preservative solutions.

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Children's Hospital of Cincinnati.

as to keep the final concentration of total citrate and of dextrose constant after mixture with blood, while varying the proportions of citric acid and of trisodium citrate. The amount of citric acid was adjusted in such a manner as to cover the range between pH of 6.80 and 7.05 in the suspension after mixture with the red cells, taking into account the buffering properties of hemoglobin, the amount of lactic acid formed before resuspension, and the absence of plasma buffers. Colloids, where added, were brought to a pH of 7.0, which is close to the pH of the resuspended blood cells themselves, before they were mixed with the other ingredients of the preservative solutions. This was an important consideration, in view of the fact that the various products had varying initial pH values, 7.44, 6.74, and 5.63, for the globulin, gelatin, and oxypolygelatin preparations, respectively. Also their buffering powers varied considerably. A number of other resuspension fluids were prepared and tested but are omitted from this list since they did not differ significantly in their characteristics from the series tabulated.

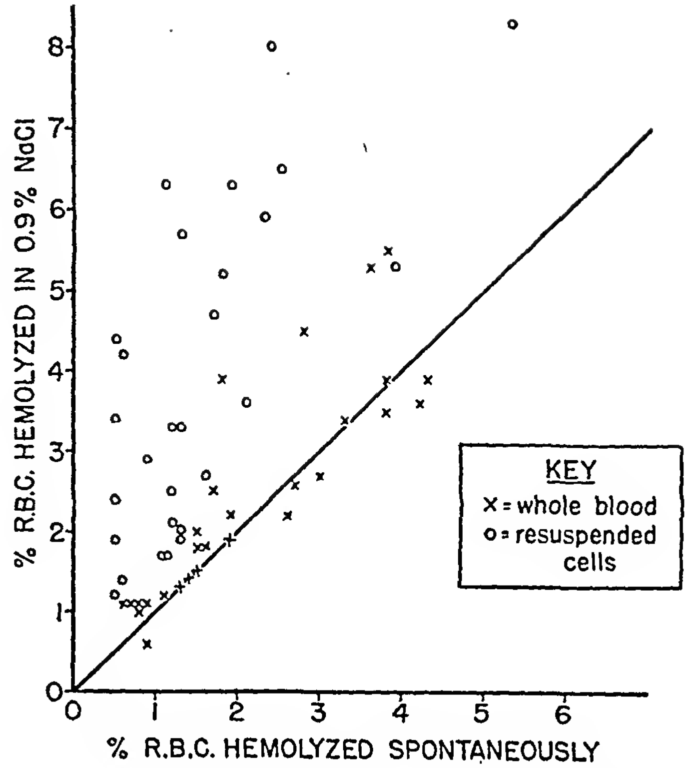

Fig. 1. Comparison of Spontaneous Hemolysis and Hemolysis in 0.9 Per Cent NaCl Solution of Resuspended Cells and of Whole Blood

RESULTS

"Spontaneous" hemolysis of resuspended cells

The measurement of so-called spontaneous hemolysis (hemolglobin in the supernatant fluid after centrifugation), used as a measure of blood preservation by some observers (11 to 14), appeared of particular interest in view of earlier indications that this test may give results in disagreement with other indices of preservation in bloods stored in solutions entailing great dilution or in suspensions of separated blood cells. In Figure 1 is presented graphically a comparison of "spontaneous" hemolysis with that in 0.9 per cent NaCl solution for erythrocytes stored as whole blood in various mixtures entailing less than 25 per cent dilution and for erythrocytes in resuspension. It may be seen that for whole blood both measurements usually gave comparable results, as indicated by the tendency of the values to group themselves around the diagonal line, while the values for all cell suspensions were above the diagonal, indicating that "spontaneous" hemolysis was much less than hemolysis in 0.9 per cent NaCl solution. It may be recalled that in earlier papers a general parallelism between hemolysis in various concentrations of NaCl, including 0.9 per cent NaCl solution and other indices of blood preservation, was demonstrated. Under the conditions described here, in resuspended cells, no correlation is found between "spontaneous" hemolysis, on the one hand, and hemolysis in 0.9 per cent NaCl solution or any of the other criteria of blood preservation, on the other. Spontaneous hemolysis under such circumstances is a fallacious index of the state of the red cell.

Optimal acidity of resuspension fluids

The beneficial effect of acidification of whole blood to a pH of about 7.0 on the preservation of erythrocytes has been established. Experiments were therefore undertaken to define the optimal amount of acid to be used in the resuspension of "citrate" cells and "ACD" cells, that is, cells derived from blood collected in simple citrate and ACD mixtures, respectively. The suspension fluids, designed to produce acidification to a varying degree and the pH values measured after suspension of the red cells, are listed in Table I. In the left-hand side of Figure 2 are presented data on the hemolysis in 0.6 per cent NaCl solution, cellular thickness, and adenosine triphosphate content of 2 suspensions of "citrate" cells after 15 days of storage. These indices are plotted against the amounts of citric acid added. It would appear from the data that 30 to 75 mgm., that is, 0.14 to 0.35 mM. of citric acid per 100 ml. of cells, provide optimal acidity for the resuspension of "ci-

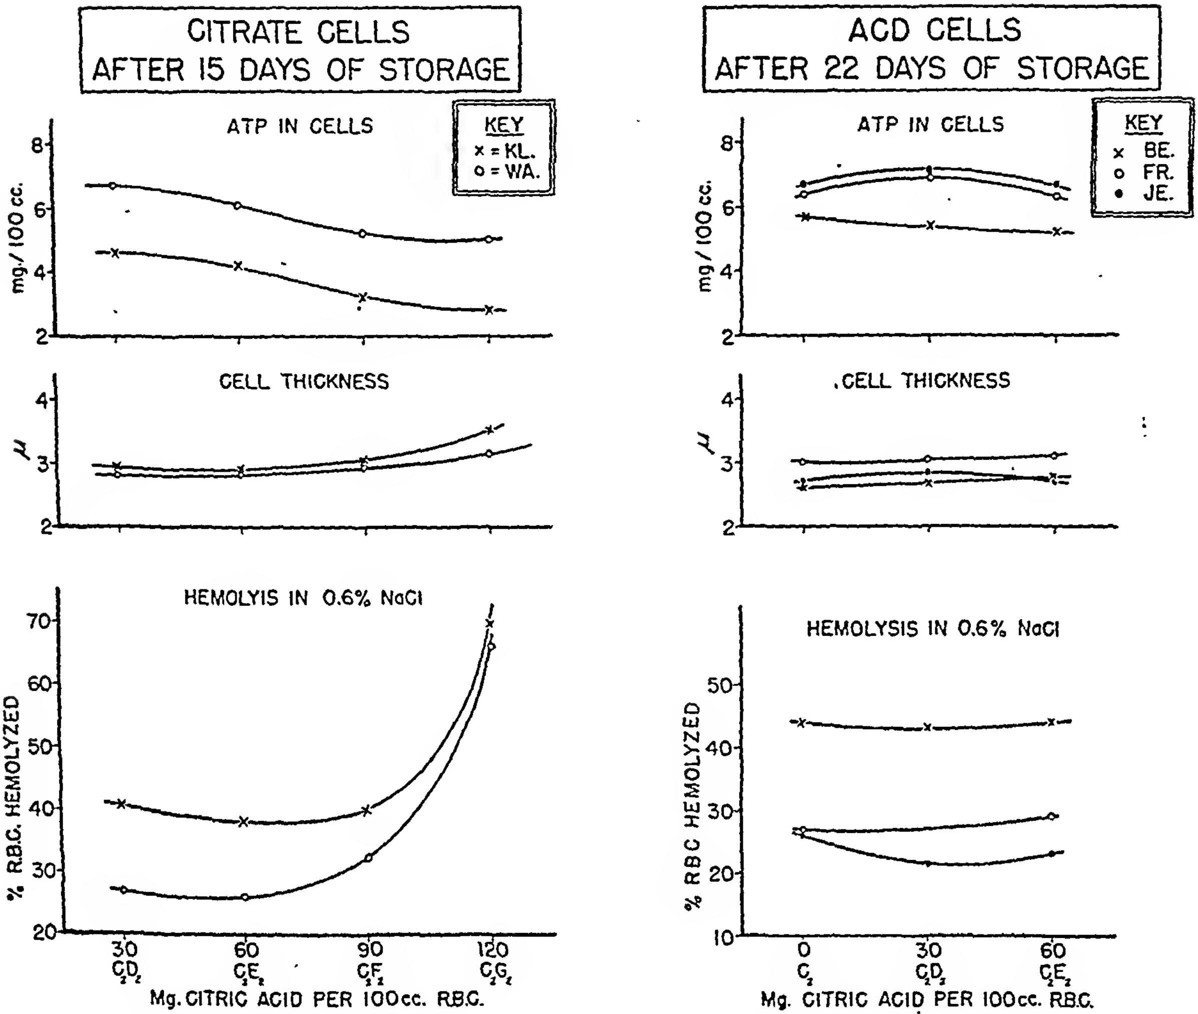

FIG. 2. CHANGES IN 3 INDICES OF "CITRATE" AND "ACD" CELLS RESUSPENDED IN SOLUTIONS OF VARYING ACIDITY

trate" cells, while greater acidification has deleterious effects.

In the right-hand side of the same figure is presented a similar experiment designed to establish the optimal amount of acid for the resuspension of "ACD" cells. It is apparent that there was no significant difference in the preservation of red cells over the entire range of acidity studied.

Comparison of cells from bloods collected in simple citrate and in ACD solution

In graphs A to C of Figure 3 are charted the individual data and in graph D the averages on the percentage of erythrocytes hemolyzed in 0.6 per cent NaCl solution after varying periods of storage and their regression lines. It may be seen that "citrate-cells," even if resuspended in ACD solution, were less well preserved than "ACD-cells." Data on changes in thickness, adenosine triphosphate content, glycolyzing power, and potassium content of erythrocytes, presented in a summary manner in Figure 4, confirm the conclusions based on the osmotic behavior of the red cells. In Table II are presented the numerical values for the regression equations of the 5 indices against time. It may be seen that the changes in all characteristics of the red cell progressed at their most rapid rate in citrate cells suspended in neutral solution and most slowly in ACD cells. It is noteworthy that the values of the various indices extrapolated to zero time approximated those actually observed in whole blood at the beginning of storage, indicating that the changes in resuspended cells tended to progress at an approximately linear rate. These find-

ings support the opinion that conditions during the first 24 hours of storage are of decisive importance for the subsequent survival of red cells. The state of preservation of resuspended cells at a given time is more variable than that of whole blood, as shown by the wide scatter of points in the graphs. There is some indication, both from inspection of the data and of the errors of the regression coefficients, that "ACD-cells" are more uniformly preserved than are "citrate-cells." Finally, it should be emphasized that all cells separated from their plasma, including ACD-cells, are less well preserved than those of corresponding whole bloods.

Comparsion of preservation of erythrocytes stored in the packed state and in resuspension

In Table III is presented a comparison in 2 samples of blood of the preservation of cells stored in the packed state and in resuspension, from which it may be seen that there was no significant difference in any of the indices between the 2 modes of storage.

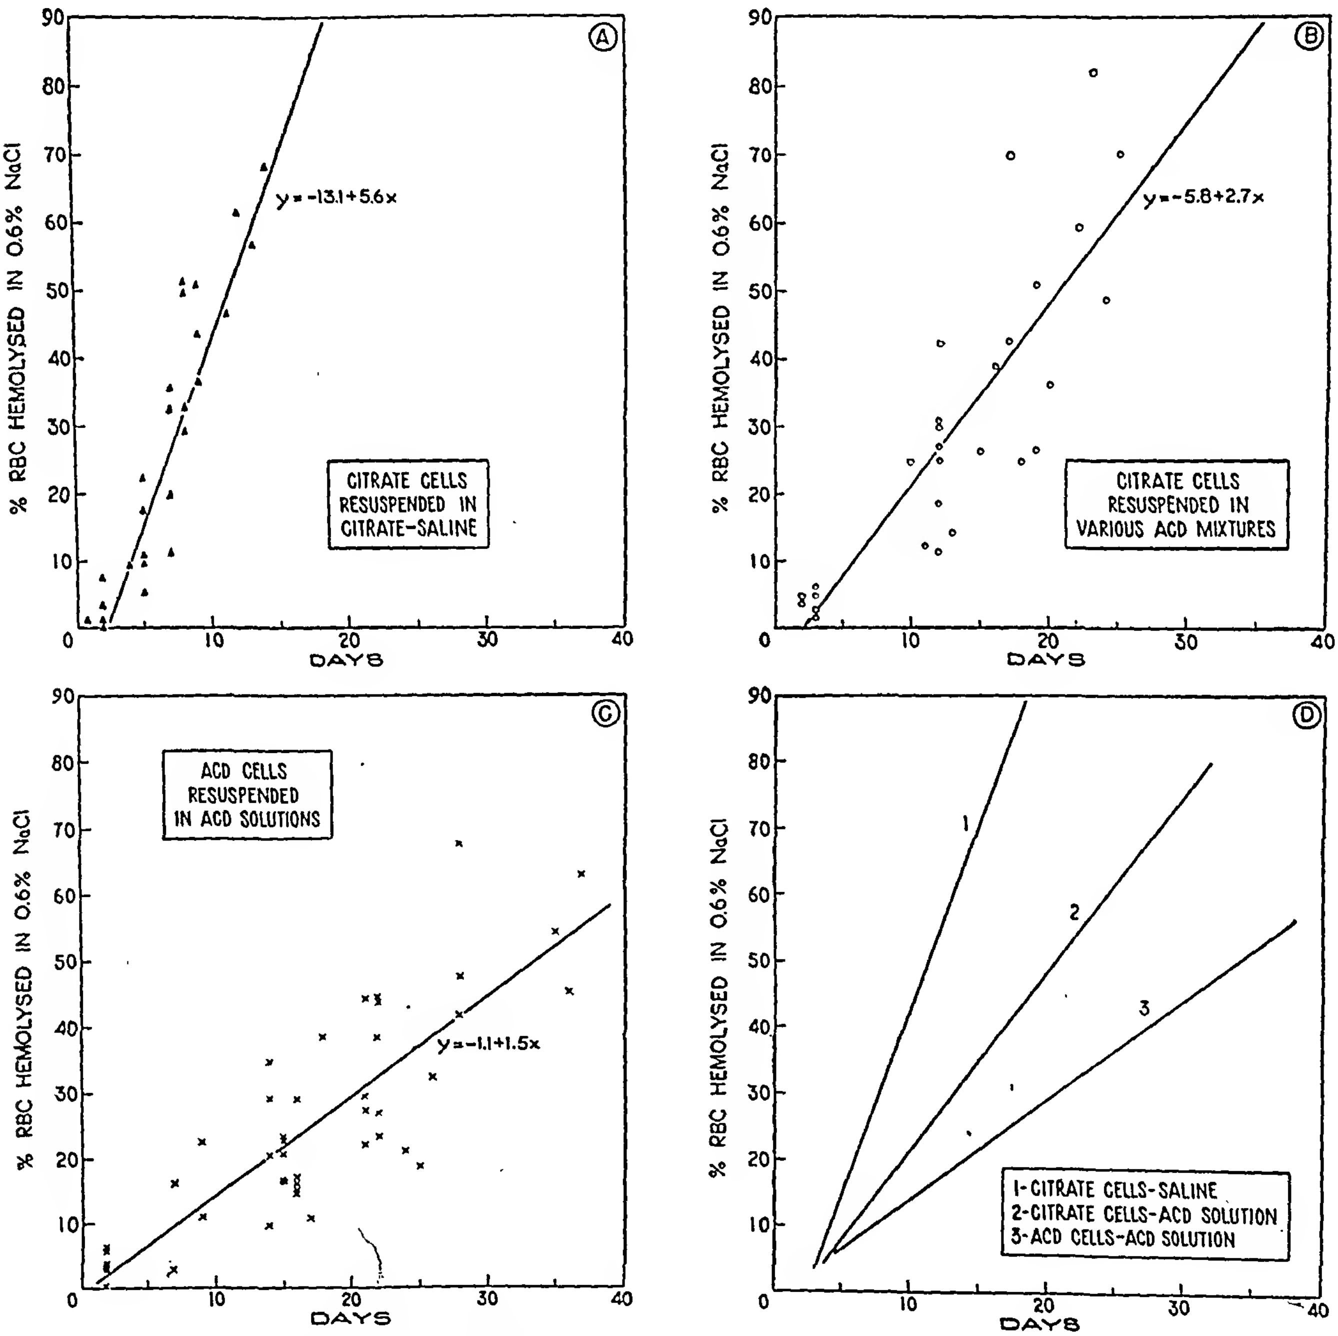

FIG. 3. COMPARISON WITH RESPECT TO HEMOLYSIS IN 0.6 PER CENT NACL SOLUTION OF CELLS DERIVED FROM BLOOD COLLECTED IN CITRATE AND ACD SOLUTION AND RESUSPENDED IN NEUTRAL AND ACID SOLUTIONS

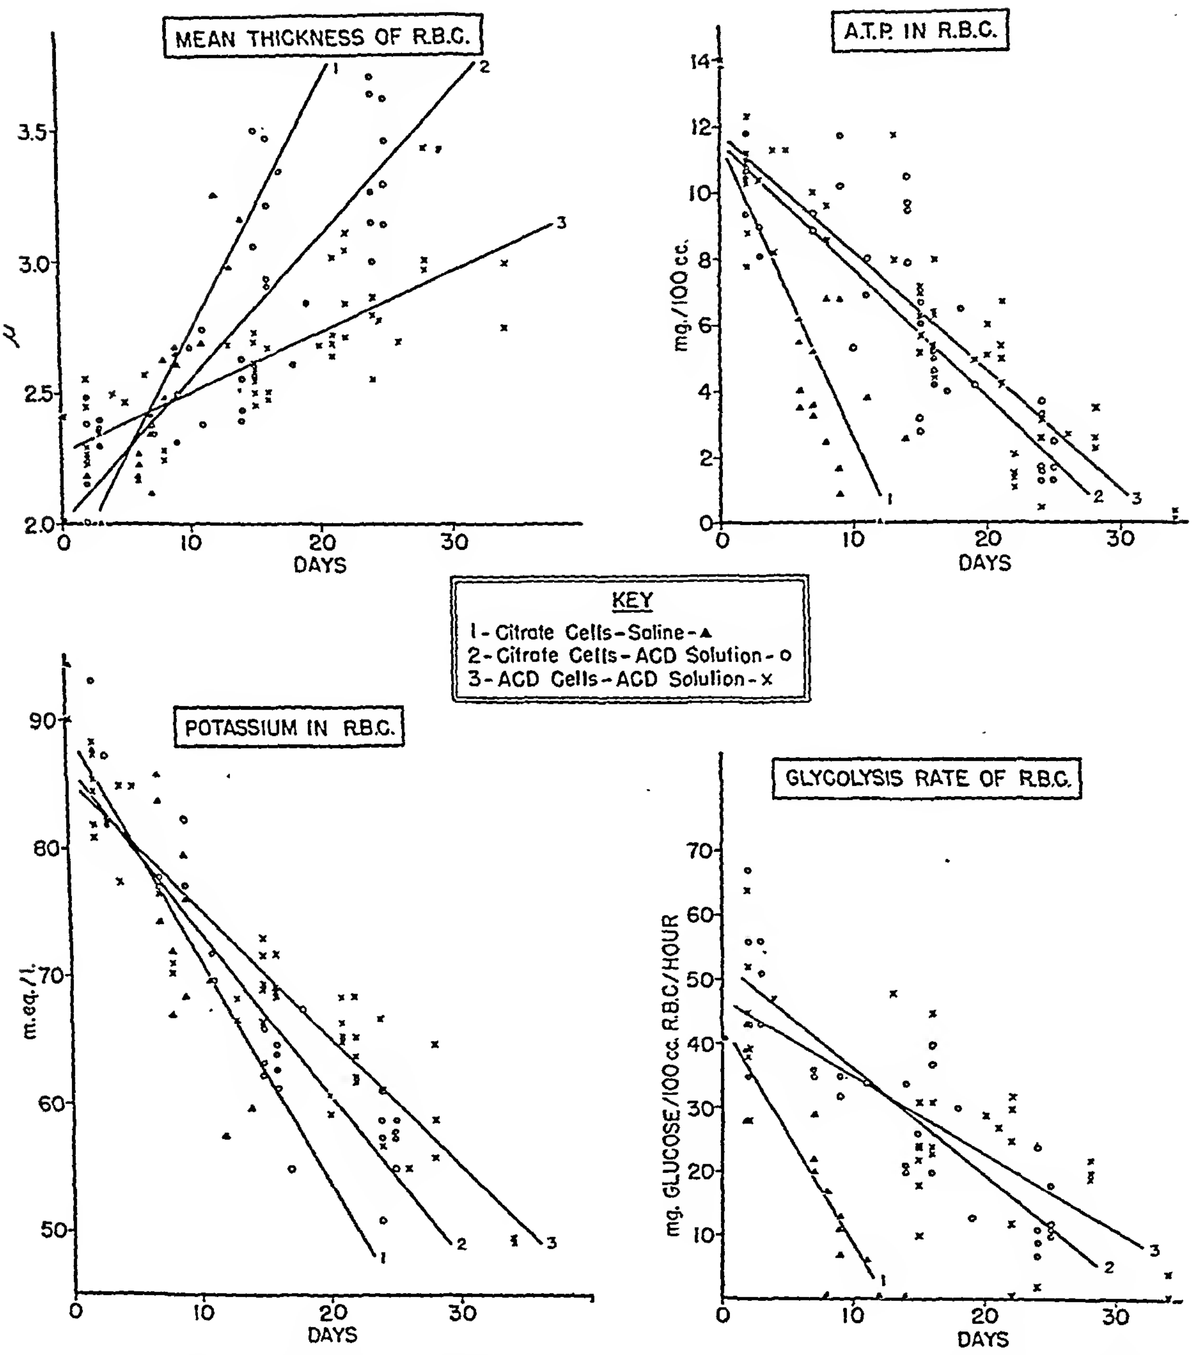

FIG. 4. COMPARISON OF "CITRATE" AND "ACD" CELLS SUSPENDED IN NEUTRAL AND ACID SOLUTION WITH RESPECT TO (1) MEAN THICKNESS, (2) ADENOSINE TRIPHOSPHATE, (3) POTASSIUM CONTENT AND (4) GLYCOLYSIS RATE

The effect of globulin, gelatin, and oxypolygelatin on the preservation of resuspended red cells

With the possibility in mind that the inferior preservation of separated red cells may be caused by the absence of the colloidal properties of the plasma proteins, the effect of several high-molecular substances on the preservation of red cells was tested. In Table IV are presented data on an experiment carried out on 2 bloods, in which the effect of globulin (Cohn fraction IV-3, 4), gelatin (Knox P16-180) and oxypolygelatin on the preservation of "citrate" cells was compared with that

TABLE II

Changes of 5 indices of preservation during storage of resuspended cells
Regression equations and their sampling errors

Cells and solution	Hemolysis of cells in 0.6 per cent NaCl	Cell thickness	ATP content of cells	Glycolysis rate of cells	Potassium in cells
	per cent	μ	*mgm. per 100 ml.*	*mgm. per 100 ml. per hour*	*m.eq. per liter*
Citrate-cells in saline	$-13.1+5.6x$ ± 0.47	$1.77+0.095x$ ± 0.009	$11.5-0.89x$ ± 0.13	$42.5-3.40x$ ± 0.43	$88.4-1.7x$ ± 0.71
Citrate-cells in ACD solution	$-5.8+2.7x$ ± 0.33	$1.99+0.054x$ ± 0.009	$11.6-0.39x$ ± 0.04	$52.7-1.66x$ ± 0.16	$86.5-1.3x$ ± 0.19
ACD-cells in ACD solution	$-1.1+1.5x$ ± 0.15	$2.27+0.023x$ ± 0.003	$11.7-0.35x$ ± 0.02	$46.8-1.20x$ ± 0.20	$85.5-1.0x$ ± 0.05

of a standard acid resuspension fluid. As may be seen from the data, no particular effect, favorable or unfavorable, was obtained by the addition of these materials. In other experiments not reported here, dextrin and small amounts of plasma protein in concentrations up to 1 per cent likewise failed to affect the preservation of cells.

The preservation of erythrocytes centrifuged and resuspended in own plasma

The data presented in Table V indicate that there was no difference in the preservation between the portion of blood that had been centrifuged and the one which had been left undisturbed, while the separated red cells showed distinctly inferior preservation. It would seem, therefore, that mechanical factors play a minor part in the determination of the preservation of the red cell.

TABLE III

Comparison of preservation of erythrocytes stored in the packed state and in resuspension

The cells studied were derived from blood collected in ACD-15 (ACD-G) solution.

Sample and condition	Storage period	Diameter	Thickness	Hemolysis in 0.6 per cent NaCl	ATP	Glycolysis rate

TABLE V

The preservation of erythrocytes, centrifuged and resuspended in own plasma

The blood studied was collected in ACD solution. One portion was left undisturbed, another one was centrifuged for 2 hours and resuspended, and a third one was centrifuged, the plasma removed and replaced by an acid crystalloid resuspension solution. Measurements of preservation were carried out after 17 days of storage.

Condition of sample	Diameter	Thickness	Hemolysis in 0.9 per cent NaCl	Hemolysis in 0.6 per cent NaCl	ATP	Potassium	pH
	μ	μ	*per cent*	*per cent*	*mgm. per 100 ml. of cells*	*m.eq. per liter of cells*	
Undisturbed	7.2	2.60	1.1	33.2	6.2	71.5	6.58
Centrifuged and resuspended in own plasma	7.2	2.65	1.0	35.7	6.8	70.4	6.61
Resuspended in crystalloid solution	6.8	3.11	2.3	49.1	4.4	63.2	6.55

the various indices *in vitro* indicates that they maintain similar relationships with each other as they do in whole blood. Even under the best conditions the preservation of separated red cells is inferior and much more variable than that of the cells of corresponding whole blood. Cells derived from bloods collected in ACD solution are better preserved than those derived from bloods collected in citrate solution. The preservation of cells from citrate blood may be improved by resuspension in acidified solutions, but even then they are not so well preserved as ACD cells. Such data indicate that processes taking place in the first 24 hours of storage before the cells are separated have a determining influence on the course of the subsequent preservation. The optimal acidity for the preservation of citrated cells may be defined within the limits of 0.14 to 0.35 mM. of citric acid per 100 ml. of cells. ACD cells may be conveniently and advantageously stored in packed form. The cause of the inferior preservation of separated red cells is unknown at present. Addition of globulin or gelatin products does not appear to improve their preservation.

I should like to thank Dr. C. G. Culbertson and Mrs. H. Zerfas of the Blood Donor Service of the American Red Cross in Indianapolis and Mr. W. A. Jamieson of the Lilly Research Laboratories for their cooperation in obtaining samples of blood cells.

THE OSMOTIC RESISTANCE (FRAGILITY) OF HUMAN RED CELLS[1]

By ARTHUR K. PARPART, PHILIP B. LORENZ, ETHEL R. PARPART, JOHN R. GREGG, AND AURIN M. CHASE

(From the Physiological Laboratory, Princeton University, Princeton, N. J., and The Marine Biological Laboratory, Woods Hole, Mass.)

(Received for publication August 31, 1946)

The degree of resistance of red cells to a decrease of the salt content of their environment has long been used experimentally as one measure of their viability and clinically as a diagnostic characteristic. The experimental basis for this measure has been the fact that when any red cell, of a population of red cells, reaches a certain volume (the hemolytic volume, Jacobs [1]), the hemoglobin of that cell diffuses to equilibrium inside and outside the cell, usually without rupture of the plasma membrane of the cell. Since any given population of red cells possesses individual cells which differ from one another in the volume at which hemoglobin is permitted to diffuse out, the osmotic resistance of such a population of red cells is assumed to follow a normal probability distribution. In fact, the "Fragility Test"[2] is based on this assumption. This is a reasonable assumption for freshly collected red cells of normal man (Figure 1) (Hunter [2], Guest and Wing [3]).

Clinical data on fragility and frequently laboratory experimental data have been collected by visual selection of the salt concentration at which the maximal and minimal degree of hemolysis occurs. Unfortunately this method of observation means that the data have been obtained on the least accurate parts of the osmotic resistance curve, namely at its extremes. In these extreme regions of the curve, small differences in the degree of hemolysis correspond with large differences of salt concentration (Figure 1); and, hence, one would expect divergent results, particularly since subjective, visual observation of the degree of hemolysis has been used.

During the course of studies on the storage of whole blood it became necessary to determine accurately the variation in osmotic resistance of stored red cells. A method was devised for this purpose which in some respects is similar to that of Hunter (2). It took into account, however, several factors which markedly affect the normal osmotic resistance (Jacobs and Parpart [4]). The chief factor is the pH of the sodium chloride solutions (Figure 1). It is obvious from these curves that it is necessary to buffer the salt solutions. For this reason a stock solution was prepared containing the following: 180.00 grams NaCl, 27.31 grams Na_2HPO_4, 3.74 grams NaH_2PO_4, all made up to 2 liters with distilled water. This "Stock NaCl–PO_4" solution is equivalent to a 10 per cent solution of NaCl and will keep for a number of months.

The salt concentrations for measurement of the osmotic resistance were prepared from this stock solution as follows:

A calibrated 50 ml. burette was filled with the "Stock NaCl–PO_4" solution and the volumes given in column 2, Table I, run into a 250-ml. volumetric flask. This was made up to the 250-ml. mark with distilled water and put into a glass stoppered pyrex bottle labeled with the salt concentration shown in column 1. The pH of these salt

TABLE I

Column 1 NaCl–PO_4	Column 2 Stock NaCl–PO_4 made up to 250 ml.	Column 3 Stock NaCl–PO_4 made up to 250 ml. "Complementary Solutions"
per cent	*ml.*	*ml.*
0.8	20.00	30.00

0.10	2.50	47.50

[1] The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Princeton University.

[2] The term "Osmotic Resistance" will be used throughout this paper in a sense that is somewhat analagous to the term "Fragility." It is used because it more adequately defines the physical changes occurring in red cells under these conditions than does the term fragility.

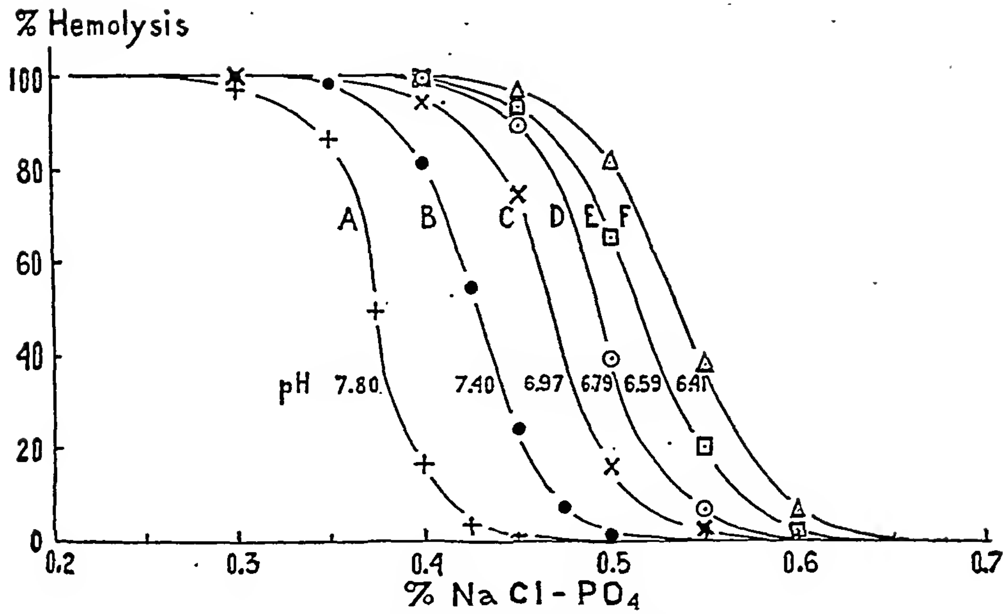

FIG. 1. OSMOTIC RESISTANCE CURVES OF NORMAL HUMAN BLOOD (MALE, WHITE) AS AFFECTED BY THE pH OF THE SALT SOLUTIONS

The per cent $NaCl-PO_4$ is equivalent to per cent NaCl of the usual fragility plot. Curve B is the average of determinations on the blood of 12 normal young men, no individual sample of which varied by more than 0.015 per cent NaCl from the average.

solutions is 7.40. The remainder (as shown in column 3, Table I) of each 50 ml. of Stock $NaCl-PO_4$ used for a particular salt concentration was also run into a 250-ml. flask made up with distilled water and stored in pyrex bottles labeled $C_{0.8}$; $C_{0.75}$, etc.

The osmotic resistance series was set up by transferring 5 ml. of each of the salt concentrations to centrifuge tubes and adding 0.020 ml. of citrated blood (4 mgm. $Na_3C_6H_5O_7 \cdot 2\,H_2O$, added dry, per ml. blood). The transfers were made with a 5-ml. syringe fitted with a 3-inch No. 18 needle, and the blood was added from a hemoglobin pipette. The blood and the salt solution were equilibrated for 45 minutes. At this time the hemolytic process was stopped by the addition of the corresponding "Complementary Solution" ($C_{0.8}$; $C_{0.75}$, etc.), column 3, Table I. Thus, the osmotic pressure around the unhemolyzed cells was returned to normal tonicity and further hemolysis stopped.

The percentage hemolysis was then determined either by a calibrated photoelectric densitometric method (Parpart [5]); or by centrifuging of the blood-salt solutions for 5 minutes at 1,500 r.p.m.; removing[3] the supernatant cell-free hemoglobin solution and determining its concentration in a photoelectric colorimeter at the wave length 540 mμ.

Calibration for the per cent hemolysis was run on the same sample of blood. Where a photoelectric colorimeter is used to read the amount of hemoglobin in the supernatant solution, the calibration is performed as follows:

Transfer 5 ml. of 0.1 per cent $NaCl-PO_4$ solution to a test tube and add 0.020 ml. of blood; allow to stand for 15 minutes, then add 5 ml. of $C_{0.1}$. Mix well and read in colorimeter. This reading gives the value for 100 per cent hemolysis. If the hemoglobin solutions in the particular photoelectric system used have been shown to obey Beer's Law, the per cent hemolysis in the various salt solutions may be calculated as follows:

$$\frac{D_{\text{exp.}}}{D_{100\text{ per cent}}} \times 100 = \text{per cent hemolysis}$$

where the optical density, D, equals the $\log_{10}$ of the reciprocal of the transmission value obtained in the colorimeter. $D_{100\text{ per cent}}$ is that for the calibration solution; $D_{\text{exp.}}$ is that for the supernatant fluid of any particular blood-salt solution.

In the practical use of this method one soon learns that not all of the 14 salt solutions recommended in Table I need be used for every sample of blood. Occasionally, finer gradations of salt concentration (*e.g.*, 0.325, 0.375, 0.425, 0.475 etc.), may be needed. Such intermediate salt concentrations are readily prepared by mixing equal volumes of the salt solution in Table I above and below the desired concentration.

Two very useful criteria of osmotic resistance come out of data obtained in this way. By using

[3] A syringe fitted with a long No. 18 needle, whose end is bent up to form a J, is convenient for removing the hemoglobin solution.

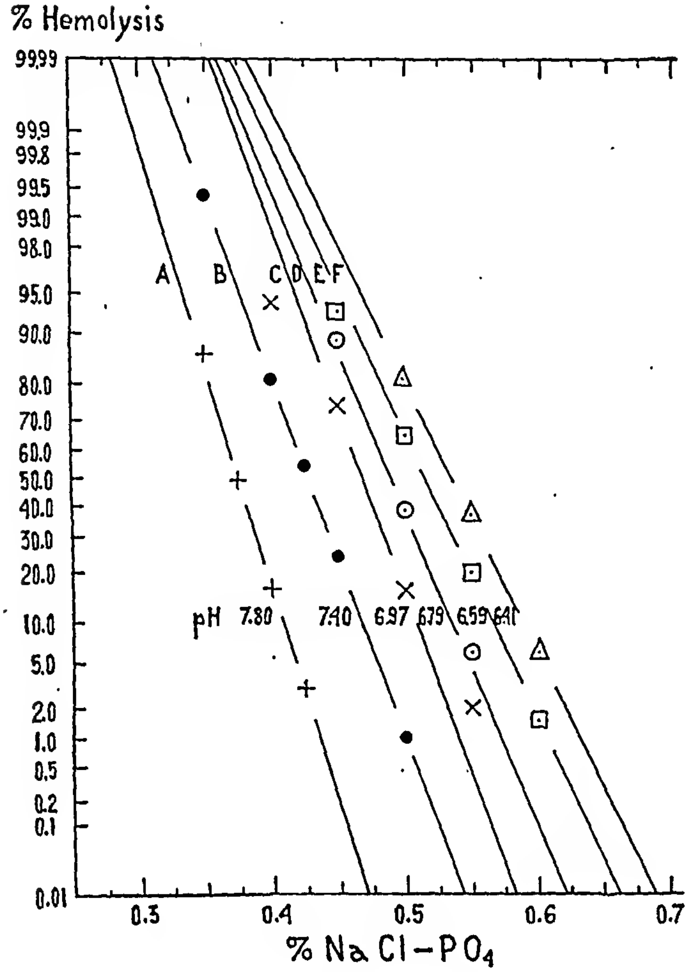

FIG. 2. A PROBABILITY PLOT OF THE OSMOTIC RESISTANCE CURVES OF FIGURE 1

This figure illustrates the ease with which the spread and the median of osmotic resistance may be determined graphically.

Probability Paper,[4] (Hunter [2]), the spread of the osmotic resistance and the median may be obtained graphically (Figure 2). It shoud be emphasized that accurate data on the spread and the median can be obtained only if 3 or more of the salt concentrations used give degrees of hemolysis between 10 per cent and 90 per cent (*i.e.,* in the critical concentration range).

The importance of stopping the hemolytic process at a fixed time by the addition of the complementary solution, is illustrated in Figure 3. These data were obtained by putting 0.020 ml. of blood into 5-ml. samples of salt solution which had been brought to and were kept at the temperatures given and at the time indicated on the abscissa, adding 5 ml. of the complementary solution, and determining the per cent hemolysis in the manner described. Red cells equilibrated for 45 minutes at 20° ± 0.1° C. in a hypotonic salt solution causing about 20 per cent hemolysis, are very near the equilibrium per cent of hemolysis. At higher temperatures the equilibrium is attained more rapidly (5 to 10 minutes at 40°); the Q_{10} is of the order of 2.6. At temperatures below 20° C. a time increasingly longer than 45 minutes must be allowed for attainment of equilibrium, particularly for blood in salt solutions which cause less than 50 per cent hemolysis. At 10° C. equilibrium is reached after about 2 hours. When a salt solution of low concentration, which brings about complete hemolysis, is used the equilibrium is reached in a few minutes even at 10° C., (Jacobs, Glassman and Parpart [6]).

If room temperatures fluctuate widely, consistent data on the osmotic resistance can be obtained only by equilibrating the blood-salt solutions in a water bath the temperature of which does not vary by more than a degree. A further, though less striking, illustration of this point is presented in the data on the spread and median of the osmotic resistance of normal human blood at 10°, 20°, 30° and 40°, as given in a probability plot (Figure 4). As would be expected the osmotic resistance increases (fragility decreases), with increasing temperature (Jacobs and Parpart [4]). Thus, the spread at 10° is from 0.330 to 0.531 per cent NaCl–

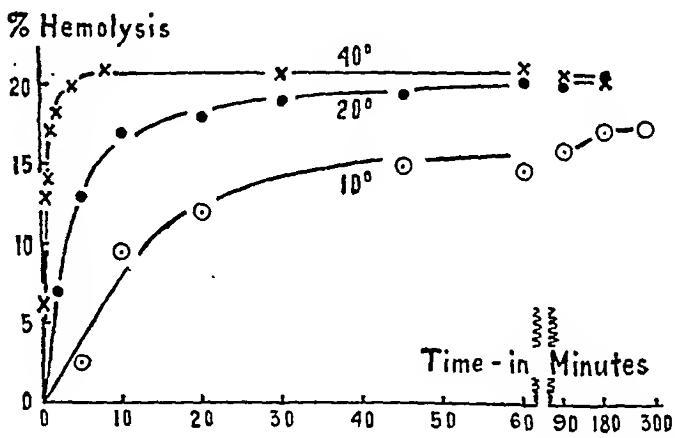

FIG. 3. ILLUSTRATES THE RATE AT WHICH THE EQUILIBRIUM DEGREE OF HEMOLYSIS IS ATTAINED AT 3 TEMPERATURES

Salt concentrations were chosen (from data in Figure 4) so that the equilibrium degree of hemolysis (17 to 20 per cent) would be approximately the same at the 3 temperatures. Details are given in the text.

[4] Keuffel and Esser Probability Paper No. 359–23.

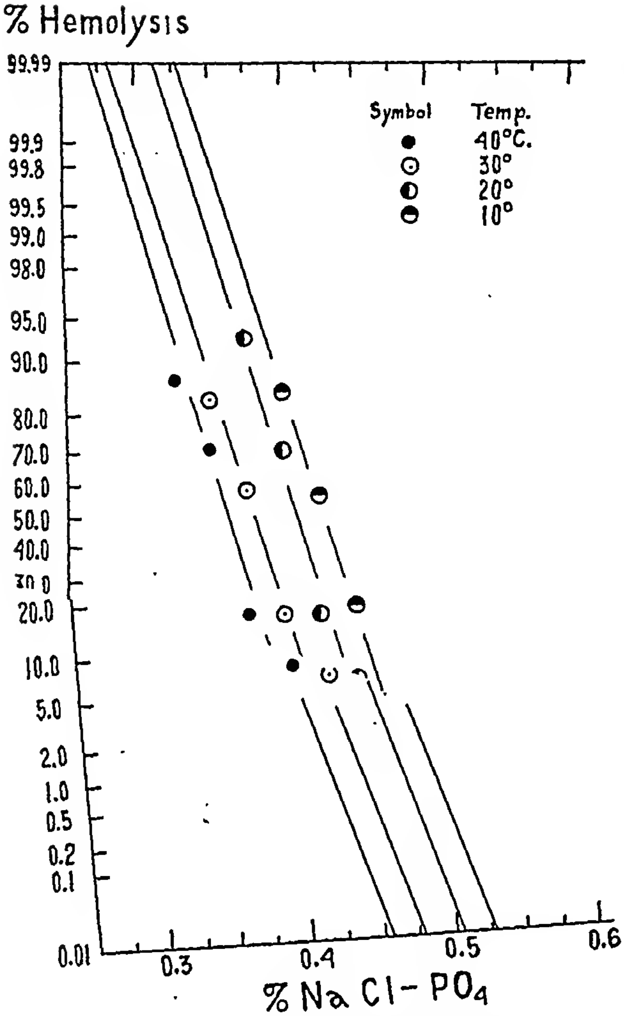

FIG. 4. ILLUSTRATES THE EFFECT OF TEMPERATURE ON THE SPREAD AND MEDIAN OF THE OSMOTIC RESISTANCE OF NORMAL HUMAN BLOOD

PO_4, while that at 40° is from 0.270 to 0.455; and the medians are 0.430 and 0.361 respectively.

It is obvious that temperature markedly affects the time at which the equilibrium degree of hemolysis may be attained, especially for blood-salt solutions in which low degrees (20 per cent) of hemolysis occur (Figure 3). Equally pertinent is the fact that once the equilibrium has been reached the temperature at which it is attained is a factor in determining the amount of hemolysis that will take place in a salt solution in the critical concentration range for solutions causing between 10 and 90 per cent hemolysis (see Figure 4).

The data on the effect of pH on the osmotic resistance (Figures 1 and 2) clearly demonstrate that this factor must be adequately controlled if reliable results are to be obtained. Examination of the data in Figure 2 will show that a change of pH by 0.1 of a pH unit is equivalent to altering the salt concentration by 0.01 per cent. The extreme variation for 12 normal adult males (curve B, Figure 2), is 0.02 per cent of salt concentration; if the pH had not been carefully controlled, this variation could have been caused by a shift of only 0.2 of a pH unit.

The osmotic resistance of blood may be greatly altered if it is collected under conditions where a large volume of an isosmotic glucose solution is added to it or where the salt content of the fluid surrounding the cells is reduced. Thus the red cells of blood collected by the method of De Gowin (7) have their median osmotic resistance (M.O.R.) at 0.800 per cent NaCl within 3 hours after collection, instead of at the normal M.O.R. of 0.425 per cent NaCl (curve B, Figure 1). On of pure ... rapid ion exchanges and resuspended in solutions Parpart [8]) which lead to an increase ... dergo osmotic resistance. In short, the environment ... the red cells prior to measuring their resistance to changes in osmotic pressure must be considered in the analysis of their behavior.

SUMMARY

1. The factors which affect the measurement of the osmotic resistance of red cells (human) are analyzed. A method for such measurements is presented.

2. The factors: pH, temperature, rate of attainment of equilibrium, and chemical environmental changes each markedly influence the measurement of osmotic resistance. The magnitude and direction of their effects are considered.

WHOLE BLOOD PRESERVATION; A PROBLEM IN GENERAL PHYSIOLOGY.[1] AN *IN VITRO* ANALYSIS OF THE PROBLEM OF BLOOD STORAGE

By ARTHUR K. PARPART, JOHN R. GREGG, PHILIP B. LORENZ, ETHEL R. PARPART, and AURIN M. CHASE

(From the Physiological Laboratory, Princeton University, Princeton, N. J. and the Marine Biological Laboratory, Woods Hole, Mass.)

(Received for publication August 31, 1946)

A study of the storage of whole blood presents numerous problems in the field of cellular physiology. An understanding and solution of these problems can be of great aid in prolonging the viability of red cells of stored blood.

A major part of the problem centers around experimental studies on the influence of a number of environmental factors on survival. The more important factors are: temperature, range and optimum; degree of dilution; tonicity of the diluent; composition of the diluent; ion balance, maintenance of the colloidal osmotic pressure; pH range and optimum; buffer systems; glucose and rate of glycolysis; acid metabolite formation.

There have been many studies of the effect of some of these environmental factors on blood storage. In most cases, however, they have been studied as isolated, incomplete events by methods that frequently did not allow proper judgment of the state of preservation of the red cells. More recently, several excellent studies along these lines have appeared (Loutit [1]).

It is essential that an *in vitro* study of the blood preservation be accomplished by a thorough examination of a number of carefully controlled experimental criteria. We have found that the correlation obtained from the following *in vitro* methods permits one to arrive at a reasonable judgment of the state of preservation of the stored red cells and to predict the *in vivo* survival of such cells. Such predictions have been confirmed by *in vivo* tests (Gibson, *et al* [2]).

IN VITRO METHODS EMPLOYED IN THESE STUDIES

1. *The degree of spontaneous hemolysis,* obtained spectrophotometrically on the plasma after thorough resuspension of the cells and subsequent separation in an air turbine (Chase, *et al* [3]).

2. *The mean and spread of the osmotic resistance,* determined by an experimental analysis of the full curve of osmotic resistance, in buffered salt solution at fixed pH and temperature (Parpart, *et al* [4]).

3. *Rate of loss of potassium from the red cells,* obtained by potassium analysis on red cells and plasma (Weichselbaum, Somogyi, and Rusk [5]).

4. *The rate of glycolysis,* as determined by the rate of disappearance of glucose from the stored blood (Hoffman [6]).

5. *Rate and amount of lactic acid formation* (Barker and Summerson [7]).

6. *Changes in hydrogen ion concentration of the plasma,* by glass electrode measurements.

7. *Hematocrit and cell volume changes,* determined by an accurate (standard deviation of 0.86 per cent) air turbine method (Parpart and Ballentine [8]).

8. *Initial total hemoglobin, methemoglobin formation and cell counts,* methods of Chase, *et al* (3) and Parpart (9).

9. *Rate of exchange of anions across the membrane of the red cells,* measured photoelectrically (Parpart [10]).

10. *Rate of passage of non-toxic organic molecules into the red cells,* measured photoelectrically (Parpart [10]).

All of the data reported in this paper were obtained on blood samples collected by venipuncture from healthy human males (18 to 40 years of age).

RESULTS

Appropriate correlations between these criteria have served as a satisfactory index of the state of preservation obtained in the various procedures we have applied to stored blood. The results of these studies will be outlined under separate headings, though it is important to realize that this separation is purely for convenience. Only full cognizance of the interaction of the various variables studied will allow for proper comprehension of the factors involved in blood storage.

1. Optimal temperature for preservation.

Studies have been made on whole blood samples stored at different temperatures under a variety of

[1] The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Princeton University.

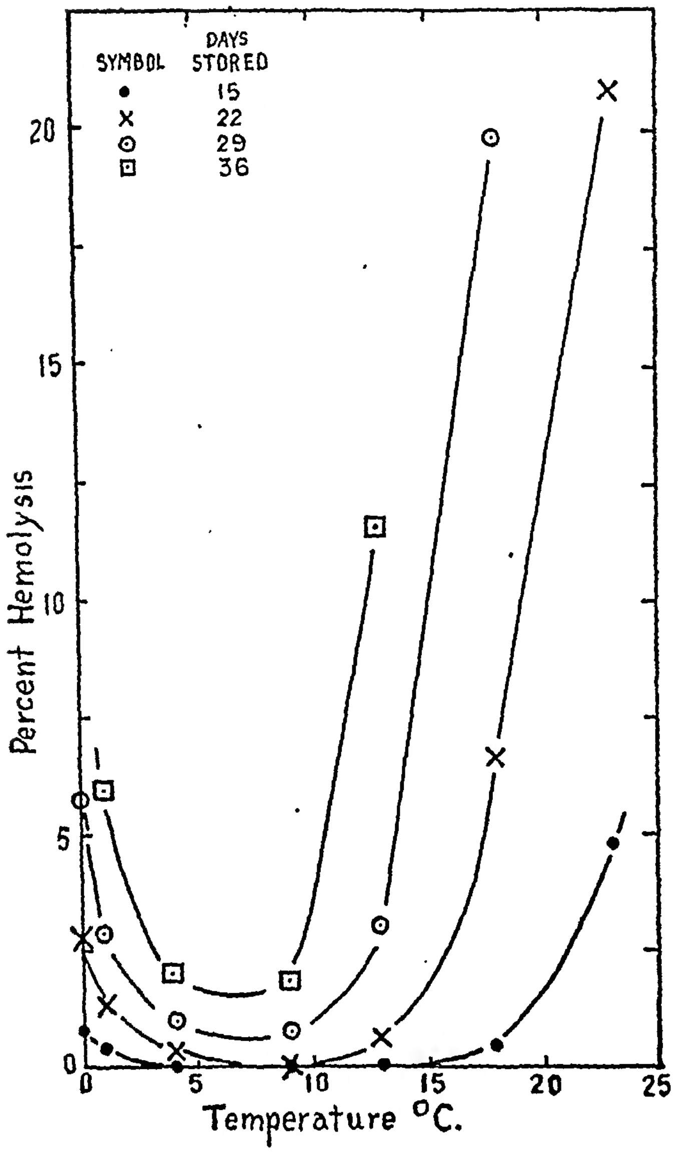

FIG. 1. EFFECT OF TEMPERATURE ON THE SPONTANEOUS HEMOLYSIS OF STORED BLOOD

experimental conditions (*e.g.* diluted, defibrinated, citrated, normal, and added glucose).

Figures 1, 2, and 3 illustrate the typical influence of temperature on the survival of stored human blood. These data were obtained on 270 ml. of blood collected in a bottle containing 30 ml. of 3.25 per cent $Na_3C_6H_5O_7 \cdot 2\,H_2O$ (0.11 M). This blood was then diluted to 70 per cent of normal whole blood by the addition of an isosmotic solution (5.4 per cent) of glucose and within 30 minutes of collection stored at the temperature indicated in the figures.

Figure 1 gives the rate of spontaneous hemolysis with respect to temperature and length of storage; Figure 2 presents the data on the mean osmotic resistance and Figure 3 illustrates the effect on the ability of the red cells to retain their normal potassium content. Four complete repetitions of these experiments gave the same results.

It may be seen from Figures 1, 2, and 3, that the optimum temperatures for survival of the human red cell lie between 4° and 9° C.; with an optimal at about 7° C. ± 1°. This has been confirmed by the *in vivo* studies of Gibson, *et al* (2).

These experimental conditions do not represent the best we have found for human red cell survival, but they do illustrate the optimal temperature conditions for such survival.

Figure 4 presents data on survival of red cells

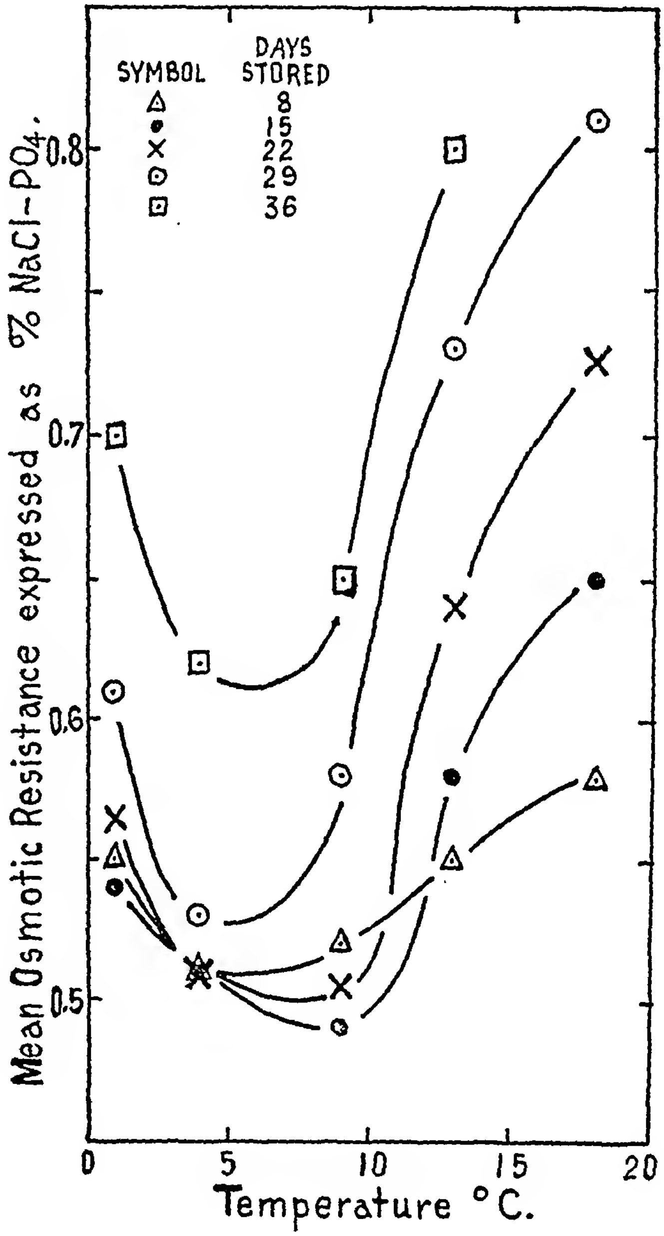

FIG. 2. EFFECT OF TEMPERATURE ON THE MEAN OSMOTIC RESISTANCE

under a variety of storage conditions at 2 different temperatures. One of these temperatures is in the optimal range (5° C.) while the other is well outside this range (23°). Figure 4 quite clearly shows that while temperature is a variable in the survival of stored red cells (one of prime importance as shown in Figures 1, 2, 3), and one whose effect is consistently in the same direction irrespective of large variations in the composition of the environment of stored red cells, nevertheless the effect of temperature may be overshadowed by the environmental composition. Curves a and b (Figure 4) contrast the rate of spontaneous hemolysis in the case of 12 collections of carefully defibrinated blood stored at 23° (a) and 6 collections stored at 5° (b) respectively. These blood samples had nothing else done to them except defibrination. It may be observed that the effect of temperature is present but its action is slight.

Compare these curves a and b with curves c and d (Figure 4). The latter 2 curves were obtained in 5 collections of blood according to the method of De Gowin, *et al.* (11) and stored at 23° and 5° respectively. In this case the effect of temperature is exceedingly striking and could have been deduced from the effect of temperature on the rate of penetration of glucose into human red cells, since the citrated bloods stored by De Gowin's method have been diluted to 40 per cent of their original concentration with an isosmotic solution of a compound that penetrates the red cells (5.4 per cent glucose). Such penetration of glucose leads to an abnormal increase in volume of the red cells (Figure 8).

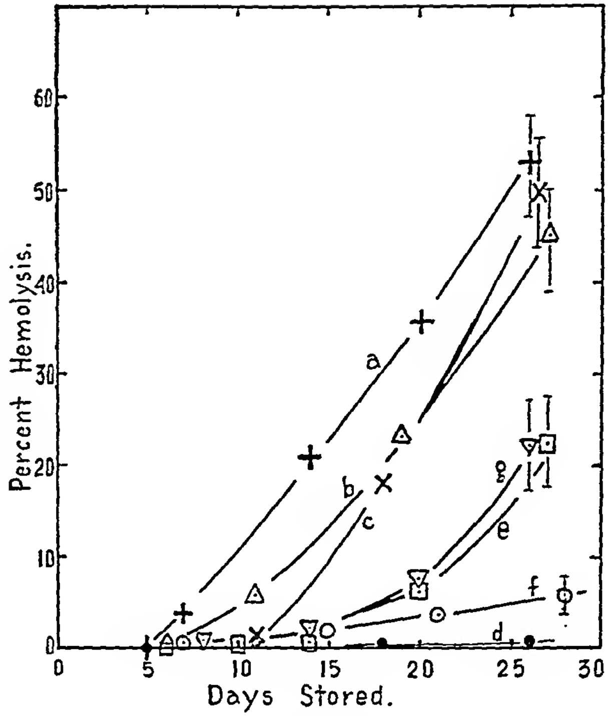

FIG. 4. SPONTANEOUS HEMOLYSIS AT 2 TEMPERATURES IN A VARIETY OF SOLUTIONS

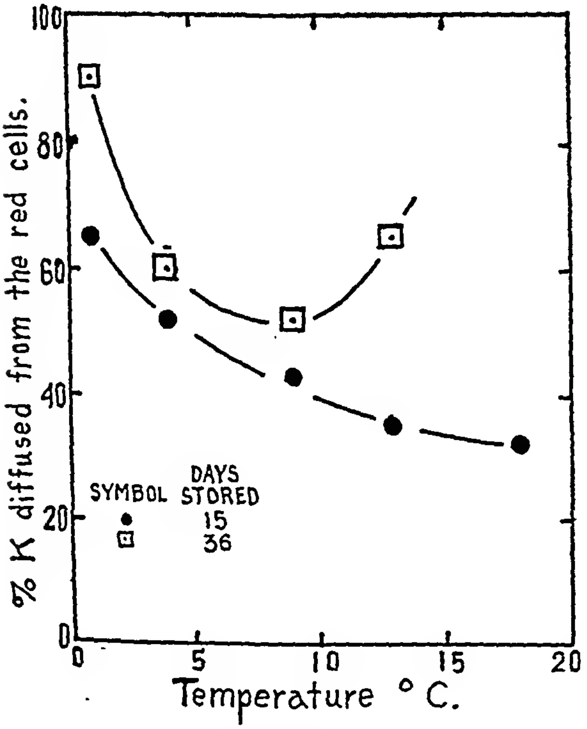

FIG. 3. INFLUENCE OF TEMPERATURE ON THE LOSS OF POTASSIUM FROM THE RED CELLS

One may also contrast curves e and f with a and b (Figure 4). The only difference other than temperature between the stored bloods represented in these 4 curves is the addition of sterile, solid glucose to give a final concentration of 0.5 per cent added glucose to the blood samples of curves e and f. These latter curves are the average for 6 and 9 individual blood collections. Comparison of curve e with f shows a very marked effect of temperature, over and above the strikingly better survival of the red cells to which glucose has been added.

Spontaneous hemolysis with time of storage for 90 parts of blood collected into 10 parts of an isosmotic $Na_3C_6H_5O_7 \cdot 2\ H_2O$ (0.11 M) solution

is shown in curve g (Figure 4). The better, though still poor, preservation under these conditions as compared with defibrinated blood stored at 5° C. (curve b) is primarily associated with the dilution of the blood and not with any effect of the added citrate. This point will be taken up later under the following section on the effect of dilution.

Figure 4 is intended solely to illustrate further effects of temperature on spontaneous hemolysis. It is not intended, however, to indicate that any of the methods of preservation illustrated in it is better than any other when considered from the point of view of *in vivo* survival. The other *in vitro* criteria that have been used on all of the samples of stored blood in Figure 4 indicate that none of these methods of preservation would give satisfactory *in vivo* survival expectancy.

2. The degree of dilution and preservation.

A review of the extensive literature on blood preservation reveals that a great variety of dilutions of the whole blood have been used. This has varied from 10 per cent whole blood through a great many intermediate degrees of dilution up to undiluted blood. In most cases in the literature, the use of a particular dilution, whether 10, 40, 50, 80, 90 per cent of whole blood or whole blood itself, has been purely arbitrary with no supporting data for a particular dilution. Further, the tonicity and glucose content of the dilution medium have varied along with the degree of dilution. The work described below was an attempt to correlate the survival of red cells with the degree of dilution of the stored blood.

In addition to the immediate problem of the

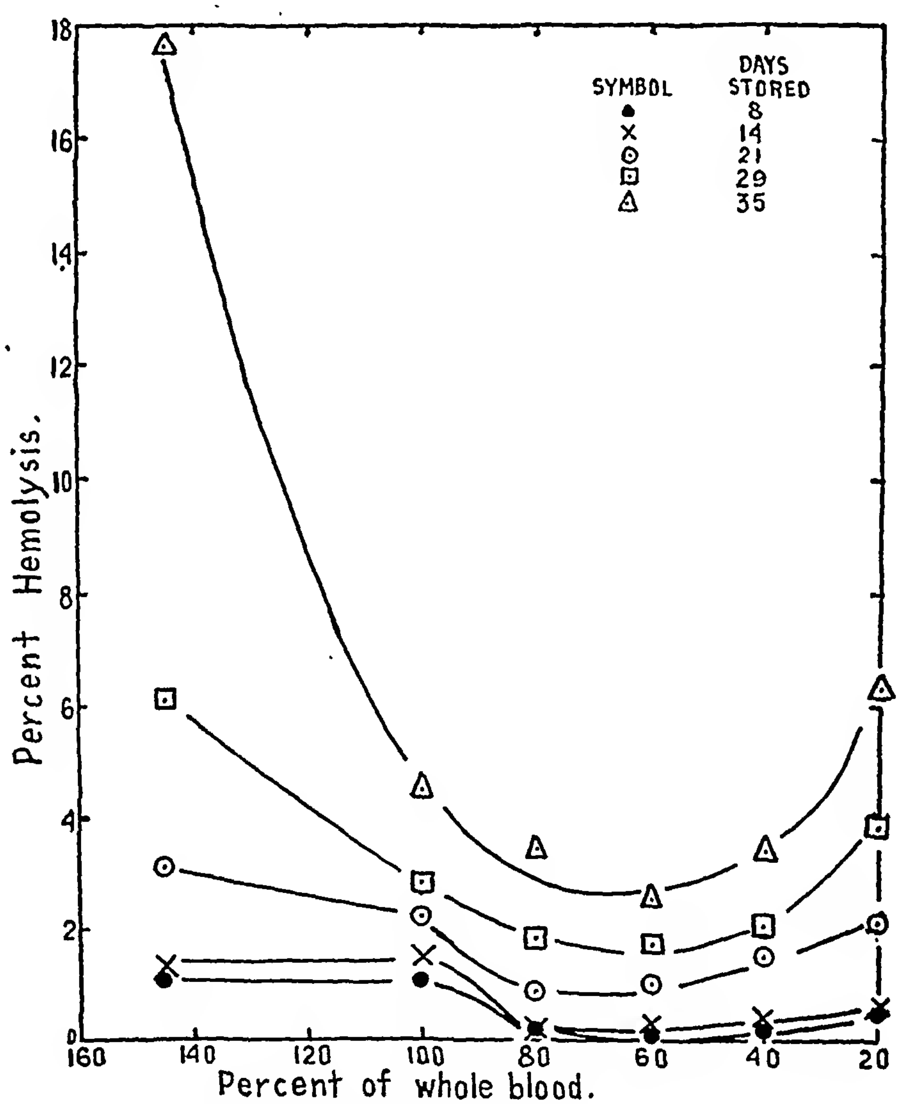

Fig. 5. Dilution of Whole Blood with Plasma and the Spontaneous Hemolysis During Storage

degree of dilution of stored blood on the survival of the red cells, there is a practical aspect of this problem in relation to transfusion. If it is necessary to increase the available hemoglobin of a patient, minimum dilution of the blood would be advisable. On the other hand the transfusion may also be used to combat dehydration, to supply glucose or salts, or plasma proteins, in which event high dilution of the red cells might be desirable. The answer to this must hinge upon a knowledge of what dilution is best for the survival of stored red cells.

An obvious perfect diluent might be plasma. We have run 5 experiments in which the donor's blood was diluted by varying amounts with its own plasma. A typical set of such data is given in Figure 5. The blood used in this experiment was collected by venipuncture into a bottle containing enough solid $Na_3C_6O_7 \cdot 2\ H_2O$ to give a final citrate content of 400 mgm. per 100 ml. of blood. A portion of the blood sample was transferred to sterile centrifuge tubes and citrated plasma obtained from it. This citrated plasma was then used to dilute the original blood by the amount indicated on the abscissa of Figure 5. Each of these diluted blood samples had 500 mgm. of glucose added to them and they were stored at the optimum temperature, 7° C. One of these blood samples was concentrated centrifugally and enough plasma removed to give a final concentration of 145 per cent relative to the whole blood concentration which was designated as 100 per cent. The blood of 3 other individuals had been stored and examined periodically in this way. Exactly similar results were obtained with only minor fluctuations in the absolute values.

The data contained in Figure 5 show quite clearly that the optimum dilution range for red cell preservation, with these conditions, lies between 80 per cent and 60 per cent of the whole blood concentration. It may also be noted that the optimum shifts from close to 80 per cent toward 60 per cent as the time of storage increases. On the average, blood which has been diluted to 70 per cent of its original concentration might be expected to give the best preservations of its red cells.

The question arises as to whether other types of diluents have an analogous effect. The data in Figure 6 illustrate this. Curve a (Figure 6) is

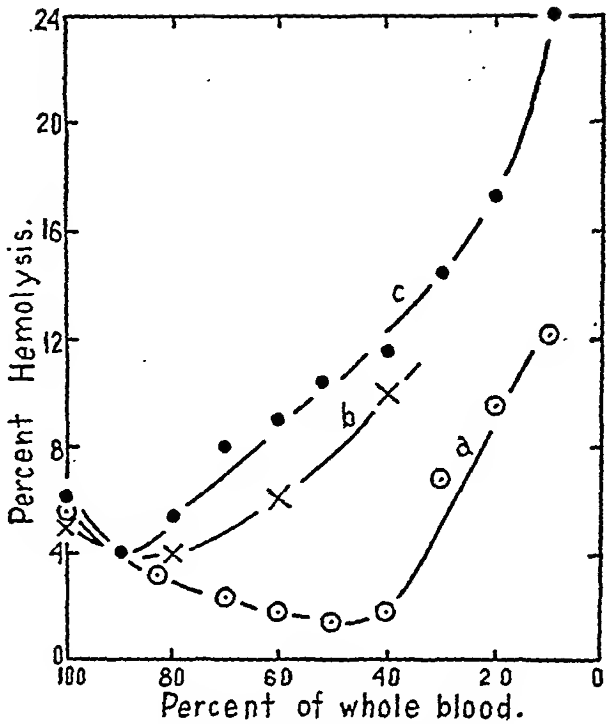

Fig. 6. Effect of Several Diluents on the Hemolysis Rate of Stored Blood

a plot of the degree of spontaneous hemolysis in blood stored for 48 days, at 7° C., under the following conditions. Five parts of blood were collected into 1 part of a 3.2 per cent solution of $Na_3C_6H_5O_7 \cdot 2\ H_2O$, cold (5° C.). A portion of this blood had 500 mgm. per cent (mgm. per 100 ml.) of glucose added, was stored at 7° C. and was examined at weekly intervals. This appears as 83.3 per cent of whole blood in curve a. Aliquots of the rest of this citrated blood were diluted with an isosmotic solution of glucose (5.4 per cent) to give the percentage concentrations of curve a. All were stored at 7° C. and examined at weekly intervals. The data in curve a (Figure 6) are those for the forty-eighth day of storage. They show that the optimum dilution lies between 60 and 40 per cent of the whole blood concentration and that a dilution which gives 40 per cent of the whole blood concentration is close to the borderline which may lead to rapid hemolysis. The latter is the preservative solution used by De Gowin, *et al* (11). The fact that survival of red cells in this solution is very poor when judged from the other *in vitro* criteria we have used has been previously mentioned under Figure 4, curve d.

Curve b (Figure 6) contains data for blood collected into solid citrate (see page 645) while curve c gives data for defibrinated blood. These blood samples were diluted with a sterile isotonic salt solution of the following composition: NaCl, 0.90 per cent; KCl, 0.042 per cent; $NaHCO_3$, 0.024 per cent; NaH_2PO_4, 0.05 per cent. They had 500 and 1,000 mgm. per cent of glucose added respectively and were stored at 7° C. The curves represent the degree of spontaneous hemolysis occurring at 35 and 21 days of storage respectively. The shapes of these curves and of curve a did not alter appreciably with time of storage, *i.e.* after the first week, though their position on the ordinate altered. It will be shown in section 5 that the difference in glucose concentration of these 2 samples does not account for the survival differences.

Curves b and c also show an optimum dilution and this occurs at about 80 and 90 per cent of whole blood. The effect is slight until blood concentrations of 60 per cent or lower are examined. It is obvious that dilutions of 60 per cent or greater are definitely deleterious when a balanced salt solution is used as the diluent. It is again noteworthy that defibrinated blood does not survive as well as citrated blood.

Figures 5 and 6 are convincing evidence of the fact that earlier experiments in the literature on blood preservation which failed to take account of the effect of dilution on survival of the red cells must be considered with respect to the actual dilution that was used. The foregoing experiments, combined with an analysis of data from a number of others, have led us to the conclusion that the survival time of stored red cells is increased when the blood is diluted. The data in Figures 5 and 6 would further indicate that for a variety of diluents a dilution consisting of 70 parts of blood and 30 parts of diluent (70 per cent whole blood) might be expected to give optimum survival.

Even this value of 70 per cent must be employed with caution, as the data of Figure 7 will show. In this case blood was collected into a minimum amount of citrate and diluted with a 6 per cent gelatine solution prepared in 0.9 per cent NaCl at pH 7.2.[2] The days of storage are indicated on the figure. Through 24 days of storage the survival was good at all dilutions and excellent at 40 per cent. At later periods of storage the survival was poor, but it is evident that the greater dilutions (40 and 20 per cent of whole blood concentration) gave better protection.

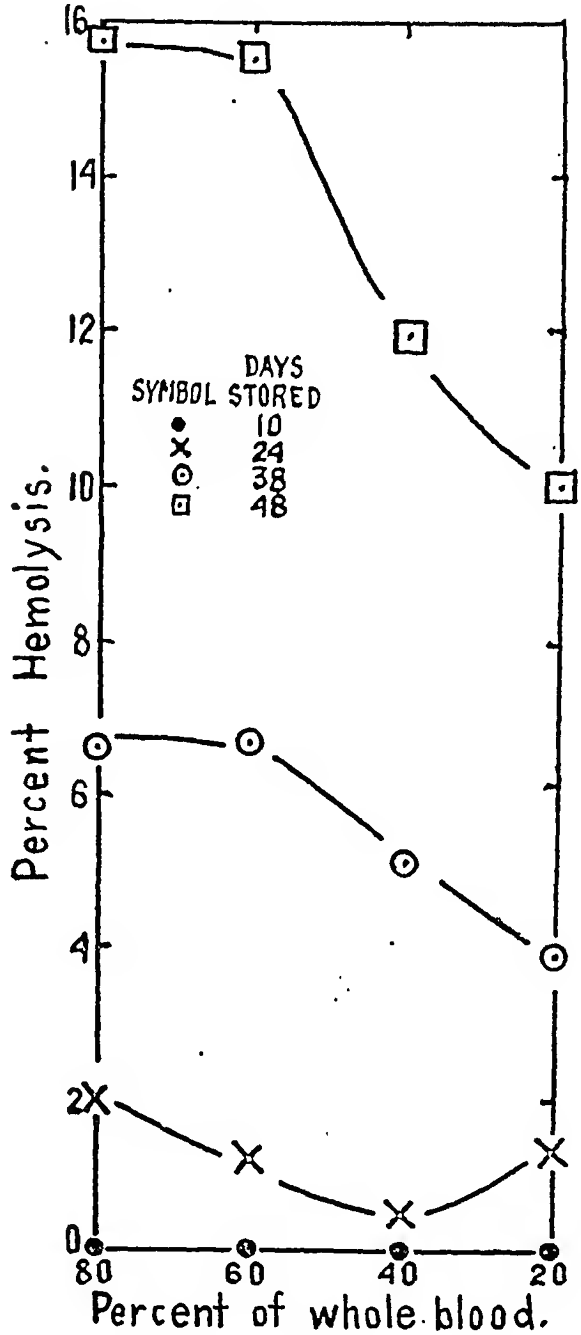

Fig. 7. Dilution with Gelatin

3. Tonicity, chemical composition and colloidal osmotic pressure of the diluent.

The diluent of historical interest is an isosmotic solution (5.4 per cent) of glucose (Rous and Turner [12]). They diluted whole blood as fol-

[2] This diluent was supplied through the courtesy of Dr. D. Tourtellotte, and is a product of Knox Gelatine Protein Products, Inc.

lows: 30 parts blood, 20 parts of 3.8 per cent $Na_3C_6H_5O_7 \cdot 5\ H_2O$ and 50 parts of a 5.4 per cent glucose solution. This has been used more recently at a 40 per cent concentration by De Gowin and his coworkers (11).

Those who have used this isosmotic glucose solution as a diluent for human red cells have ignored the fundamental fact that the human red cell is readily permeable to glucose. Thus, human blood collected by the methods of Rous and Turner or of De Gowin would be expected to show a marked increase in the volume of its red cells. That this is the case is shown in Figure 8, curve a, which expresses the relation between the red cell volume and the degree of dilution of the whole blood, under conditions where whole citrated blood was diluted with isosmotic glucose solution. The measurements given are for the seventh and forty-eighth days of storage at 7° C.

Contrasted with the very marked increase in volume of curve a are the much smaller red cell volume changes which occur during the storage of citrated blood which has been diluted with Ringer-Locke solution (calcium-free). The latter are represented in Figure 8, curves b and c, and are the data for the first and forty-ninth days of storage at 7° C. These diluted blood samples had 500 mgm. of added glucose.

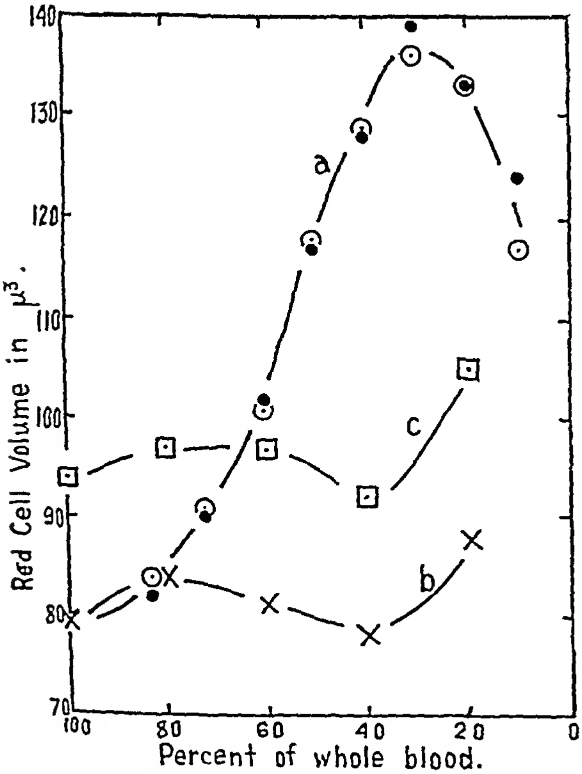

Fig. 8. Dilution and Red Cell Volume

The pronounced swelling of red cells diluted under the conditions of De Gowin or of Rous-Turner is the result of the penetration of the glucose. These red cells would continue to swell to the hemolytic volume were it not for the fact that they are being subjected to a shrinking effect brought on in part by the loss of chloride ions from the cells (Jacobs and Parpart [13]). An additional and more important factor in checking the swelling of human red cells diluted with isosmotic glucose solution is the rapid loss of potassium from these cells. Our data on potassium ion loss from the red cells stored under these conditions indicate that 50 per cent of the diffusion equilibrium is attained between the fifth and eighth days of storage, while the outward diffusion of potassium is complete after 10 to 20 days.

The balance between these several factors acting on the cell volume is a delicate one and needs only a slight change in environmental conditions (*e.g.* temperature rise) to cause a rapid rate of spontaneous hemolysis by the red cells of blood thus diluted, see curve c (Figure 4). Human blood stored under conditions where it is diluted to 40 or 30 per cent of its original concentration with an isosmotic glucose solution would be expected to show very poor *in vivo* survival of its red cells (Gibson [2]).

The question has been frequently raised as to whether it is important to maintain the normal colloidal osmotic pressure of the fluid surrounding the stored red cells. In an earlier section of this paper we have demonstrated that dilution of whole blood to 70 per cent of normal affords a better environment for the survival of the red cells. This was true irrespective of whether the diluent was (*1*) plasma, (*2*) a 6 per cent gelatine in isotonic NaCl solution, (*3*) a balanced salt solution, (*4*) an isosmotic glucose solution, or (*5*) an isotonic phosphate solution which when added to the blood established an initial pH of 7.1 (Figures 5, 7, 6, and 9).

Diluents (*1*) and (*2*) above had normal colloidal osmotic pressure while the other 3 diluents reduced the colloidal osmotic pressure of the plasma of the stored blood to 70 per cent of normal. The

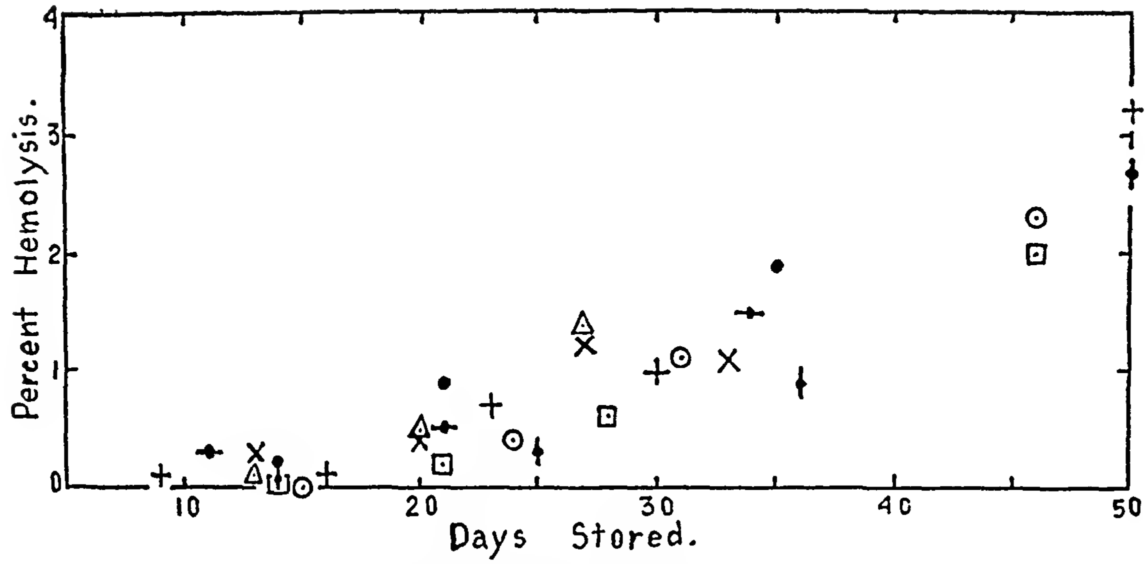

FIG. 9. COMPARISON OF DATA ON PHOSPHATE DILUTED BLOODS

rate of spontaneous hemolysis in these various diluents, however, did not differ greatly and what differences there are certainly cannot be ascribed to this factor. In fact, the survival of the red cells in stored blood diluted to 70 per cent of whole blood concentration with the phosphate solution (Figure 9) is much better than that in plasma or gelatine solution judged from our *in vitro* data and the *in vivo* data of Gibson (2).

It should be pointed out that the differences that do exist are outside the limits of variation of individual blood samples. This is also illustrated by Figure 9, where the degree of spontaneous hemolysis is plotted against the days of storage. The 8 individual blood samples represented in Figure 9 were from data taken at random over a period of 1½ years on citrated human blood samples stored at 7° C. and diluted as follows: 70 parts of whole citrated blood (4 mgm. $Na_3C_6H_5O_7 \cdot 2\,H_2O$ per ml. of blood) and 30 parts of a solution containing 60 volumes of 0.11 M $Na_2\,HPO_4$ and 40 volumes of 0.11 M NaH_2PO_4. The initial pH of blood thus diluted is 7.1 and during 50 days of storage drops to pH 6.7.

Another series of tests on the influence of the colloidal osmotic pressure of the plasma on red cell survival were run on 4 different samples of human blood. The blood samples were collected into citrate (in amount indicated above), divided into 2 equal volumes, transferred to sterile centrifuge tubes, spun, and the major portion of the plasma removed aseptically. The plasma of 1 aliquot of cells was exactly replaced by a solution recommended by Gibson, viz.:

$Na_3C_6H_5O_7 \cdot 2H_2O$	480 mgm.
Glucose	1,080 mgm.
NaCl	590 mgm.
Conc. HCl (Sp. G. 1.19)	0.25 ml.

made up to 100 ml. with pyrogen-free water.

The other aliquot had its plasma replaced by the same solution except that 3 grams of plasma protein- lipid Fraction IV–3, 4 Run S301, Cohn (14), were added to the 100 ml. of solution before replacing the plasma.

In the case of all 4 blood samples thus treated there was good survival over 45 days storage, but the difference slightly favored the solution without the added Fraction IV. In brief, the colloidal osmotic pressure of the medium surrounding human red cells does not appear to be a factor in their *in vitro* survival.

4. pH range and optimum, buffering.

The influence of pH on the survival of stored red cells has not been consistently investigated. Recently Loutit (1) has gathered together data on a number of samples of blood stored in acid citrate-dextrose that indicate that blood diluted with this solution and having an initial pH of 7.1 to 7.3 shows a better survival of its red cells.

In a report, dated October, 1943, to the Blood Substitutes Committee of the Committee on Medical Research we showed the very marked influence of pH on the survival of the red cells of stored human blood. Our studies of the influence of pH

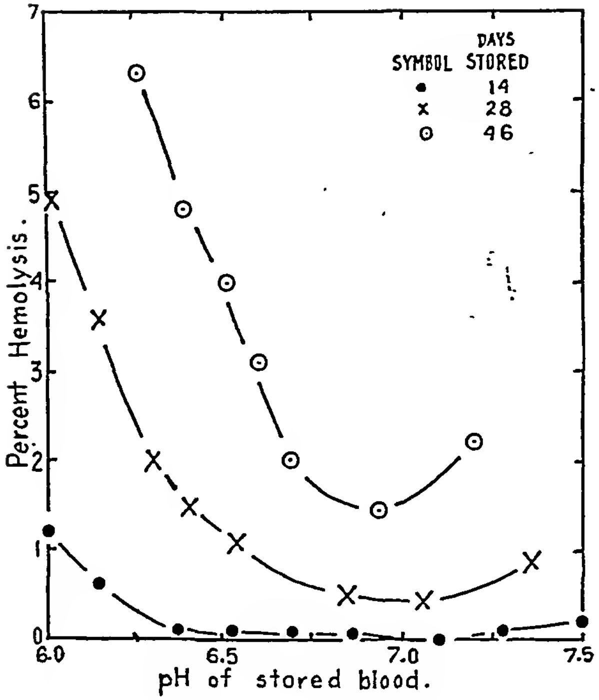

FIG. 10. INFLUENCE OF pH ON HEMOLYSIS RATE OF STORED BLOOD

on *in vitro* survival have been carried out under conditions where a minimum shift in the pH of stored blood was attained during long periods of storage. The citrate buffer system has no buffer capacity over the pH range for maximum survival of stored red cells (Figure 10). The rate of glycolysis of blood and the rapid formation of lactic acid, even at the optimum temperature (7° C.), is so high that over long storage periods blood samples will show marked decreases in pH unless adequately buffered.

We, therefore, turned to the phosphate buffer system and studied survival of the red cells at various hydrogen ion concentrations. These blood samples were followed over long time periods under conditions where a minimum decrease in pH with time of storage occurred. Citrated blood was diluted with isotonic (0.11 M) phosphate buffer solutions in the proportion of 30 parts of buffer to 70 parts of whole blood. In all cases these stored bloods had 0.5 per cent added glucose and storage was at 7° C. Thus, a number of blood samples having an initial pH between 6.0 and 7.5 were prepared and red cell survival determined at frequent intervals. Seven individual blood samples were run in this manner; the typical result of the effect of pH is shown in Figure 10 where the per cent of spontaneous hemolysis is plotted against the pH of the blood samples at the fourteenth, twenty-eighth, and forty-sixth days of storage.

Figure 10 demonstrates that the optimum pH for prolonged storage of human blood lies between pH 6.7 and 7.0. It may also be noted that during the first 2 weeks of storage there is slight effect of pH over the range pH 6.5 to 7.5. Longer storage periods, however, show a marked influence of pH. Thus storage for 4 and 7 weeks clearly requires a pH between 6.7 and 7.0 if optimum preservation of the red cells is to be attained.

Another striking action of pH on the survival of the red cells of stored blood is on the ability of the red cells to retain their normally high potassium content. This effect is illustrated in Figure 11, where the per cent of the original amount of potassium in the red cell which has diffused out of the cell at various times of storage is plotted against the pH of storage. In this experiment the blood was buffered by phosphate solutions as described above and 0.5 per cent glucose added and stored at 7° C.

Figure 11 illustrates that human red cells stored at a pH between 6.7 and 7.0 will lose their potas-

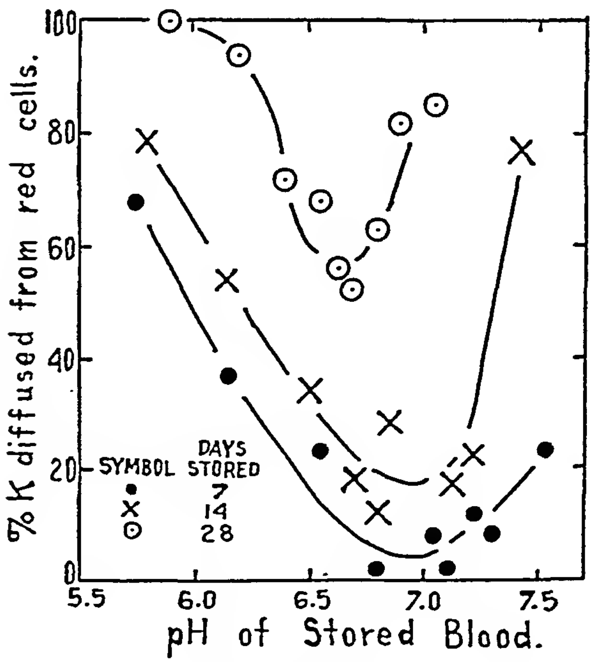

FIG. 11. EFFECT OF pH ON THE RATE OF LOSS OF POTASSIUM

sium at a much less rapid rate than at a pH higher or lower than this optimum range. Even after 4 weeks of storage at pH 6.8 the potassium of the red cells has diffused to only 60 per cent of equilibrium.

The studies thus far dealt with have employed the phosphate system. The results outlined are due primarily to the pH and not to specific action of the phosphate itself. This has been established by experiments involving storage of human blood in maleic, in maleic-succinate, and in glycyl-glycine buffer systems, under conditions otherwise identical for the phosphate system. The data obtained for these 3 systems as concern the optimum pH range for red cell survival are the same as that for the phosphate system, though the absolute magnitude at the optimum pH for cell survival does vary with the buffer used (Table I).

TABLE I

Comparison of the per cent of spontaneous hemolysis in human blood after 4 weeks' storage at 7° C. in the presence of different buffer systems

Each blood sample was composed of a mixture of 30 parts isotonic buffer solution and 70 parts whole (citrated) blood. The initial pH of each was 7.10 to 7.20 and the pH on the fourth week of storage is given. Each blood sample had 0.5 per cent glucose added.

Buffer system	pH after 4 weeks' storage	Spontaneous hemolysis after 4 weeks	Original glucose utilized by fourth week
		per cent	*per cent*
NaH_2PO_4/Na_2HPO_4	6.82	0.5	20
Glycyl-glycine/Na glycyl-glycine	6.75	0.7	18
Maleic-succinic acids/Na maleate-Na succinate	6.95	7.0	13
Maleic acids/Na maleate	6.82	15.0	0
None	6.94	1.8	36

In this respect, Table I shows that the phosphate system was better than the other buffers. It is thus certain that in addition to the pH effect on survival the phosphate itself markedly increases survival. The glycyl-glycine buffer is also exceptionally effective in prolonging red cell survival of stored blood (Table I).

Table I also shows that red cell survival in the maleic and maleic-succinate systems is poor even at the optimum pH. This effect, however, is probably associated with the low or completely inhibited glycolytic rate in the presence of these latter buffer systems (Table I).

Citrated blood, diluted to 70 per cent of whole blood with its own plasma and with 0.5 per cent added glucose, stored 4 weeks at 7° C., but with no buffer system added is included in Table I. It may be seen that while the degree of spontaneous hemolysis is low at this time, it is, however, considerably greater than in the blood with phosphate or glycyl-glycine buffer system (see also Figure 5).

From the foregoing it would appear that the phosphate buffer solutions which have on mixing with blood an initial pH between 7.1 and 7.3 and a pH after 4 weeks of storage at about 6.9 (with 0.5 per cent added glucose and storage at 7° C.) are exceptionally fine for increasing the survival period of the red cells of stored blood of man. The question remains as to what might be the minimal concentration of phosphate buffer to add to blood for optimal or good preservation of the red cells.

To answer this question, whole citrated human blood was diluted with varying amounts of phosphate buffer (Table II). The degree of dilution

TABLE II

Blood sample	Citrated blood	Phosphate buffer mixture	Balanced salt solution	Added glucose	pH 0 days storage	pH 50 days storage
no.	*ml.*	*ml.*	*ml.*	*mgm.*		
397	70	30	0	500	7.29	6.74
398	70	20	10	500	7.35	6.78
399	70	10	20	500	7.48	6.86
400	70	3	27	500	7.54	6.90
401	70	0	30	500	7.59	7.03

(70 per cent whole blood) was maintained constant (Table II), by using a calcium and phosphate-free Ringer-Dale solution. The glucose added to each blood sample was 0.5 per cent and all bloods were stored at 7° C. The data in Table II are expressed in terms of 100 ml. of blood plus diluent. The phosphate buffer mixture used consisted of 60 parts of 0.11 M Na_2HPO_4 and 40 parts of 0.11 M NaH_2PO_4.

The degree of spontaneous hemolysis which occurred in these stored samples after 14, 36, and 50 days of storage is illustrated in Figure 12. The "mean osmotic resistance" initially and at the same storage times is given in Figure 13.

As noted before, the presence or absence of the phosphate buffer has little or no effect during the first 2 weeks of storage (Figure 12). However,

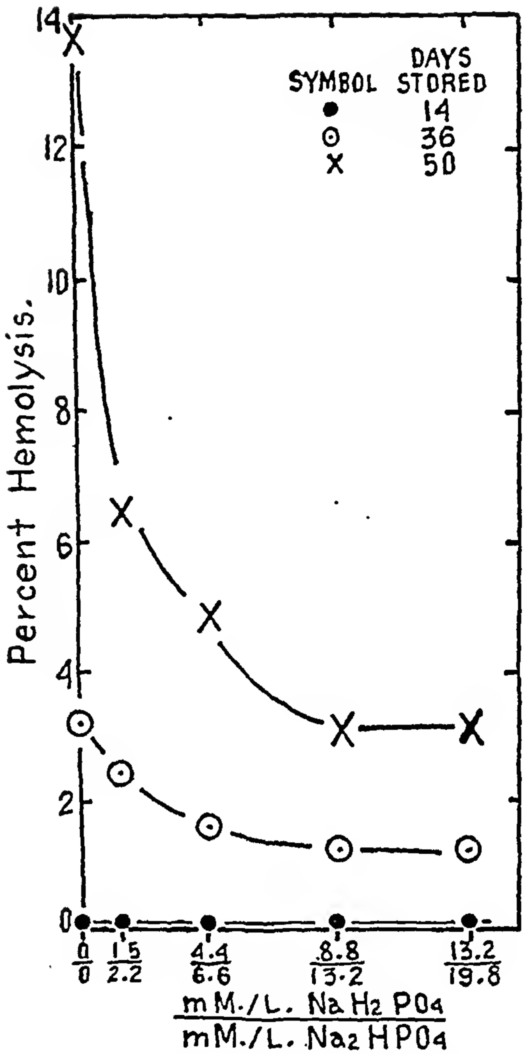

FIG. 12. EFFECT OF PHOSPHATE CONCENTRATION ON SPONTANEOUS HEMOLYSIS

when one examines the mean osmotic resistance curves (Figure 13) one observes that even after 2 weeks of storage the bloods stored with no, or a small amount of, phosphate buffer would be poor risks in transfusion and this becomes more striking on the fifth and seventh weeks of storage.

Blood stored with 0.0044 M NaH_2PO_4 and 0.0066 M Na_2HPO_4 per liter of blood and with 0.5 per cent added glucose, 30 per cent dilution and at 7° C., has its red cells well preserved over 5 weeks of storage. Blood stored under these conditions and injected in 500 ml. amounts would increase the normal plasma phosphate level by only 40 per cent.

5. Optimal Glucose Content.

Glucose added to stored blood increases the red cell survival. This is a fact upon which all experiments on blood preservation have concurred. No other sugar has been observed to have a comparable effect.

Surprisingly no one has investigated the effect of varying the glucose concentration while keeping other possible variables as constant as possible. We therefore performed a series of experiments on the effect of glucose concentration on red cell survival of stored human blood. Several series compared the survival in whole blood to which varying amounts of glucose were added. Blood was collected directly into solid citrate in the proportion of 400 mgm. $Na_3C_6H_5O_7 \cdot 2\ H_2O$ to each 100 ml. of blood. To aliquots of this citrated blood, amounts of glucose varying from 0 to 6 per cent were added and the survival followed over a 7-week period. The glucose was added on the basis

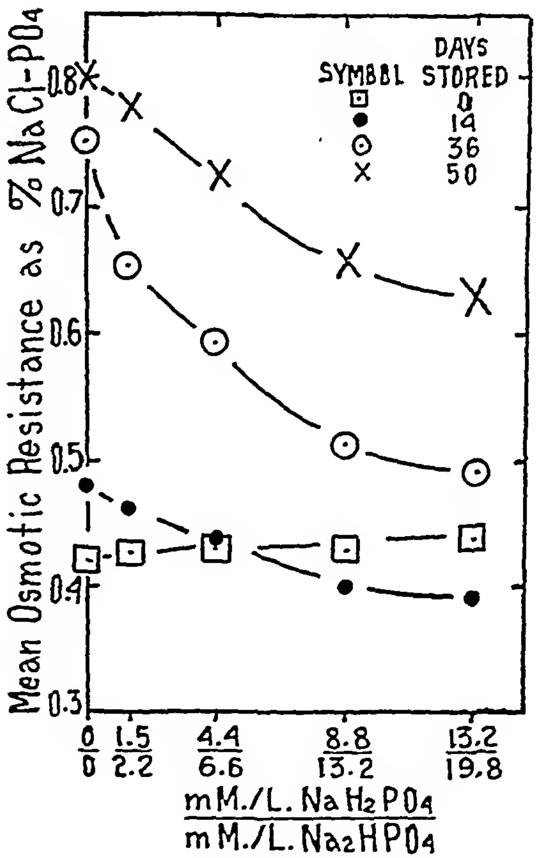

FIG. 13. EFFECT OF PHOSPHATE CONCENTRATION ON MEAN OSMOTIC RESISTANCE

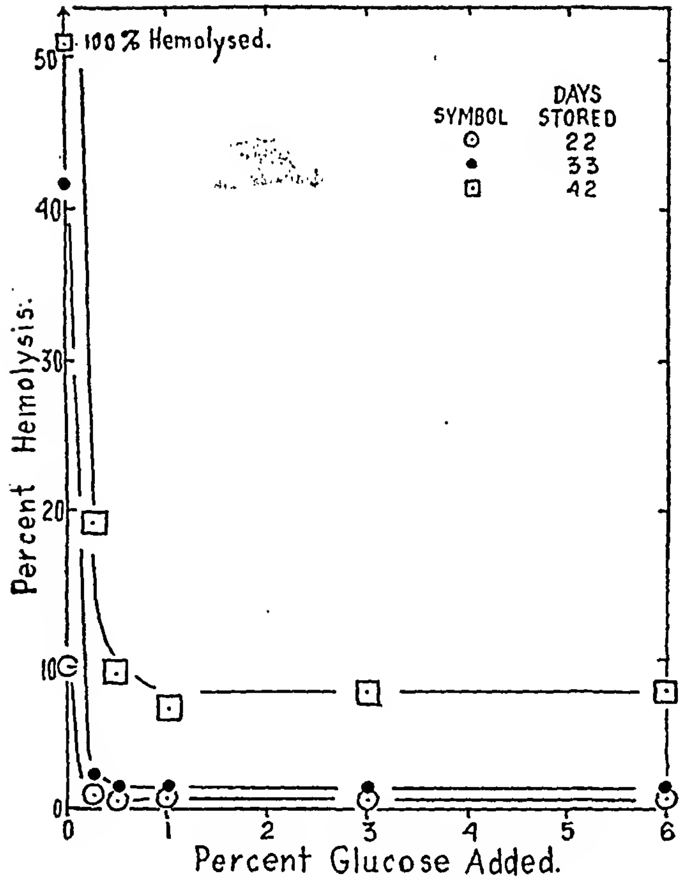

FIG. 14. OPTIMAL GLUCOSE CONCENTRATION FOR STORAGE

of grams of glucose per 100 ml. of stored blood, *e.g.* 1 per cent means 1 gram per 100 ml. blood. All bloods were stored at 7° C. The results of such experiments are illustrated in Figures 14, 15, and 16.

Data on the effect of added glucose on the degree of spontaneous hemolysis occurring during storage are given in Figure 14. The data in this figure show quite clearly that even a low total concentration (0.25 per cent) of added glucose aids in the red cell survival for 33 days of storage when compared with the cells of blood stored with no added glucose. From 33 to 42 days of storage, however, this low concentration becomes insufficient. It may also be noted in Figure 14 that amounts of glucose, including 0.5 per cent and greater, increase to a considerable degree the red cell survival although there is no cumulative effect of the greater amounts of glucose. It must be emphasized that these experiments were designed to vary only 1 factor, namely, glucose concentration. This, of course, precluded the possibility of studying survival under the optimal conditions of dilution and buffering against pH change. The results as far as the minimal effective amount of glucose to add to stored blood, viz. 0.5 per cent, are quite conclusive. Glucose penetrates the human red cell and, hence, its osmotic effects may be neglected under the conditions of these experiments.

Completely analagous results have been obtained on citrated blood diluted to 70 per cent with phosphate buffer at the optimal pH and stored with and without added glucose. After 42 days of storage these blood samples showed 8 per cent spontaneous hemolysis when no glucose was added and 1.8 per cent in the presence of 0.5 per cent added glucose. These data contrast only in the magnitude of the hemolysis with those for 42 days' storage in Figure 14 but are parallel as to the action of glucose. They show again the importance of dilution and buffering. In fact, blood stored under these latter conditions is in better state for

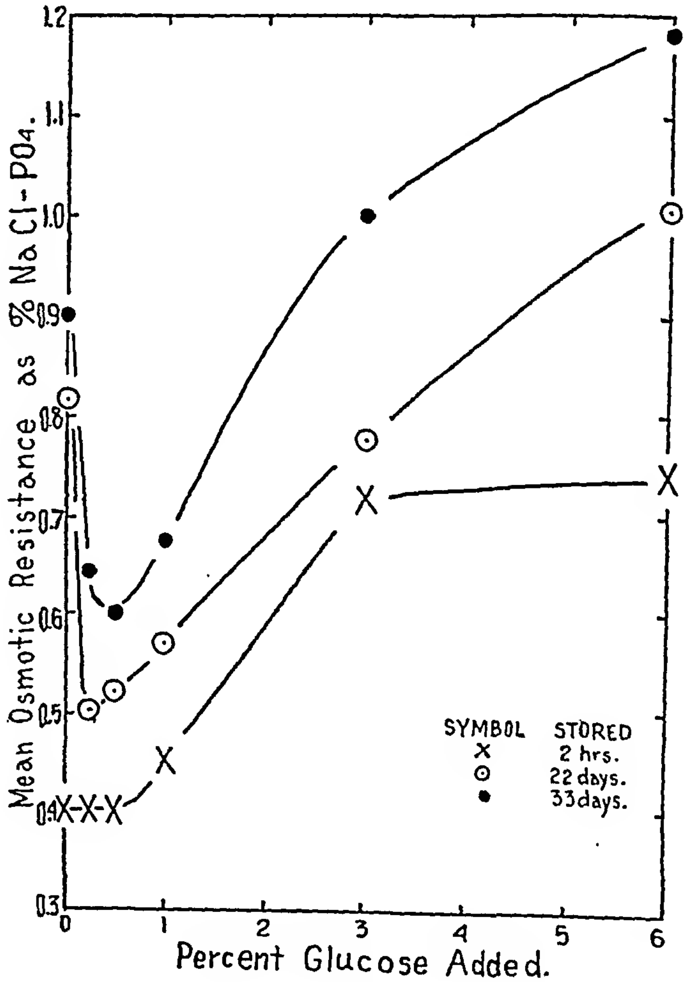

FIG. 15. EFFECT OF ADDED GLUCOSE CONCENTRATION ON THE MEAN OSMOTIC RESISTANCE

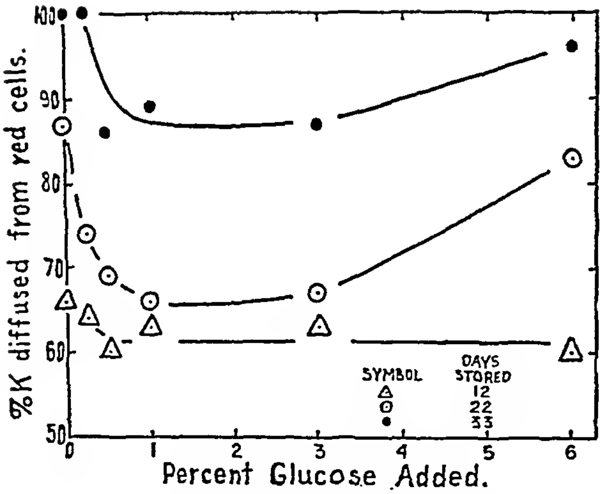

FIG. 16. EFFECT OF ADDED GLUCOSE ON THE LOSS OF POTASSIUM

transfusion after 42 days of storage than undiluted, unbuffered blood was at 22 days, regardless of added glucose.

Figure 15 brings out the noteworthy fact that high concentrations of added glucose, 1 per cent and higher, lead to a rapid decrease in the osmotic resistance of the stored red cells. These experimental observations are obviously the resultant of the effect of the increased concentration of glucose in the cells stored with this high amount of added glucose and the consequent swelling this would produce in the hypotonic saline solution in which the osmotic resistance was measured. They do give point to the fact, however, that such red cells when transfused would undergo rapid osmotic hemolysis, thus rendering them useless for such purposes. This danger point lies between 1 and 3 per cent added glucose (Figure 15).

The slight, but noticeable effect of added glucose on the retention of potassium by the stored red cells is illustrated in Figure 16 and may be contrasted with the good retention of potassium when the blood is diluted and buffered to the optimum pH (Figure 11).

We have studied the preservative action of a number of sugars in comparison with glucose. In all of these studies the particular sugar was compared with identical conditions for survival with added glucose. The sugars used were xylose, lactose, fructose, maltose, sucrose. None of these sugars gave as good survival of the red cells of stored blood as compared with cells stored with added glucose. In all cases except xylose the red cell survival was better than under parallel experiments where no sugar was added. Xylose gave no better survival than control blood with no added sugar.

SUMMARY

An analysis has been made of a number of factors concerned in prolonging the life of the red cells of stored human blood.

Blood collected and stored under the following conditions has been found to give excellent survival of its red cells over a period of at least 6 weeks: Seventy parts of blood collected into 10 parts of 4 per cent $Na_3C_6H_5O_7 \cdot 2\ H_2O$ and 20 parts of a phosphate buffer solution (composed of 60 volumes 0.11 M Na_2HPO_4 and 40 volumes of 0.11 M NaH_2PO_4); 500 mgm. per cent of glucose is added and the blood is stored at 7° C.

Blood thus stored will be under the optimal conditions of (*1*) pH (initially *7.2* and 6.8 after 6 weeks), (*2*) good buffering, (*3*) dilution (*70* per cent), (*4*) glucose concentration (500 *mgm.* per cent), (*5*) temperature (*7°* C.).

ESTIMATION OF CELL SURVIVAL AFTER TRANSFUSION BY SELECTIVE AGGLUTINATION

By DOROTHY E. OSBORNE and ORVILLE. F. DENSTEDT

(From the Department of Biochemistry, McGill University, Montreal, Canada)

(Received for publication August 31, 1946)

Selective agglutination, as a means of estimating the number of donor's erythrocytes in the circulation of a recipient after transfusion, was used first by Ashby (1) in 1919. In the procedure, group-O blood was administered to a subject of group A (or B), and in blood specimens taken periodically thereafter, the number of surviving donor-cells was estimated by selectively agglutinating those of the recipient with anti-A (or anti-B) serum, and counting the unagglutinated group-O cells in a hemocytometer. Wiener and Schaefer (2, 3), in 1939, obtained the same result by using the M and N blood types. More recently still Wiener (16), and Mollison (4) have extended the technique to the Rh blood types using Rh-negative donors and Rh-positive recipients with anti-Rh as the agglutinating serum. Wiener and Peters (5), and Mollison and Young (6) have demonstrated the adaptability of the method by following the survival of 2 donors' cells simultaneously in the same recipient. The results obtained by these techniques are in good agreement, and show that if fresh blood is used for transfusion the donor's erythrocytes disappear from the recipient's circulation at the rate of about 1 per cent per day, which is the normal rate of red cell destruction. In the past 8 years the method has proved to be of great value in studies on blood preservation, particularly in testing the effects of various methods of preservation on the viability of erythrocytes during storage. From the practical standpoint, the O and A blood groups offer the advantage that they occur frequently in the population and that highly potent anti-A serum is readily obtainable.

The original agglutination procedure of Ashby has been modified in various laboratories with regard to the amounts of cell suspension and antiserum used, temperature conditions, and technique. Numerous workers (1, 3, 7, 8, 9, 10) perform the reaction in small serological test tubes with or without agitation. Maizels and Paterson (11) use small beakers, and Loutit (12), small bottles with a relatively small amount of antiserum. Thalhimer (13) has reduced the number of manipulations to a minimum by carrying out the reaction in a red-cell pipette. The present authors have modified their former method by using light centrifugation to accelerate agglutination. This treatment is also a feature of the method of Dacie and Mollison except in the use of anti-M and anti-N sera (14) which are said to give some non-specific agglutination with centrifugation. All these procedures are based on extensive experimentation and, in the hands of experienced workers, give comparable results.

In determining the number of the donor's erythrocytes in the recipient's circulation by selective agglutination, it is necessary beforehand to know the recipient's "free" or "unagglutinable" cell count. In other words since complete agglutination of erythrocytes is impossible by ordinary methods the number of unagglutinable cells per mm.^{3} must be ascertained prior to transfusion. The number of donor's cells in the post-transfusion samples may be determined by subtracting the recipient's free-cell count from the total number per mm.^{3} Experience has shown that the free-cell count of the individual is fairly constant with a given potent antiserum, but it may vary with different antisera depending largely on the agglutinin potency, or titre. Authorities are agreed that strong antiserum is essential for accurate results. The consensus is that an antiserum for selective agglutination tests should be specific for the recipient's red cells and should give a free-cell count not exceeding 50,000 per mm.^{3} of blood.

From time to time the reliability of the selective agglutination method has been queried. The various criticisms and their refutation have been discussed by Maizels and Paterson (11) and by Mollison and Young (15).

The study reported in the present paper arose from certain anomalies observed in an earlier investigation on red cell survival carried on during

1940 to 1943. At that time we were using the method of Wiener and Schaefer (3) with anti-M and anti-N sera prepared in our laboratory according to the methods of Wiener (16) and of Davidsohn and Rosenfeld (17). The antisera, which were prepared aseptically, were potent and highly specific. Prior to use, the serum for a complete experiment was given an additional absorption with a light suspension of saline-washed red cells of the prospective recipient to ensure the absence of nonspecific agglutinins. Frequently, the serum, if strong, was diluted further before dispensing it into small serological tubes. The latter then were stored at 0° C. These antisera were of high avidity, producing visible and compact agglutination within a few seconds. The free-cell count usually was less than 30,000 per mm.^{3} but up to 50,000 was considered satisfactory.

The above mentioned anomalies in our cell-survival results were periodic increases in the number of unagglutinable cells, a condition which should not have existed provided that the recipient's free-cell count remained constant and the transfused cells were being destroyed continuously. That the increases were not attributable to errors in counting or to alteration in the antiserum was ruled out by repetition of the counts with several lots of the antiserum. Some of the tests were repeated as many as 12 times with consistent results; others were checked by both authors. In several instances the deviations in the survival counts followed a steady course over a period of 2 or 3 weeks and exhibited a periodicity which was inexplicable. That some erythrocytes were being sequestered from the circulation and released again periodically was hardly tenable. As other investigators (3, 15) in similar studies had not encountered the same type or degree of irregularity, it was decided to investigate further into the cause of the phenomenon. Attention was directed first to ascertaining the constancy of the free-cell count and secondly to the influence of the titre and avidity of the antiserum on the completeness of agglutination.

Discussion of the more theoretical aspects of agglutination will be reserved for a later publication. For a survey of the literature relevant to the present study the reader is referred to recent reviews (16, 18, 19) and to papers by Eagle (20, 21), Duncan (22) and Kendall (23).

Whatever the mechanism of agglutination may be, authorities are agreed that the phenomenon involves 2 main stages, namely; (*1*) the combination of the antigen (agglutinogen) with the antibody (agglutinin) and (*2*) aggregation of the sensitized cells. Sensitization is known to occur very rapidly while aggregation is a slower process. Eagle (21) and others have shown that mechanical agitation accelerates the rate of agglutination by increasing the incidence of collision of the cells. The process is very rapid at first but decreases logarithmically with time. It may be brought about more rapidly and firmly with the aid of centrifugation. Thus the titre of an antiserum, when determined with centrifugation is from 6 to 10 times that without the treatment. Up to a point agglutination increases with the concentration of agglutinin. Very potent antisera may not produce agglutination or may not give a maximum reaction until diluted. This upper zone of inhibition is usually called the "prozone" to distinguish it from the lower zone, the "postzone" where aggregation of cells is diminished due to dilution of the antibody. The mechanism of prozone inhibition is not fully understood although considerable light has been thrown upon the subject by the studies of Jones and Orcutt (24).

The inadequacy of the ordinary titre method for characterizing the potency of an antiserum has been stressed by numerous authors. Obviously the titre, expressed as a number, merely gives a rough and comparative idea of the agglutinin concentration of the original material. For the purposes of the clinical laboratory, however, the method is valuable particularly for determining the point of optimal proportion of antigen and antibody, *i.e.*, the dilution which produces most rapid agglutination. With moderately strong or weak serum, the maximum rate of agglutination is obtained with the undiluted material. As erythrocytes of different individuals of the same blood group vary considerably in properties, the titre of a given serum and the concentrations of optimum proportion may vary with the blood tested.

In the present study the authors have sought an answer to the following questions:

(*1*) Can the free-cell count be abolished by careful adjustment of the antiserum concentration and by control of conditions of the reaction?

(2) What is the normal variation in the free-cell count?

(3) To what degree is incomplete agglutination of red cells influenced by the following factors:

(a) Too rapid agglutination and insufficient time for completion of the reaction.

(b) Insufficient antibody.

(c) Under-sensitization of cells due to deficiency in antigen content, or to age.

EXPERIMENTAL

In 1944 the present authors modified their agglutination technique by introducing centrifugation, thus reducing the time of the procedure to about one-third. Also, with the increased availability of highly potent anti-A and anti-B sera a change was made to the O, A, and B blood groups in preference to the M and N types.

METHODS

1. *Selection of antiserum*

In selecting an antiserum for an experiment an ordinary titre series is set up for each serum to be tested using the saline-washed red cells of the prospective recipient. With the aid of a microscope the particular dilution in the series which gives the most complete agglutination is ascertained. This concentration may not be the one which produces the most rapid agglutination or the most compact cell sediment. Having selected the optimum serum concentration for completeness of reaction, a larger quantity of the particular dilution is prepared and dispensed aseptically into small tubes which then are stoppered and stored at 0° C. Prior to use, each tube is permitted to come to room temperature and is inverted several times to ensure uniformity of the contents.

Very potent anti-A or anti-B sera, particularly those prepared by concentrating the globulin fraction, frequently develop a surface precipitate of lipid when stored at 0° C. or after having been frozen. Unless removed, this material may prove a source of much annoyance and confusion during cell counting since many of the particles are about the size of the erythrocytes. One of the authors (D. E. O.) has found that the lipid can easily be removed by keeping the serum in a centrifuge tube in the cold for a few days and then cautiously overlaying the surface with physiological saline followed by centrifugation at high speed. If the saline is applied slowly with a fine capillary pipette, no mixing with the serum will occur and, after centrifuging, the saline layer, on the surface of which the lipid will have collected, can be removed by aspiration through a capillary tube.

2. *Collection of blood samples*

Prior to transfusion, and periodically thereafter, blood samples are taken from an antecubital vein of the recipient. Approximately 10 ml. are delivered into a graduated centrifuge tube containing 1 ml. of sterile sodium citrate solution (3.2 per cent). The tube is stoppered and inverted gently several times. By emptying the syringe against the wall of the tube and by using gentle mixing methods excessive frothing of the sample can be avoided. Foam may be collapsed by touching it with a fine wire or needle the mere tip of which has been dipped into caprylic alcohol. The total volume of the specimen is recorded to obtain the dilution factor. The hemoglobin concentration of the specimen is determined with a photoelectric colorimeter, and the hematocrit, using the Wintrobe tube. A total red-cell count is performed on the pretransfusion specimen.

3. *Agglutination procedure*

Blood samples, if refrigerated, are permitted to come to room temperature. The red cells are suspended by gently and repeatedly inverting the tube for about 1 minute. Another light mixing is performed immediately before pipetting.

Blood is drawn up to the 0.5 mark in a white-cell pipette which is then filled to the 11 mark with sodium chloride solution (0.9 per cent). After the pipette is shaken for a few seconds, it is emptied into a serological tube (10×75 mm.).

The tube is shaken a few times, and the cell suspension is drawn up to the 1.0 mark in a dry white-cell pipette. The latter is then filled with the agglutinating serum. After the pipette is shaken vigorously for a few seconds, the contents are transferred to a serological tube and centrifuged in an electric table centrifuge at 1500 r.p.m., the machine being turned off automatically at the end of 2 minutes.

The sedimented red cells are dispersed by flicking the tube sharply several times by hand and shaking for an additional 45 minutes on an electric shaker[1] at 176 vibrations per minute. (The table of the shaker in our laboratory is covered with a 2-inch slab of fiberglass to insulate the specimens from the heat of the motor.)

Finally, the tube is flicked sharply to suspend the cell sediment, the larger clumps are permitted to settle for a couple of seconds, and a sample of the supernatant fluid is transferred to the hemocytometer by means of a white-cell pipette filled to the 1.0 mark. Counts are made in duplicate and usually agree within 10 per cent.

The free-cell counts are calculated to the number per cubic millimeter of uncitrated blood. With experimental mixtures of O and A erythrocytes or OM and ON in the proportion of 1:30, the lesser component can be determined by selective agglutination within 5 per cent.

4. *Transfusion procedure*

In the majority of our red-cell survival experiments since 1944, the practice has been to determine the blood volume of the recipient prior to transfusion and to determine accurately the quantity of blood administered by

---

[1] No. 3623 rotating apparatus, obtainable from A. H. Thomas Company, Philadelphia.

weighing the container before and after the transfusion. The hemoglobin, hematocrit and total red-cell count also are determined on a sample taken from the bottle immediately before the experiment. The number of donor cells per mm.[3] of the recipient's blood immediately after transfusion, therefore, can be quite accurately calculated.

If the number of cells found is considerably less than the theoretical number, as is often the case when preserved blood is administered, the discrepancy is assumed to represent the number of the donor's erythrocytes eliminated by the recipient during the transfusion.

The volume of citrated blood administered in our experiments formerly was 450 ml., but since 1944 has usually been about 200 ml.

RESULTS

1. *Influence of agitation on the rate of agglutination*

The rate of combination of antigen with antibody is known to be extremely rapid. Hence, as numerous workers have shown, the accelerating effect of various modes of agitation and sedimentation on the rate of agglutination is due chiefly to increasing the incidence of contact between the sensitized cells. The size and shape of the container also may influence the rate especially if shaking is the mode of agitation.

Figure 1 illustrates the influence of the rate of horizontal shaking on the completeness of agglutination of erythrocytes at the end of 90 minutes with our apparatus. The unagglutinated-cell count is expressed as the number of free cells observed in the entire field of the hemocytometer, *i.e.*, in 0.9 mm.[3] of cell suspension. The effect of agitation above 190 vibrations per minute could not be determined with our facilities, but presumably a maximum eventually would be reached beyond which agglutination would be less complete and the damaging effect of the shaking would become a serious factor. Experiments with higher, but unknown, rates of shaking invariably have revealed considerable hemolysis. The results of shaking also vary somewhat with the blood, the antiserum, and the mode of agitation.

Agglutination may be accelerated greatly by an initial light packing of the cells by centrifugation. Figure 2 gives a comparison of the degrees of agglutination with and without centrifuging and at 2 rates of shaking. It will be observed from curve D that centrifugation, followed by shaking for 30 minutes, produces as complete agglutination as does shaking alone at 176 vibrations per minute at the end of 6 hours. Attempts to reduce the unagglutinated-cell count by agitation for more than 6 hours invariably resulted in visible hemolysis. Centrifuging also tends to damage red cells, and, if too prolonged or too rapid, will result in early hemolysis on subsequent shaking.

2. *Influence of strength of antiserum*

In determining the agglutinating titre of a strong antiserum by the ordinary method of progressive dilution, one tube in the series usually shows more rapid agglutination than those preceding or following it. This particular dilution represents, or approximates, the concentration of optimum proportion of the antigen and antibody as far as rate of agglutination is concerned. If aggregation of the

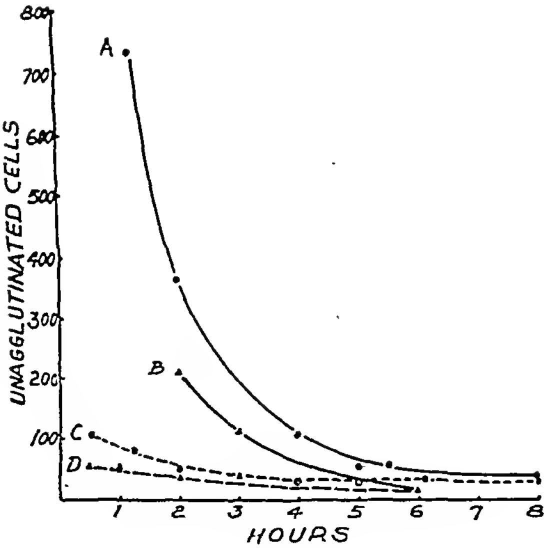

FIG. 2. PROGRESS OF AGGLUTINATION AT TWO RATES OF SHAKING WITH AND WITHOUT AN INITIAL LIGHT CENTRIFUGATION

Curves A and C, 146 vibrations per minute; curves B and D, 176 per minute.

red cells takes the form of a single, compact clump, one easily may be misled into assuming that agglutination is complete. On examination under the microscope, however, a surprisingly large number of unagglutinated cells may be observed. The concentration which affords the most rapid agglutination, therefore, may not produce the most complete reaction. This is true especially of antisera of marked avidity, notably anti-M and anti-N sera, which, even when diluted many times, may produce visible and compact agglutination within a few seconds. In preparing an antiserum for selective agglutination, therefore, it is essential to ascertain the relative concentration which produces the most complete aggregation of cells. This concentration usually is in the neighborhood of that which produces most rapid agglutination. With serum of only moderate potency, the maximum is obtained with the undiluted material.

The relation between the strength of the antiserum and the completeness of agglutination or the free-cell count is illustrated in Figures 3 to 9 inclusive. To facilitate comparison, the data are presented in the form of graphs. In doing so the authors wish to direct attention to the inconsistency in the results with different dilutions of serum rather than to imply that the fluctuations are due to variation in the properties of the erythrocytes or the antiserum, although either, or both the latter conceivably may occur.

(*a*) CONSTANCY OF THE UNAGGLUTINABLE-CELL COUNT

Figures 3 to 6 inclusive illustrate the fluctuations in the free-cell count with various dilutions of antiserum and in different individuals, over a period of 2 months. The results are expressed as thousands of cells per cubic millimeter of the recipient's blood. Attention is directed to the magnitude of the fluctuations in Figure 6. The counts were done in duplicate.

The variability of the free-cell count with the lower concentrations of antiserum is pronounced. With serum of marked avidity, *e.g.*, anti-M and anti-N, the rapidity, firmness, and compactness of agglutination may easily mislead one into thinking that agglutination is complete.

The stronger concentrations, on the other hand, produce a low free-cell count, which, in the case of the optimum concentration, remains practically constant within the counting error. Occasionally we have found that the recipient's free-cell count, after the donor's cells have disappeared from the circulation, is slightly higher than before the transfusion. In these cases the higher count has been used in calculating the results. For the purpose of the red-cell survival test, provided a strong serum is used, the unagglutinable-cell count of the recipient may be assumed to remain constant.

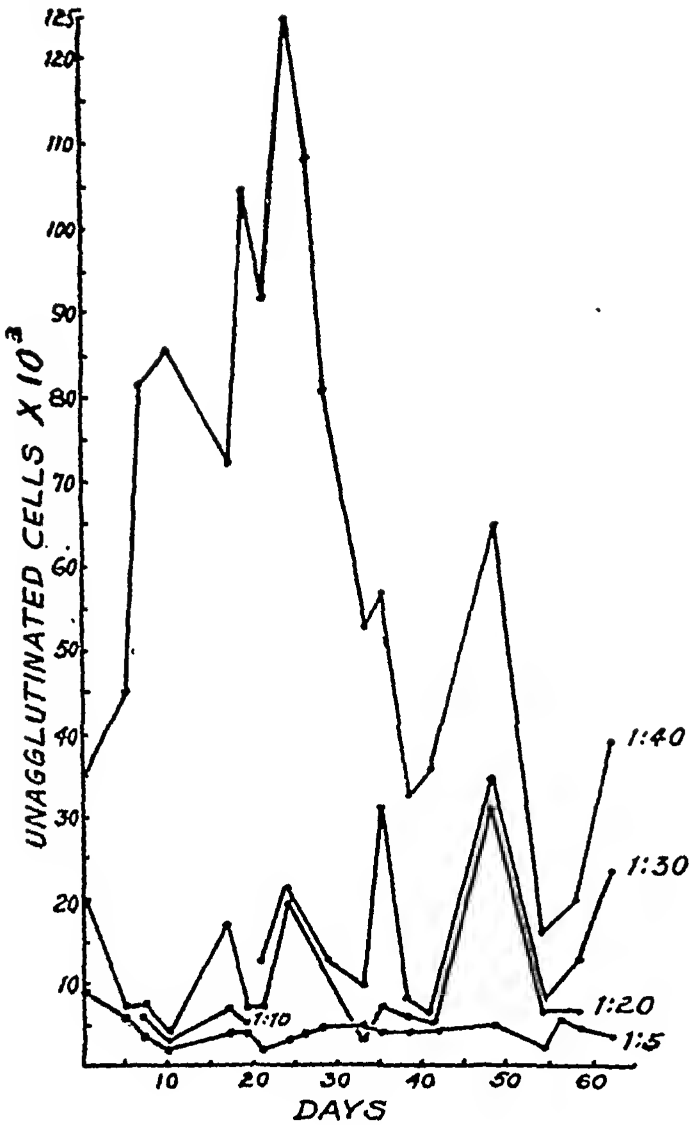

FIG. 4. VARIATION IN THE FREE-CELL COUNT OF A GROUP-A SUBJECT WITH A POTENT ANTI-A SERUM (TITRE 5,000) DILUTED 5, 10, 20, 30, AND 40 TIMES, RESPECTIVELY

(b) AGGLUTINABILITY OF PRESERVED ERYTHROCYTES

It was anticipated that if the fluctuations observed in the agglutinability of erythrocytes with weak sera are due to changes in the agglutinogens on the cell membrane, the agglutinability of the cells might become increasingly erratic with storage.

In Figure 7, the curves "A" represent periodic free-cell counts on blood (group $A_1MRh_1Rh_2$) preserved in citrate-dextrose solution at 5° C. over a period of 50 days; "B", the counts on fresh blood from the same donor. Here again the stronger serum (anti-A diluted 1:5) gave more constant results than the weaker lot (diluted 1:10). It is noteworthy also that under optimum conditions of preservation the agglutinability of the stored erythrocytes does not differ from that of the fresh blood. The counts are expressed as the number of free cells in the hemocytometer field in order to accentuate the fluctuations. (The factor for converting the count to cells per mm.[3] is approximately 270.) Since many of the erythrocytes, by the fiftieth day of storage, become nonfunctional (at least 50 per cent of the cells), it appears that agglutinability is not greatly impaired by the loss of viability provided conditions of preservation are favorable.

The curve in Figure 8 illustrates the behavior of the free-cell count in a sample of preserved blood of group OMRh using a potent anti-M serum diluted 20 times. The variation is typical of that observed with diluted antisera even in fresh blood. There is no evidence in this and in similar experiments that the reactivity of the M and N agglu-

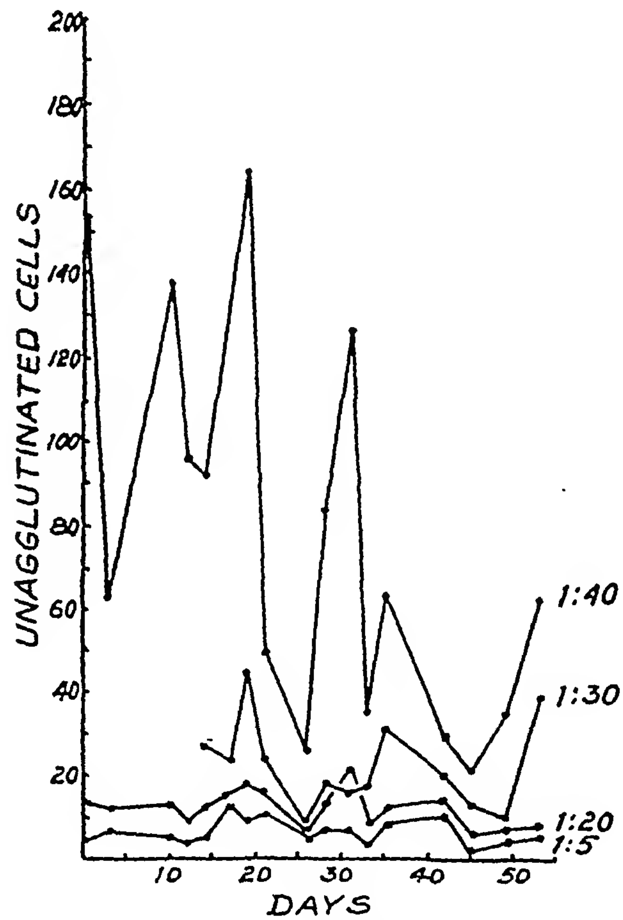

FIG. 5. FLUCTUATION IN FREE-CELL COUNT OF A GROUP-A INDIVIDUAL WITH POTENT ANTI-A SERUM (TITRE 5,000) DILUTED 5, 20, 30, AND 40 TIMES, RESPECTIVELY

tinogens is impaired during storage under optimum conditions at least up to 6 weeks.

3. *Estimation of transfused erythrocytes*

In view of certain anomalies observed up to 1944 in our experiments on mental patients it was thought advisable to perform a few cell-survival tests on normal subjects. Accordingly 200 ml. of fresh citrated blood of a donor group ONRh$_1$ was administered to each of 2 recipients and counts were followed daily for about 60 days. Figure 9 illustrates the disappearance of the donor's cells from the circulation of a recipient, group OMNRh$_2$, as determined with anti-M serum (titre 64), and Figure 10, the curve for the second recipient, group AMRh$_1$Rh$_2$, as determined simultaneously with anti-A (dotted curve) and anti-M sera. The gaps in the curves were occasioned by a holiday. It is noteworthy that despite the ir-

Curves A represent preserved blood and curves B, fresh blood.

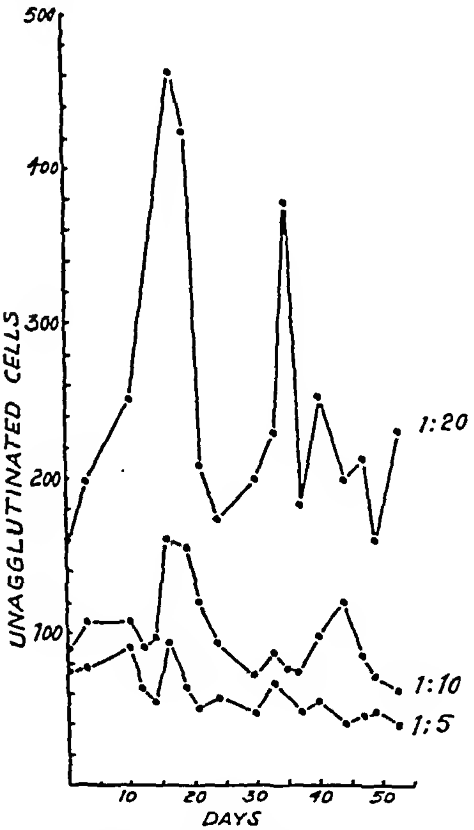

FIG. 6. FLUCTUATION IN FREE-CELL COUNT OF A GROUP-A INDIVIDUAL WITH A POTENT ANTI-A SERUM (TITRE 5,000) DILUTED 5, 10, AND 20 TIMES, RESPECTIVELY

regularities due to the use of diluted sera, the course of the red-cell elimination is quite accurately indicated. With diluted antisera, cell counts should be performed at least weekly in order to be able to correct for irregularities.

Figure 11 represents a transfusion series, performed in June 1944, in which 150 ml. of blood from 1 donor of group ON, was administered to each of 4 recipients. The first received a fresh specimen and the others, in turn, samples that had been preserved in citrate-dextrose at 5° C. for 12, 22, and 40 days, respectively. The free-cell counts of the recipients are included in Table I.

The rapid elimination of non-viable red cells within 3 to 6 hours after transfusion is indicated in curves B, C, D. In our experience, with blood stored for more than 3 weeks, there usually is indication of a partial elimination of the non-viable cells even during the period of the transfusion (200 ml.). The 100 per cent count in the post-transfusion sample in recipient D, therefore, is exceptional. It is noteworthy that a rapid elimination of erythrocytes always occurs with preserved blood within a few hours after transfusion, the loss amounting roughly to 1 per cent of the cells per day of storage (or more if conditions of preserva-

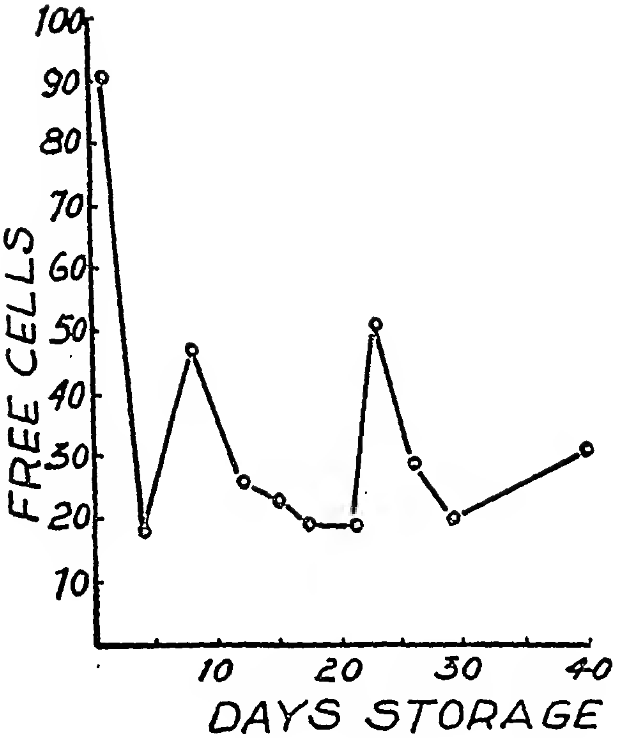

FIG. 8. FLUCTUATION IN THE FREE-CELL COUNT OF A PRESERVED BLOOD SAMPLE, GROUP-AM, USING AN AVID, BUT DILUTED, ANTI-M SERUM

tion are not optimum). With strong antisera the survival curves, for the most part, are free from gross irregularities.

One type of anomaly which the writers have encountered occasionally in exaggerated form with potent anti-M and anti-N, and even with

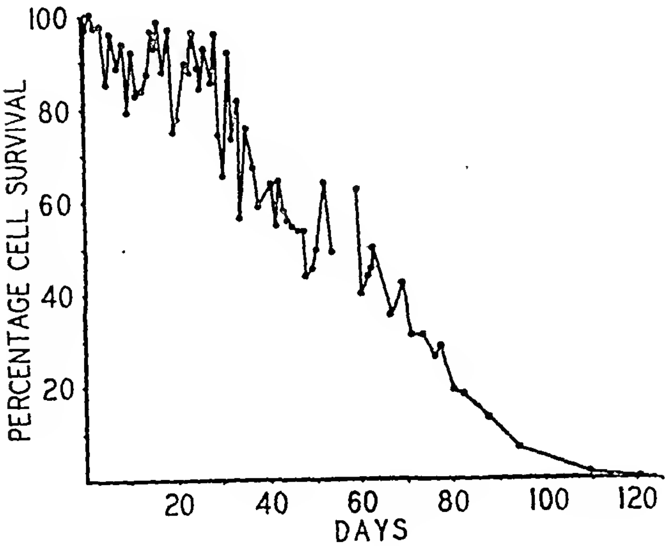

FIG. 9. ELIMINATION OF THE ERYTHROCYTES OF A GROUP-ON DONOR FROM THE CIRCULATION OF A GROUP-OMN RECIPIENT USING DILUTED ANTI-M AGGLUTINATING SERUM

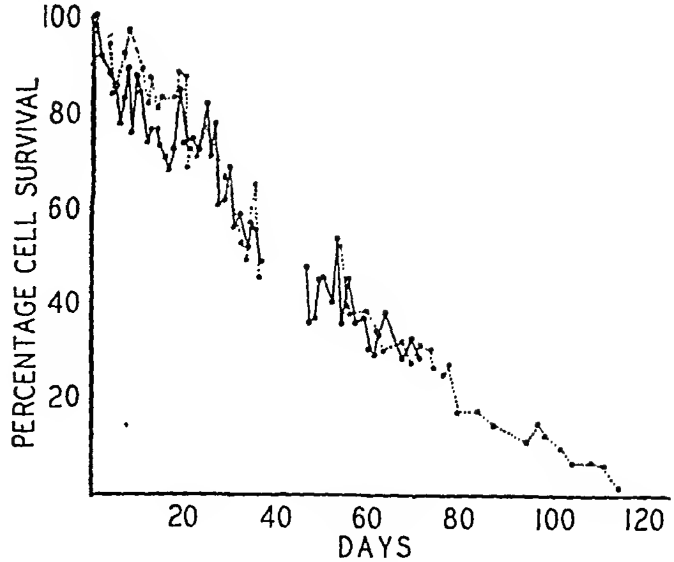

FIG. 10. ELIMINATION OF THE ERYTHROCYTES OF A GROUP-ON DONOR FROM THE CIRCULATION OF A GROUP-AM RECIPIENT, COUNTS BEING MADE SIMULTANEOUSLY WITH ANTI-A (DOTTED CURVE) AND ANTI-M SERA

strong anti-A serum, is illustrated by the large discontinuities in Figures 12, 13, and 14. The particulars of these experiments are given in Table II.

It will be observed that the free-cell counts of one of the recipients of type M differs considerably from the others. The same anti-M serum was used in each case. It is noteworthy also that the large deviation in Figure 13 was given by the recipient with the lower free-cell count. The irregularities in the 3 figures exhibit a remarkably smooth course, a circumstance which makes explanation difficult on the basis of technical errors.

DISCUSSION

Of the various factors that may influence the accuracy of selective agglutination, the strength of the antiserum is of major concern. As yet there is no practical method for characterizing a serum quantitatively as to its avidity and agglutinin content. The titre method of estimating potency gives only comparative values. Nevertheless, it is valuable for testing the strength of the serum for typ-

TABLE I

Recipient	Group	Antiserum	Free-cell count
			per mm.^{3}

ing purposes and for estimating the optimum concentration of red cells and antiserum.

The term "optimum," as applied to agglutination, usually implies rapidity of reaction rather than completeness. The point of optimum proportion in the titre series, for example, is the concentration of cells and serum which produces the most rapid or most compact agglutination. As mentioned previously, this concentration does not necessarily produce maximum agglutination and, with sera of marked avidity, *e.g.*, anti-M and anti-N, the number of unagglutinable cells may be relatively large. Rapidity, compactness and firmness of agglutination, therefore, are not reliable criteria of the completeness of the reaction.

As shown in the foregoing graphs (Figures 3 to 9) antisera, particularly diluted sera, which give a high free-cell count, usually display marked variability. It is noteworthy, however, that the free-cell count even with undiluted sera may vary with different bloods. Thus, in Table II, the free-cell count with one individual was 5,000 and with another, was 18,000. Occasionaly also, one meets with a potent serum which gives a constant free-cell count with one person and a variable count with another. There are instances when dilution of the serum reduces the free-cell count, *e.g.*, when the serum concentration is above the optimum. In general, however, one can say that a high concentration of agglutinin is necessary for maximum and consistent agglutination, and that dilution of the serum tends to increase the number of unagglutinated cells and the variation in the counts.

TABLE II

Figure	Donor	Recipient	Storage period	Anti-serum	Recipient's free-cell count
			days		*per mm.*^{3}
12	ON	$OMRh_1$	fresh	anti-M	4,000
		$OMRh_2$	25		3,000
13	Pooled $ONRh^+$	$OMRh_1Rh_2$	22	anti-M	18,000
	$ONRh_1$	$OMRh_1$	22		5,000
14	$OMRh_1$	$ONRh_2$	21	anti-N	42,300

The reason for the high free-cell count with markedly avid antisera is not clear. Anti-M and anti-N sera, like many heterologous immune sera, produce a very rapid and firm type of agglutination. It is significant that the unagglutinated cells apparently do not adhere to the agglutinates already formed nor are they occluded to any considerable extent among the rapidly aggregating masses. The failure of many of the cells to become agglutinated cannot be attributed to a lack of antibody. Centrifugation will cause further aggregation but not to the extent one would expect with fully sensitized cells.

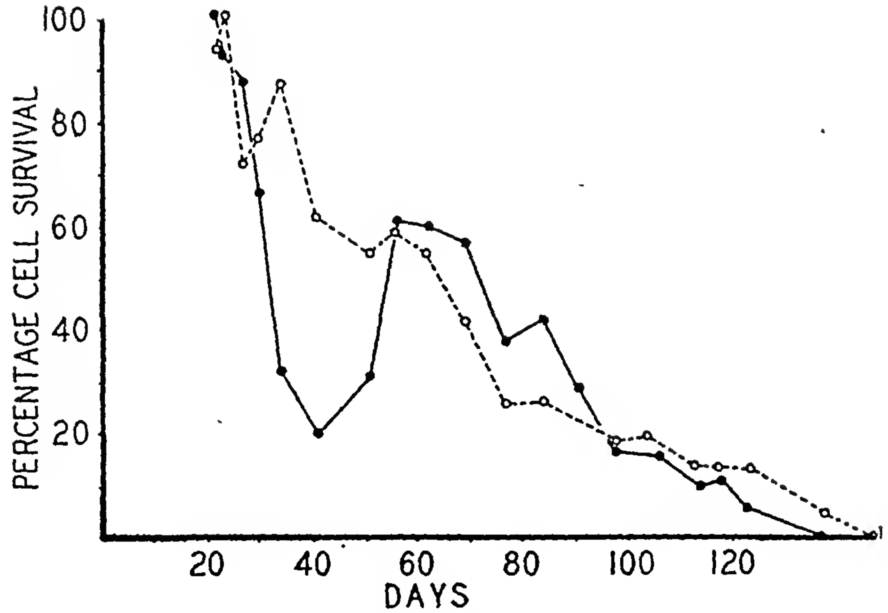

FIG. 13. ELIMINATION OF PRESERVED ERYTHROCYTES OF 2 GROUP-ON DONORS (POOLED SAMPLE) FROM THE CIRCULATION OF 2 GROUP-OM RECIPIENTS. (SEE TABLE II.)

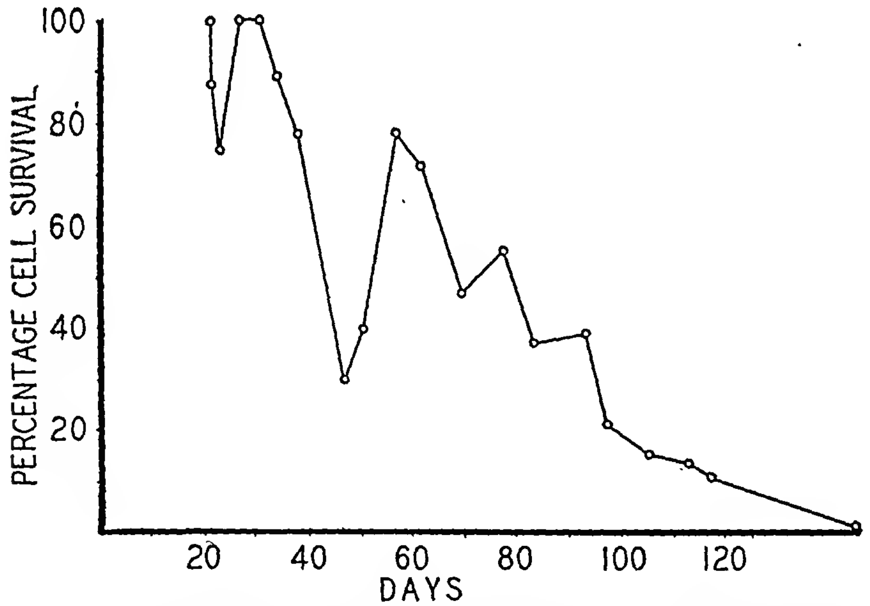

FIG. 14. ELIMINATION OF PRESERVED ERYTHROCYTES OF A GROUP-OM DONOR FROM THE CIRCULATION OF A GROUP-ON RECIPIENT. (SEE TABLE II.)

On first thought, the failure of some cells to be agglutinated with strong antiserum suggests that the red-cell population possibly may be made up of cells ranging in agglutinability from extremely to feebly reactive, and that, while the latter may be loosely agglutinated by centrifuging, like weak Rh agglutinates, they may be dispersed again by agitation. Such a hypothesis would imply that the so-called "unagglutinable" cells may be deficient in the content, distribution, or quality of their agglutinogens due perhaps to imperfect formation.

In opposition to this reasoning, one may point out that the addition of a strong antiserum to the residual free cells after agglutination with a weak antiserum, does not effect as complete agglutination as when the strong serum is applied directly to fresh cells. Weak serum may give rise to agglutinates in the form of doublets, or chains which can be broken by shaking. Addition of stronger antiserum does not consolidate the aggregates into

a compact mass. It is significant also that 2 volumes of half-strength antiserum are not necessarily equivalent in agglutinating strength and effect to 1 volume of undiluted serum for a given volume of cell suspension even when centrifugation is employed. On the basis of these observations, one is inclined to attribute the differences in free-cell count and agglutinability to a reversible change in the state of the agglutinins or other components of the system with dilution and changes in temperature.

The variability in the counts with diluted antiserum is of considerable interest since the fluctuations are not due to systematic errors. In the writers' experience the free-cell counts are likely to vary from day to day but they may be quite consistent on any day.

While the use of diluted, though avid, anti-M and anti-N sera explains some of the sharp irregularities observed in our earlier study, the larger and more regular deviations of the type illustrated in Figures 12, 13, and 14 are not so easily explained. Our former interpretation, that perhaps some of the donor's erythrocytes are sequestered from the recipient's circulation and released later, has been abandoned. The deviations doubtless are connected in some way with reversible changes in the properties of the antiserum, or possibly to reversible changes in the reactivity of the recipient's cells. It is evident from Table II that they are not attributable to the use of weak antiserum, nor are they confined to the use of the M and N blood types. Other factors such as agitation, temperature, salt concentration, and pH have been ruled out. The study of this phenomenon is being continued.

Highly potent anti-A and anti-B sera being easy to prepare, or being readily obtainable the writers recommend for selective agglutination, sera which give a free-cell count not exceeding 10,000 per $mm.^3$ The lowest free counts obtained in our studies were about 2,500. With strong serum the variation in the free-cell count is usually within 5,000 per $mm.^3$ Irregularities in the cell-survival curve become noticeable when the free-count exceeds 15,000, and, above 40,000, fluctuations may occur ranging up to 200,000 from day to day. Obviously it is desirable to keep the variation within the limits of error of the technique. With small transfusions, *e.g.*, 200 ml., it is especially important to select antisera which will reduce the free-count to a minimum.

CONCLUSIONS

From the evidence submitted and additional work not reported herein, it appears that there is no routine method for achieving complete agglutination of erythrocytes and that such an attainment is not possible when agitation is involved. In some experiments, however, the unagglutinable-cell count has been reduced to as low as 2,500 per $mm.^3$ With strong agglutinating serum the free-cell count of the individual remains practically constant for the majority of persons, especially of group A_1. The sharp irregularities observed in the cell-survival curves in an earlier study are attributable to the use of diluted anti-M and anti-N sera. The larger and more regular type of deviation, however, still remains unexplained; it is doubtless connected with some obscure change in the properties of the anti-serum or of the recipient's red cells. These deviations and irregularities do not necessarily vitiate the results of the cell-survival method. A high degree of accuracy can be obtained in the estimation of survival if the blood volume of the recipient and the number of erythrocytes transfused are accurately known.

SUMMARY

The presentation concerns the factors that affect the accuracy of the selective-agglutination procedure for estimating the survival of erythrocytes after transfusion. The influence of agitation, centrifugation, and the agglutinin titre of the antiserum on the rate and completeness of agglutination of red cells is discussed. The unagglutinable-cell count cannot be eliminated, but it can be reduced to a minimum and practically constant quantity by careful selection of the antiserum. Some of the irregularities observed in an earlier study undoubtedly were due to the use of diluted, though avid, anti-M and anti-N sera. The larger and more regular deviations, however, are not so easily explained; they appear to be related to reversible changes in the properties of the antiserum or to reversible changes in the properties of the recipient's red cells. If the blood volume of the recipient and the number of red cells transfused

are accurately known, the progressive elimination of the donor's cells from the circulation of the recipient can be followed with a fairly high degree of accuracy.

ACKNOWLEDGMENTS

This study is part of an investigation on blood preservation carried on with the financial support of the National Research Council of Canada.

The authors are indebted to Dr. L. K. Diamond for a supply of high-titred anti-A and anti-B serum, and to Dr. A. S. Weiner for anti-M and anti-N sera, and for Rh-typing.

Thanks are due also to Dr. H. Lehmann of the Verdun Protestant Hospital who performed most of the transfusions and collected the blood specimens.

THE PRESERVATION OF WHOLE BLOOD[1]

By MAX M. STRUMIA, ALTON D. BLAKE, JR., AND WILLIAM A. WICKS
WITH THE TECHNICAL ASSISTANCE OF MISS KATHERINE DONNELLY, MISS MARGARET DOLAN, AND MISS LOUISE COLWELL

(From the Laboratory of Clinical Pathology of the Bryn Mawr Hospital, Bryn Mawr, Pennsylvania)

(Received for publication August 31, 1946)

The purpose of this paper[2] is to present the results of experimental work on the preservation of whole blood *in vivo* and *in vitro* carried out over a period of several years. Certain standards of preservation *in vitro* (the osmotic resistance) and *in vivo* (the serum bilirubin variations) have been carried out extensively in the early as well as in the late experiments, thus affording a means of comparison.

More specifically, it will present results obtained from comparative studies of several preserving solutions employing the radioactive iron technic.

The conclusions from early experimental work (1) can be summarized as follows:

(*1*) The absence of spontaneous hemolysis is not a satisfactory proof of good preservation of erythrocytes of stored blood.

(*2*) The fragility of erythrocytes to hypotonic salt solution is a dependable measure of blood preservation and parallels the *in vivo* studies provided that the preserving solution does not contain dextrose in high concentration.

(*3*) Serum bilirubin determinations before and after transfusion are readily available and constitute a reliable index of the survival of transfused erythrocytes.

(*4*) The determination of the total bile pigment is a good means of measuring post-transfusion destruction of erythrocytes.

(*5*) The safe period of preservation at 4° C. of blood collected in plain sodium citrate solution is not over 5 days.

(*6*) Experimental work has shown that the addition of glucose to sodium citrate solution does increase the period of safe preservation of whole blood (2 to 6) but generally not enough to compensate for the disadvantage of the greater dilution of the plasma proteins.

(*7*) The administration of blood collected in a solution with a high volume of water and relatively high glucose content (4, 6) has been found to be followed often by an increase in serum bilirubin even when the blood is fresh. This bilirubinemia does not increase noticeably for the first few days of storage, suggesting that it probably has to do with the immediate effect of glucose on a certain type of cells, the least resistant, possibly either the youngest or the oldest.

In the present work the radioactive iron technic was applied to the study of whole blood preservation along with other means.

RADIOACTIVE IRON TECHNIC

The iron isotope 55, with a half life of 5 years, was used in these experiments. This material was synthesized into ferric ammonium citrate in neutral aqueous solutions. Two donors were selected for preparation with radioactive iron. They were both healthy young white males belonging to the "O" blood group, Rh positive and with low anti-A and anti-B titre. Each received 12 intravenous injections of 10 ml. of radioactive ferric ammonium citrate at 2- to 3-day intervals over a 4-week period. The preparation of the iron isotopes used in this work and the radioactivity of blood samples were carried out by Gibson *et al*, as a cooperative plan outlined elsewhere (7). At the end of this period, one donor (SD–1) had a unit activity of 15.35 and the second (SD–2), a unit activity of 15.8.

The interpretation of the results is based on the assumption that as long as the cell membrane remains intact there is no interchange of radioactive iron between the cells and plasma, therefore the cells become "tagged" for the duration of their life.

---

[1] This paper is the 19th of a series on blood, plasma, and plasma substitutes from the Laboratory of Clinical Pathology of the Bryn Mawr Hospital. The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Bryn Mawr Hospital, and with the aid of the Bryn Mawr Research Foundation.

[2] To avoid useless repetitions, references to previous work and to work published in this series of papers have been kept to a minimum.

At the end of the 12 intravenous injections, the radioactivity titre of the donor blood was high enough to permit bleeding and transfusing into recipients.

Technic of bleeding, division into aliquots, and storage

The donors were bled of 400 to 500 ml. into the solution to be tested. This was precooled and by mechanical means maintained in constant gentle motion during collection and for 3 minutes after completion of bleeding. The blood immediately after mixing was divided by a closed system into a number of aliquots, of approximately equal size, and these were stored at 4° C. except for 1 specimen, which was used for immediate transfusion.

Administration of blood

The aliquots from each donor were administered to different recipients. The recipients used were all hospital patients known to have a normal erythropoiesis. All were convalescing and ranged in age between 18 and 86.

Proper grouping, Rh typing, and cross matching were carried out in all instances. Blood volume measurements, hemoglobin, and hematocrit determinations were also carried out. All recipients were Rh positive.

The transfused blood was well mixed by gentle rotation before and during the administration. The rate of transfusion was maintained at about 5 ml. per minute, the whole procedure requiring 24 to 30 minutes. The amount of blood given to the various recipients was measured volumetrically by calibration of each bottle before and after transfusion. All the blood remaining in the tubing and filter was washed into the recipient by saline solution immediately following the blood transfusion. The amount of blood remaining in the bottle, usually amounting to 10 ml. was carefully measured after removal with measured amounts of saline solution and used for radioactivity measurements. The exact number of packed red cells given was also determined by this method.

Samples of blood were taken from each of the recipients within 1 minute of the completion of the transfusion, ½ hour and 3 hours after transfusion, and twice daily for 5 days and at the end of the seventh day. These samples were withdrawn with new syringes and needles and without stasis. The blood was drawn into a double oxalated tube, and the hematocrit was determined. The red cells were then "laked" with 30 ml. of distilled water and used for radioactivity measurements. The patient's blood volume was measured with the dye method (8 to 11) and also calculated from the unit activity of the donor's blood and the unit activity of the first sample after transfusion.

The cell survival was calculated from the unit activity of the donor's blood, the volume of cells given, the unit activity of the recipient's blood, and the volume of the recipient's blood cells.

Citrate-glucose solution (McGill No. 1)

The 2 radioactive donors were bled of about 400 ml. into 200 ml. of McGill solution No. 1. This latter solution was prepared by using 80 ml. of a 3.2 per cent solution of sodium citrate and 120 ml. of a 5.4 per cent dextrose solution. These 2 solutions were sterilized separately and mixed in the proper proportion before use in the standard donor bottles.

The results are expressed as per cent of cell survival against time (see Figure 1). The survival of erythrocytes using the fresh blood appeared to be optimal in recipient SR–1. In recipient SR–2, however, a drop of 10 per cent of the transfused blood apparently occurred in the first 24 hours with further cell loss in the first 7 days to a total of about 16 per cent. Erythrocytes from blood stored at plus 4° C. for 10 days appear to be definitely less resistant. An average of 50 per cent of the cells appear to be lost from the circulation within the first 24 hours. This confirms findings obtained by the determination of the serum bilirubin and total bile pigment. The state of preservation of erythrocytes from blood stored for 20 and 30 days appears to be extremely poor. Eighty per cent or more of the erythrocytes from 4 samples appears to be destroyed within the first 3 hours.

No untoward reactions were encountered in any of the transfusions given.

A.C.D. solution (Rapoport)

The formula suggested by Rapoport is as follows:

Sodium citrate ($2H_2O$) .	1.66 grams
Citric acid (H_2O)	0.59 gram
Distilled water	100.00 ml.

To 90 ml. of this solution 22.5 ml. of 15 per cent dextrose were added in the collection bottles and the mixture was sterilized by autoclaving for 20 minutes at 120° C.

Four hundred and fifty ml. of the donor's blood were collected in the above A.C.D. solution according to the method described above. The blood was then divided by a closed system into 4 aliquots of approximately 150 ml. each.

The 4 aliquots from each donor were transfused into 4 human recipients at the following intervals of time: immediately, 10 days, 20 days, and 30 days in one case; and immediately, 10 days, 21 days, and 31 days in the other.

The results of this experiment are summarized in Figure 2.

With fresh blood, in the first 24 hours after transfusion, recipient SR–9 showed a drop of 10 per cent of the transfused blood and recipient SR–13 showed a drop of 6 per cent. After 10 days of storage, recipient SR–10 showed a 10 per cent drop in 24 hours and SR–14, a 9 per cent drop. With blood stored 20 and 21 days respectively, SR–11 showed a drop of 61 per cent in the first 24 hours and SR–15, a drop of 58 per cent. At the end of 30 and 31 days of storage, in recipient SR–12 there was a drop of 89 per cent in the transfused cells and in recipient SR–16, a drop of 85 per cent in the first 24 hours following transfusion.

The preservation of erythrocytes with this A.C.D. solution is good for a period of storage up to 10 or 11 days. The erythrocyte survival after 20 to 21 days' storage is very poor.

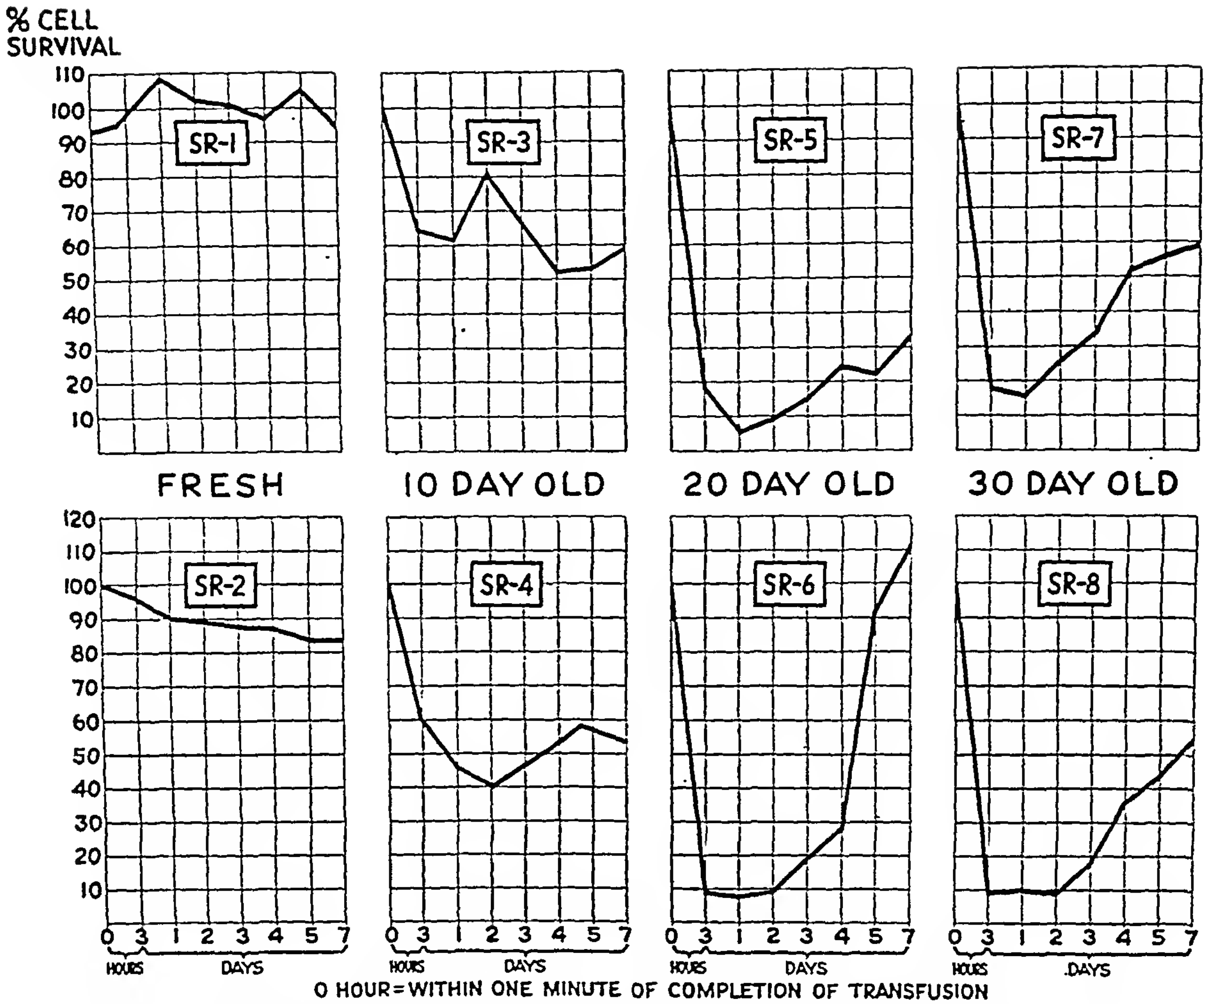

FIG. 1. POST-TRANSFUSION SURVIVAL OF ERYTHROCYTES DETERMINED BY RADIOACTIVE IRON. WHOLE BLOOD PRESERVED IN CITRATE-GLUCOSE SOL. WITHOUT BUFFER (MCGILL SOLUTION NO. 1)

Citrate-glucose solution (Baxter-Alsever)

The citrate-glucose solution (Baxter-Alsever) was furnished by the Baxter Company ready for use. The formula is as follows:

Trisodium citrate	0.8 per cent
Dextrose	2.05 per cent
Sodium chloride	0.42 per cent
Water	500 ml.

pH 6.0

Four hundred and forty-three ml. of the donor's blood were placed in 500 ml. of this solution. The blood was then stored at plus 4° C. for 13 days. At the expiration of this period of time the blood was thoroughly mixed and divided into 2 aliquots of approximately equal size. The blood was then administered immediately to 2 recipients. After 13 days of preservation, the survival of the erythrocytes transfused was 70 per cent and 64 per cent respectively. In both recipients hyperbilirubinemia occurred.

Recipient SR–17 was a male, aged 54, convalescing from a subtotal gastrectomy, weight 60 kgm., height 170 cm. This patient received 132.8 ml. of packed erythrocytes and the survival measured with the radioactive iron technic showed within 3 hours of transfusion a drop of 21 per cent, indicating the destruction of 27.8 ml. of packed erythrocytes. The serum bilirubin before transfusion was 0.7 mgm. per cent, 3 hours after transfusion it rose to 1.0 mgm. per cent, and after 7 hours to 1.8 mgm. per cent; 24 hours after transfusion it had returned to normal, 0.7 mgm. per cent (see Figure 3).

Recipient SR–18 was a female, aged 47, convalescing from skin grafting, weight 71.8 kgm., height 162.5 cm. This patient received 107 ml. of packed erythrocytes and the survival measured with the radioactive iron technic showed a loss of 19 per cent of the transfused erythrocytes at the end of 3 hours, indicating a loss of 20.3 ml. of packed red cells. The patient's serum bilirubin before transfusion was 0.5 mgm. per cent; 3 hours after, it was 1.3 mgm. per cent; 7 hours after, it was 0.7 mgm. per

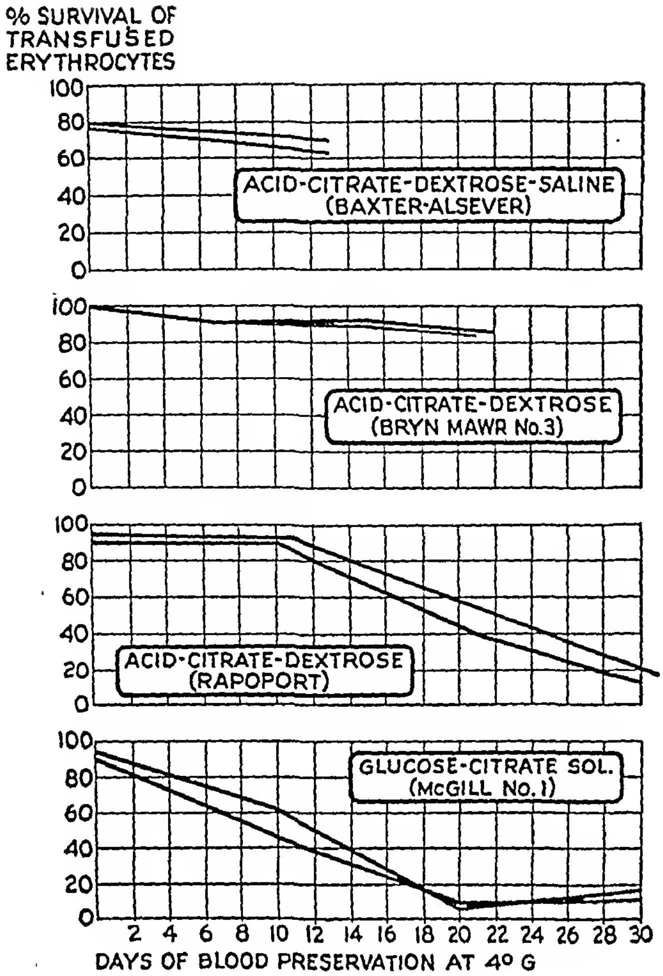

FIG. 2

cent; and 24 hours after, it was 0.8 mgm. per cent. As control, a third recipient SR-20 received a comparable amount of blood preserved in B.M. A.C.D. No. 3 for the same period of time. The radioactive iron study showed a good preservation with a destruction within 3 hours of transfusion of less than 5 ml. of packed erythrocytes. There was no significant change in this patient's serum bilirubin level.

It can be said in conclusion that with the Baxter-Alsever solution optimal preservation of whole blood is less than 13 days, probably not more than 1 week.

A.C.D. solution (*Bryn Mawr No. 3*)

The formula is as follows:

Sodium citrate (trisodium dihydric)	2.1 grams
Citric acid (monohydric)	0.66 gram
Dextrose (anhydrous)	2.0 grams
Water	100.0 ml.

75 ml. of this mixture contains:

Sodium citrate	1.6 grams
Citric acid	0.50 gram
Dextrose	1.5 grams

Five hundred ml. of blood from the same 2 donors were collected in 75 ml. of this solution according to the above technic. Each sample was divided into 4 equal aliquots by a closed system and stored at plus 4° C. until ready for use.

The 4 aliquots from each donor were transfused according to the technic described into 4 human recipients at varying intervals of time: immediately, 7 to 8 days, 14 to 15 days, and 21 to 22 days.

The recipients selected for use were similar to those used above, and their ages varied from 37 to 79.

The results are summarized in Figure 2.

With the injection of fresh blood there appears to be no immediate loss of cells. After 7 to 8 days, the loss is 10 per cent; after 14 to 15 days of preservation, the loss remains at 10 per cent; and after 21 to 22 days, it is only 16 per cent.

DISCUSSION

The radioactive iron technic as applied to the study of whole blood preservation has given results comparable to those previously obtained from the study of the serum bilirubin level before and after transfusion and from the measure of the total bile pigment output.

The data show that with the addition of dextrose to sodium citrate and with variable amounts of water to obtain a final dextrose concentration in the plasma of 1.45 per cent (McGill No. 1) to 1.28 (Baxter-Alsever), the period of preservation is increased over that obtained with plain citrate solution. The increased period of preservation is in any case relatively small. If the standard of optimal preservation of 90 per cent and 70 per

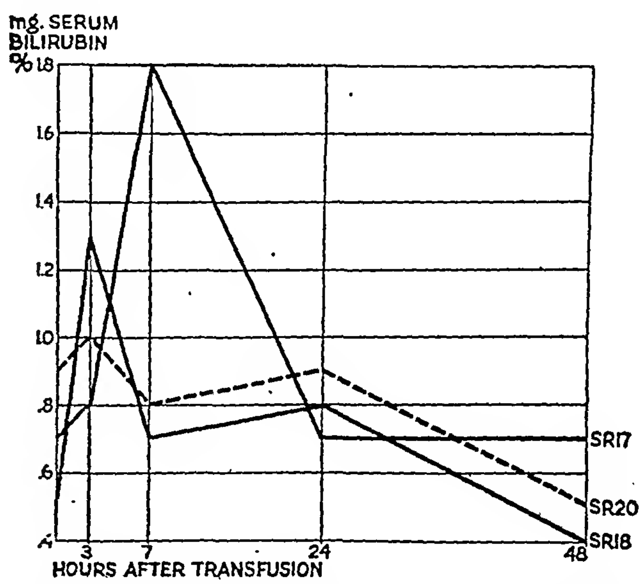

FIG. 3. HYPERBILIRUBINEMIA OCCURRING IN PATIENTS RECEIVING BLOOD PRESERVED FOR THIRTEEN DAYS IN A CITRATE-GLUCOSE SOLUTION (BAXTER-ALSEVER)

cent minimal is adopted, McGill solution No. 1 is good only for about 5 days and the Baxter-Alsever for approximately 12 to 14 days.

The acid citrate-dextrose solutions tested gave a far better preservation. The solution with less glucose (.4 per cent Bryn Mawr No. 3) gave a distinctly better preservation than the solution with more glucose (.88 per cent Rapoport).

In comparing the maximal length of satisfactory erythrocyte preservation with various solutions obtained by the different observers using a comparable technic, it will be noted that the results obtained by our group at Bryn Mawr Hospital are generally indicative of a shorter survival of the erythrocytes after transfusion. This is most likely due to the fact that at the Bryn Mawr Hospital all recipients were convalescent patients, whereas in most other studies the recipients were normal adult males. The implication of a more rapid erythrocyte destruction is borne out by other observations, particularly the higher total bile pigment output in diseases.

In addition to the means of study mentioned, we have repeatedly attempted to follow the fate of transfused red cells by means of the Ashby technic (12) as modified by Denstedt (13). The results which we have obtained are very difficult to interpret. The major difficulty, encountered by other experimenters, is due to the fact that the count of non-agglutinable cells varies a great deal. We have noted that non-agglutinable cells seem to disappear from the circulation suddenly and for irregular periods of time; their reappearance is usually at an unpredictable level. Under these circumstances, to draw a line and to interpret the slope of such line as meaning progressive loss of the transfused cells appears to us to be somewhat arbitrary. We have not been able to correlate the findings obtained with the technic of Dr. Denstedt with the results obtained with the studies of the bilirubin level following transfusion and with the results obtained from the study of the total bile pigment output in the days immediately following the transfusion nor with the results obtained with the radioactive iron technic. We are, therefore, not reporting in this paper the results of the studies on cell preservation using the non-agglutinable cell technic.

CONCLUSIONS

A.C.D. solutions are a better blood preservative than citrate or glucose-citrate solutions. With the best formulas optimal preservation can be secured for at least 22 days.

THE PRESERVATION OF ERYTHROCYTES LEFT OVER FROM PLASMA PREPARATION[1]

By MAX M. STRUMIA, ALTON D. BLAKE, JR., and WILLIAM A. WICKS

with the technical assistance of MISS KATHERINE DONNELLY, MISS MARGARET DOLAN, and MISS LOUISE COLWELL

(From the Laboratory of Clinical Pathology of the Bryn Mawr Hospital, Bryn Mawr, Pennsylvania)

(Received for publication August 31, 1946)

The practice of transfusion of red cells left over from preparation of plasma has gained some popularity (1 to 11). Whether or not this practice will ever become an accepted and widespread procedure and what its practical merits are need not be discussed at this time.

It is obvious that the use of red cells left over from plasma preparation is possible only when plasma is separated after a relatively short period of time. It has been the practice to resuspend the red cells in crystalloid solutions of which the two most popular have been physiological salt solution (5) and 10 per cent corn syrup (12). Since the red cells normally are immersed in a colloidal protein fluid, it is natural to expect *a priori* a better preservation of the erythrocytes when maintained in a protein colloidal medium. This has been found to be true in the experimental work reported here. Ross (13) has shown good preservation of red cells left over from plasma preparation when the cells are simply stored in the remaining plasma. In this paper it will be shown that globin considerably improves the preservation of red cells and that its use as a resuspension medium for red cells is practical. This does not justify at present the conclusion that for optimal preservation of erythrocytes it is necessary to add any diluting fluid to the packed cells left over after the separation of plasma.

[1] This paper is the 20th of a series on blood, plasma, and plasma substitutes from the Laboratory of Clinical Pathology of the Bryn Mawr Hospital. The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Bryn Mawr Hospital, and with the aid of the Bryn Mawr Research Foundation.

PRESERVATION OF ERYTHROCYTES IN PHYSIOLOGICAL SALT SOLUTION

This resuspension medium has been the most commonly used. The maximum recommended period of preservation is from 5 to 6 days (10) at icebox temperature. We have found that the preservation of fresh red cells in physiological saline solution at 4° C. for more than a few hours very greatly reduces the post-transfusion survival of the red cells. Injection of 200 to 450 ml. of such cells in humans (corresponding to 500 to 1,000 ml. of whole blood) is followed in the majority of cases by hyperbilirubinemia and greatly increased bile pigment output.

In these experiments the blood was collected in plain sodium citrate solution (50 ml. of 4 per cent sodium citrate for each 500 ml. of blood), and immediately stored at 4° C. The plasma was separated after centrifugation and in any case within 36 hours from the time of collection. The red cell residue was immediately mixed with .9 per cent sodium chloride solution, chilled, in an amount approximately equivalent to that of the plasma removed. The red cell-saline mixture was immediately placed at 4° C. and was maintained there until time for use. Grouping, Rh typing and cross matching were carried out as usual. A typical case is reported here.

The patient was a man, aged 54, white. This patient was chosen because hematological studies, including a bone marrow biopsy and total bile pigment output determinations, had shown that the sole defect was a greatly reduced normoblastic activity of the bone marrow, from cause unknown. On first admission to the hospital on May 23, the hemoglobin concentration was 2.3 grams per cent with a reticulocyte count of .1 per cent and a total volume of circulating packed erythrocytes of only 280 ml. The patient belonged to the B group and was Rh negative. Sixteen whole blood transfusions of compatible blood, each containing on an average of 450 ml. of blood, were given to this patient over a 53-day period. The patient appeared to tolerate well the transfusions of whole citrated blood, showing no hyperbilirubinemia nor any other signs of reaction. At the time of his discharge on July 12 the hemoglobin concentration was 9 grams per cent. The

patient was readmitted to the hospital on July 25 and at this time the hemoglobin concentration was 6.8 grams per cent, with a reticulocyte count of .1 per cent. From blood volume measurements it is estimated that on July 12 the patient had a volume of packed erythrocytes of 986 ml. On July 29 the hemoglobin concentration was 6.1 grams per cent and the volume of erythrocytes was 745 ml. or a decline of 241 ml. of packed erythrocytes in 17 days with an average loss of about 14 ml. of packed erythrocytes daily. This loss is rather low and indicates good preservation of the transfused erythrocytes. Repeated serum bilirubin determinations showed a concentration of .8 mgm. per cent with a low urobilin output. This patient was given on July 29, 791 ml. of packed erythrocytes, of O group, Rh negative, separated from plasma within 18 hours of collection after centrifugation, mixed with chilled saline solution to make a total volume of 1,071 ml. and maintained at 4° C. for 72 hours.

Following the transfusion of the resuspended erythrocytes, the patient had a hemolytic reaction, with discomfort in the lower abdomen, passage of red urine, containing hemorrhagic casts, high urobilin concentration in the urine and a rise in the serum bilirubin to over 14 mgm. per cent. In 48 hours the patient was entirely well from the reaction (see Figure 1). On August 2, the hemoglobin concentration was 6.9 grams per cent and the volume of packed erythrocytes 758 ml., indicating practically a complete loss of the injected mass of erythrocytes. On August 2, the patient received 305 ml. of packed erythrocytes as 896 ml. of whole citrated blood

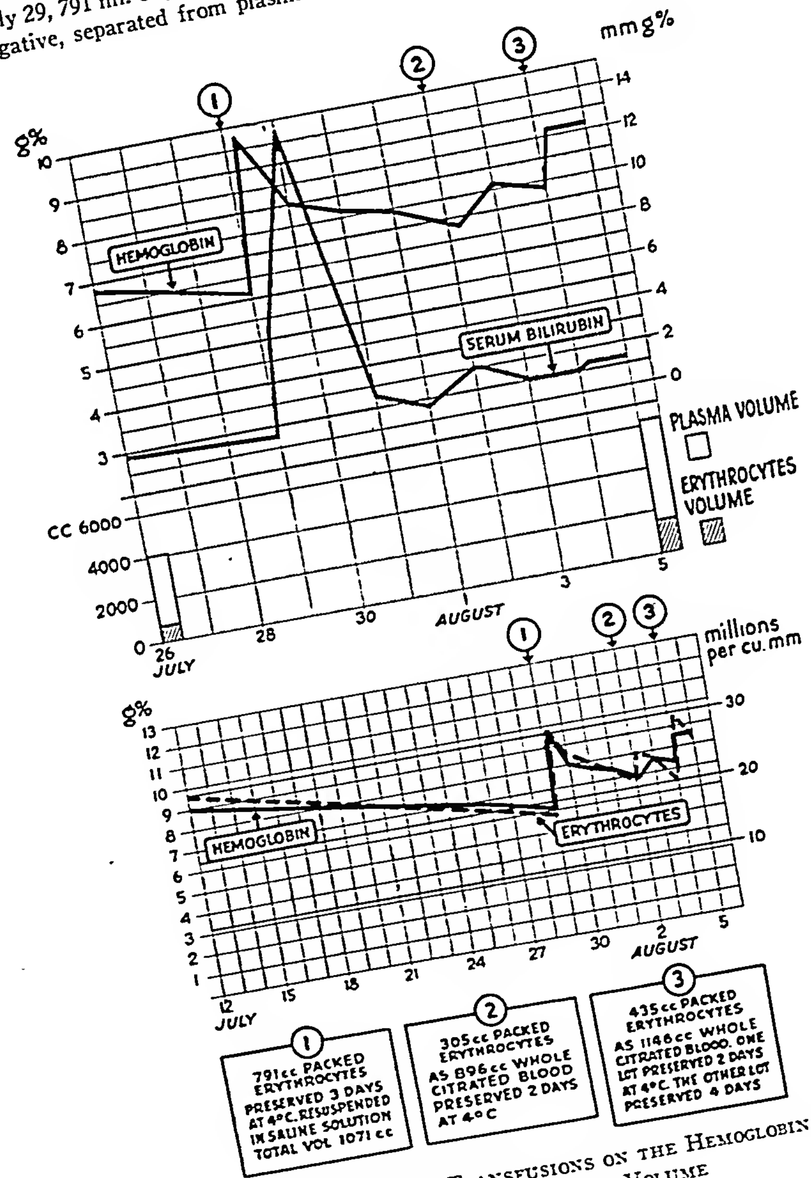

FIG. 1. THE EFFECT OF TRANSFUSIONS ON THE HEMOGLOBIN, SERUM BILIRUBIN AND BLOOD VOLUME

preserved for 2 days. On August 4, 435 ml. of packed erythrocytes as 1,146 ml. of whole citrated blood were given to the patient, one lot of blood being 2 days old and the other 4 days old. The patient had no apparent reaction to the transfusion. On August 5, the hemoglobin concentration was 8.6 grams per cent and the measured volume of packed erythrocytes was 1,538 ml. with an apparent gain of 780 ml. of packed erythrocytes. This represents for the period of time of observation a good survival of the injected red cells, the total amount of injected red cells having been 740 ml. As can be seen from Figure 1, the transfusion of whole citrated blood preserved from 1 to 4 days at 4° C. was not followed by a notable increase in the serum bilirubin level.

IN VITRO COMPARATIVE STUDIES ON THE PRESERVATION OF ERYTHROCYTES IN 4 PER CENT GLOBIN SOLUTION, SALT SOLUTION AND 10 PER CENT CORN SYRUP

The effect of a 4 per cent globin solution on the preservation of resuspended erythrocytes has been studied both *in vitro* and *in vivo*. The studies *in vitro* included pH determination, mean corpuscular volume, osmotic resistance, and the hemoglobin concentration in the supernatant fluid.

The addition of globin to a suspension of erythrocytes in salt solution does not appreciably alter the cell preservation. However, when the erythrocytes are suspended in a sodium citrate-dextrose solution, the globin exerts a definite beneficial effect on the preservation. We are well aware that the choice of crystalloids and their relative concentration as well as the final pH of the solution employed here are probably far from the ideal. We are, however, reporting a typical experiment to show the change which the addition of globin produces in the preservation of erythrocytes.

Five hundred ml. of blood from an adult healthy donor were collected in 60 ml. of a 4 per cent sodium citrate solution, chilled. The sodium citrate solution was chosen because it was the same used by the Red Cross bleeding centers. The blood was allowed to remain for 18 hours at 4° C. It was then centrifuged for 45 minutes at 1,800 times gravity. The plasma was carefully removed, leaving only about 20 ml. of it with the packed red cells. The red cell sediment was then carefully mixed with the remaining plasma, and by means of a sterile calibrated cylinder it was divided into aliquots. Each of these aliquots was mixed with an equal part of the various preserving fluids. The composition of these is given in the following table:

Salt solution:

Sodium chloride	.9 per cent

A.C.D. solution:

Sodium citrate (trisodium, dihydric)	1.66 grams
Citric acid (monohydric)	0.59 gram
Dextrose (anhydrous)	3.75 grams
Distilled water (pyrogen-free)	125 ml.

Corn syrup: 10 per cent sterile solution as obtained from Schering, Glatz Company.

Dextrose-citrate:

Dextrose (anhydrous)	2.4 grams
Sodium citrate (trisodium dihydric)	1.9 grams
Water	100 ml.

Globin-dextrose-citrate:

Globin	4 grams
Dextrose (anhydrous)	2.4 grams
Sodium citrate (trisodium, dihydric)	1.9 grams
Water	100 ml.

After mixing, the various red cell suspensions were cultured and divided into 10-ml. aliquots in hard glass, rubber-stoppered bottles. These were immediately placed at 4° C. and maintained at this temperature until the time of study.

The determination of the osmotic resistance was made by a modification of the technique suggested by Parpart (14); the mean corpuscular volume was done in duplicate; the pH was determined with a Beckman apparatus. The hemoglobin of the supernatant fluid was done after thorough mixing of the sample followed by centrifugation. All samples were cultured again at the end of the stated period of time.

ANALYSIS OF RESULTS

Mean corpuscular volume. There was swelling in all of the solutions used. This swelling was minimal with the citrate-dextrose solution and with the salt solution. It was maximal with the 10 per cent corn syrup (see Figure 2). By the fifth day of preservation and continuing on to the end of the experiment, there was a shrinkage of the cells to within the normal range, except for the A.C.D. solution in which there was an excessive shrinkage followed by a progressive swelling to normal size. The addition of globin to the dextrose-citrate solution appears to have a definite effect on the rate and range of volume changes.

Mean osmotic resistance of resuspended erythrocytes (fragility). Except for the sodium chloride, the mean osmotic resistance is considerably increased. This increase is minimal with the

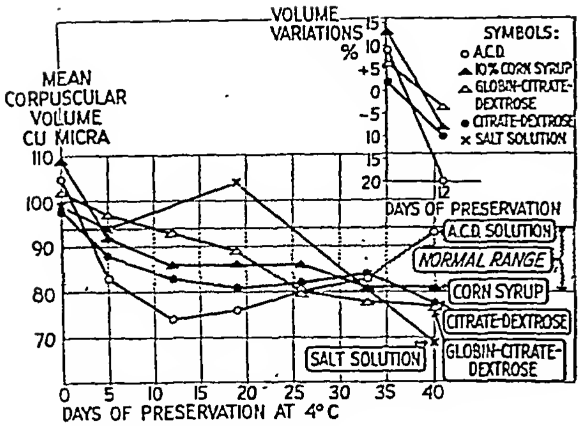

FIG. 2. MEAN CORPUSCULAR VOLUME

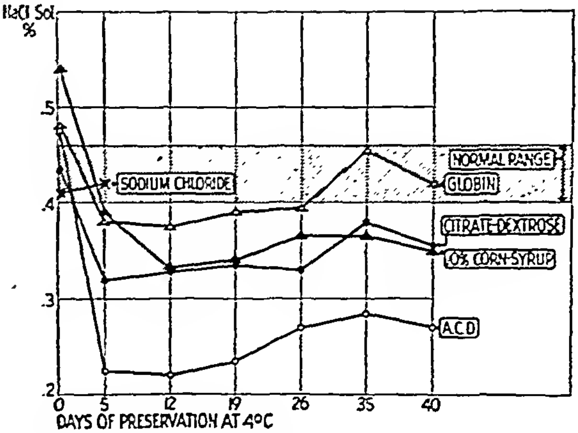

FIG. 3. MEAN OSMOTIC RESISTANCE OF RESUSPENDED ERYTHROCYTES (FRAGILITY)

globin citrate-dextrose solution, and it is maximal with the A.C.D. solution. The addition of globin to the citrate-dextrose solution definitely effects a change in osmotic resistance, maintaining it nearer to the normal change (see Figure 3).

pH variations. The variations of the pH of the original solutions of the supernatant fluid are indicated in the following table:

	A.C.D.	10 per cent corn syrup	Salt solution	Dextrose-citrate	Globin-dextrose-citrate
pH of original solution	5.04	4.22	5.52	6.05	7.71
pH of supernatant fluid					
0	6.0	7.3	7.4	7.1	7.2
5	6.0	7.5	7.7	7.05	7.4
12	6.0	7.6		7.05	7.2
19	6.0	7.6	7.4	7.0	7.2
26	6.0	7.6		7.0	7.25
33	6.0	7.5		7.0	7.2
40	6.0	7.4		7.0	7.2

Hemoglobin concentration in the supernatant fluid. To obtain this datum, the erythrocyte suspensions were thoroughly mixed and centrifuged; the determination was made by the micro method reported separately (15). The hemoglobin concentration in the A.C.D. solution, in the citrate-dextrose solution, and in the globin citrate-dextrose is comparable. It is definitely less in the 10 per cent corn syrup and increases much more rapidly in the salt solution. These data appear of little significance (see Figure 4).

POST-TRANSFUSION SURVIVAL OF ERYTHROCYTES SUSPENDED IN 4 PER CENT GLOBIN SOLUTION BY THE RADIOACTIVE IRON TECHNIC

Clinical observations

Studies on the *in vivo* survival of erythrocytes resuspended in globin solution by means of the iron isotope technic have been carried out (see Figure 5).

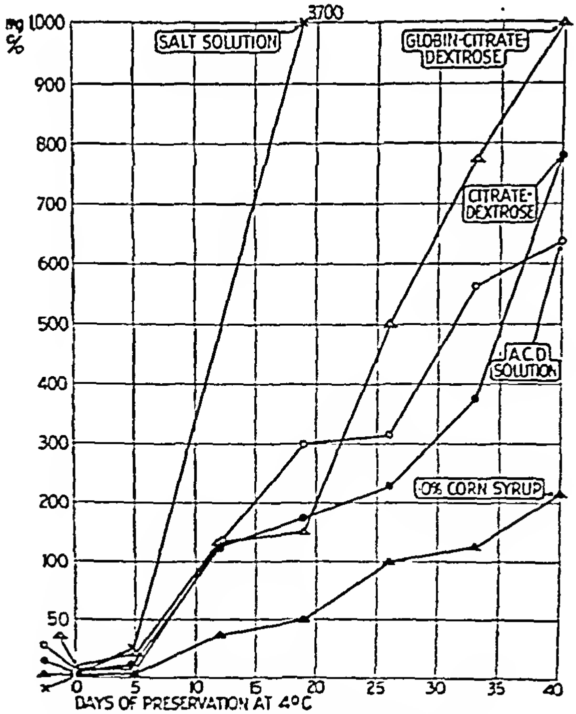

FIG. 4. HEMOGLOBIN CONCENTRATION IN THE SUPERNATANT FLUID

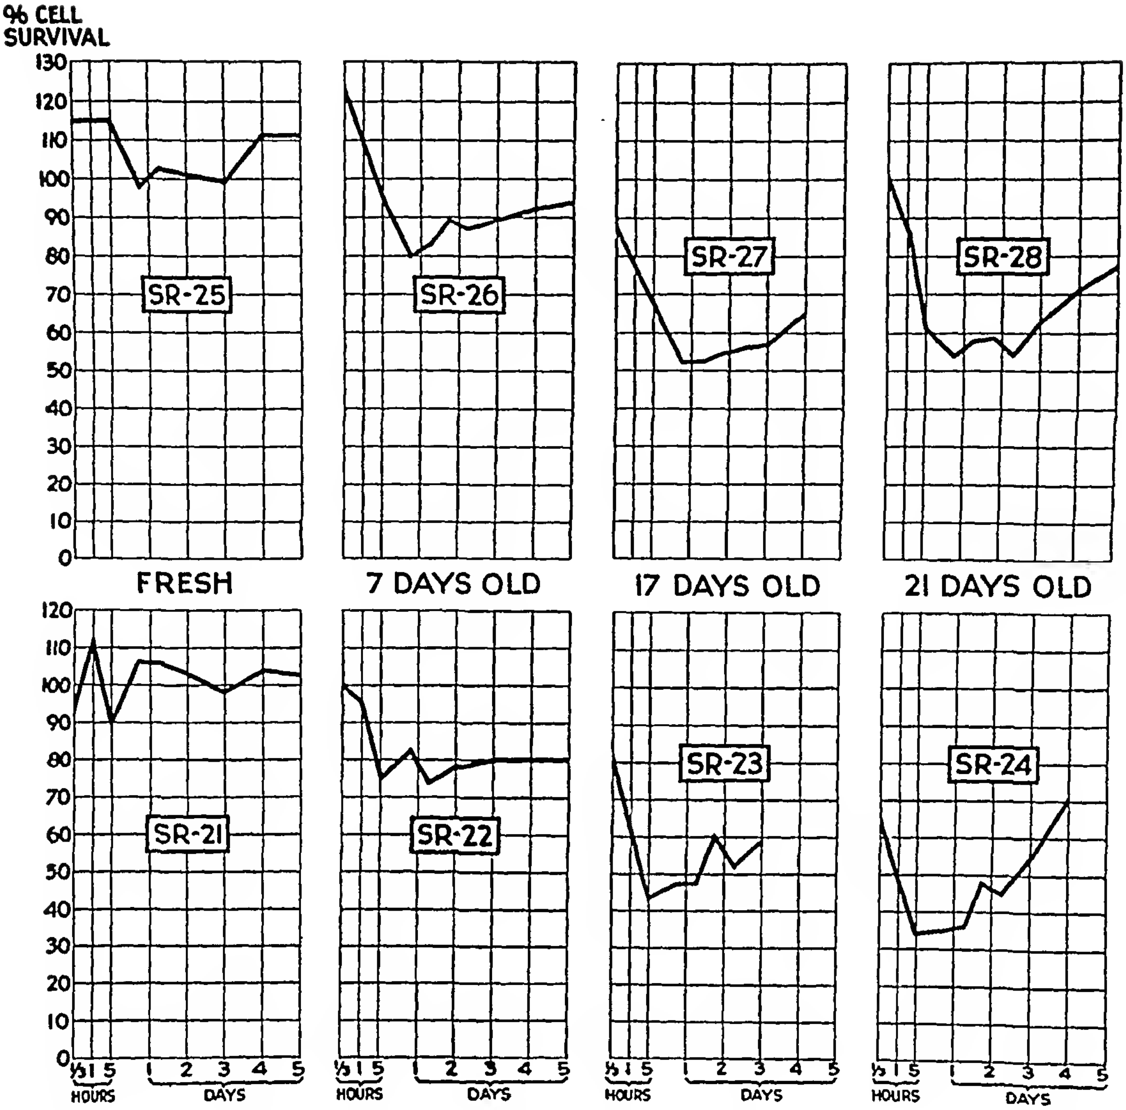

Fig. 5. Survival of Erythrocytes Resuspended in Citrate Dextrose-Globin Solution Determined by the Iron Isotope Technic

The survival of the transfused cells is 75 to 80 per cent up to 7 days of preservation and 50 per cent or better up to 15 days. It is of very great importance to note that:

(1) In our experience, using as recipients patients rather than healthy males as in the experiments reported by Gibson, the preservation of cells as determined by the iron isotope technic is generally poorer than that found by other observers, regardless of the preserving fluid employed.

(2) Whereas with all of the preserving fluids so far used the rate of cell deterioration is definitely accelerated, as the preservation is prolonged, with addition of globin it becomes definitely slower.

It is probable that an initial damage occurs and that a better choice of crystalloids to make the fluid iso-osmotic may very materially improve the preserving properties of the globin solution.

Figure 6 affords a comparison of the rate of preservation of erythrocytes resuspended in globin dextrose-citrate and of whole blood preserved in A.C.D. and glucose-citrate solutions.

The decline of the hemoglobin concentration noted in the days following was small and comparable to that noted previously. There appears to be no reason to encourage the use of erythrocytes preserved at 4° C. in saline solution for more than a few hours for the purpose of transfusion. As a matter of fact there appears to be no good reason for resuspending the red cell

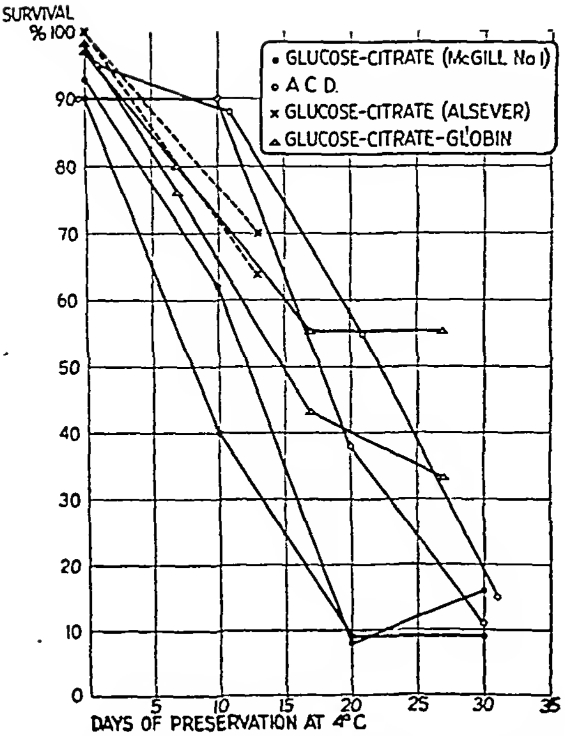

FIG. 6. SURVIVAL OF WHOLE BLOOD AND RESUSPENDED ERYTHROCYTES IN VARIOUS SOLUTIONS

residue in saline at all, as they can be transfused as they are, using an 18-gauge needle.

About 50 transfusions of 200 to 230 ml. of packed red cells, resuspended in globin solution, have been administered. Studies of the serum bilirubin content have been carried out. No hyperbilirubinemia has occurred, nor untoward reactions of any sort. The clinical results were those to be expected from well preserved cells.

CONCLUSIONS

The addition of globin in a 4 per cent concentration to an isotonic solution of dextrose-citrate increases the preservation of red cells left over from plasma preparation. With this mixture the preservation is optimal for 7 days, good up to 15 days.

AN ACID CITRATE–DEXTROSE SOLUTION WITH LOW WATER VOLUME AND LOW DEXTROSE CONCENTRATION [1]

By MAX M. STRUMIA, ALTON D. BLAKE, JR., and JOHN J. McGRAW, JR.
with the technical assistance of MISS MARGARET DOLAN AND MISS LOUISE COLWELL

(*From the Laboratory of Clinical Pathology of the Bryn Mawr Hospital, Bryn Mawr, Pennsylvania*)

(Received for publication August 31, 1946)

The blood preservative introduced by Loutit and Mollison (1) consisting essentially of a sodium citrate-dextrose mixture of relatively low pH, has proved superior to previously employed preserving fluids. The original formula and many subsequent modifications have a rather high volume. This produces considerable dilution of the plasma proteins.

The purpose of this study, begun in June 1944, was to obtain an A.C.D. solution of lower volume, so as to maintain an optimal concentration of plasma proteins, maintain or improve the capacity to preserve erythrocytes, and at the same time insure maximal stability of the resulting plasma.

The first solution tested was one proposed by Rapoport, as follows:

Sodium citrate (trisodium dihydric)	1.66 grams
Citric acid (monohydric)	0.59 gram
Distilled water	100 ml.

22.5 ml. of 15 per cent dextrose were added to 90 ml. of this solution, and the resulting solution was sterilized by autoclaving for 20 minutes at 120° C. This formula can be written as follows for the sake of comparison with other formulas:

A.C.D. Rapoport

Sodium citrate (trisodium dihydric)	1.50 grams
Citric acid (monohydric)	.55 gram
Dextrose	3.37 grams
Water	112.5 ml.

112.5 ml. of this solution were used for each 500 ml. of blood collected. The solution was cooled to 4° C. previous to use.

The post-transfusion survival of erythrocytes collected in this solution was tested with the radioactive iron technic (2). With fresh blood there was an immediate loss of 6 to 10 percent of the transfused cells. There was no increased loss of transfused cells after 10 days of preservation at 4° C. After 21 days of storage the survival dropped to 40 to 58 per cent and at the end of 31 days of storage the preservation was less than 20 per cent.

In a first modification of Rapoport's solution the amounts of citrate and glucose were slightly increased and the amount of water reduced. The formula was as follows:

Bryn Mawr A.C.D. No. 2

Sodium citrate (trisodium, dihydric)	1.6 grams
Citric acid (monohydric)	0.56 gram
Dextrose (anhydrous)	3.6 grams
Water to 100 ml.	

One hundred ml. of this solution were used for each 500 ml. of blood.

This solution was adopted for routine use in the hospital and by January 16, 1945, a total of 587 lots of blood had been collected in this solution. The results of 139 whole blood transfusions were thoroughly studied. It was concluded from these preliminary studies that this solution was no better than the previous one for preservation of erythrocytes, but it was found that the plasma obtained was somewhat more stable. The studies of the plasma composition will be reported later on. *In vitro* studies showed that the concentration of dextrose was much higher than the optimal. This conclusion was reached from studies of the osmotic resistance, mean corpuscular volume, and hemoglobin concentration in the supernatant plasma. Since this solution was not completely satisfactory, it was decided to study the effect of varying amounts of dextrose. At the

[1] This paper is the 21st of a series on blood, plasma, and plasma substitutes from the Laboratory of Clinical Pathology of the Bryn Mawr Hospital. The work described in this paper was done under a contract recommended by the Committee on Medical Research between the Office of Scientific Research and Development and the Bryn Mawr Hospital, and with the aid of the Bryn Mawr Research Foundation.

same time the volume was reduced to 75 ml. Similar results were reported by Rapoport (3).

A basic formula was then adopted:

Sodium citrate (trisodium, dihydric)	1.6 grams
Citric acid (monohydric)	0.56 gram
Water	75 ml.

Varying amounts of dextrose were added to this basic formula as follows: 1.6, 1.8, 2.0, 2.2, 2.4 grams. Seventy-five ml. of the resulting solutions, chilled, were used for 500 ml. of blood.

IN VITRO STUDIES OF A.C.D. SOLUTIONS WITH VARYING AMOUNTS OF DEXTROSE

These included mean corpuscular volume, hemoglobin concentration in the supernatant plasma, and osmotic resistance. Samples of blood were prepared for *in vitro* studies as follows: 500 ml. of blood were obtained in a chilled donor bottle containing 1.6 grams of sodium citrate and .56 gram of citric acid in 50 ml. of water. Immediately after collection, the blood was divided into 5 equal aliquots and immediately transferred to 5 bottles, chilled, each containing 5 ml. of a solution of dextrose to yield the final concentration noted previously. A determination of the hemoglobin concentartion in the 5 samples was done to correct any inequality in the measuring of the samples. All figures given have been corrected. Samples of blood were taken from each solution to be tested immediately after mixing. The blood was then stored at 4° C. and similar samples were taken at the end of 7, 14, 21, and 28 days. Before sampling, the blood was thoroughly mixed by gentle rotation for a period of 5 minutes. At the completion of this time approximately 7 to 8 ml. of blood were removed aseptically and used for the various tests.

The technic used for the determination of the mean corpuscular volume is as follows: One ml. of blood was placed in a Wintrobe hematocrit tube and this was centrifuged at 3,600 r.p.m. for 30 minutes. The hematocrit was then read and the blood was again centrifuged at 3,600 r.p.m. for 10 minutes. If there was no change in the readings, the hematocrit was then read directly and an erythrocyte count was done on the same sample. The mean corpuscular volume was calculated in the usual manner.

The technic for the determination of the hemoglobin in the supernatant plasma is as follows: a 5-ml. sample of blood was centrifuged for 10 minutes at 1,800 r.p.m. At the end of this time the plasma was removed by the use of a capillary pipette and the hemoglobin determined as described elsewhere (4).

The technic used for determining the osmotic resistance is that suggested by Parpart (5), modified as follows: .05 ml. of whole blood was added to 5 ml. of the various solutions of Series I.[2] These mixtures were then placed in the water bath at 37° C. for ½ hour. At the end of this time the tubes were removed from the water bath and 5 ml. of each of the corresponding solutions of series II were added, the tubes were thoroughly mixed, centrifuged for 10 minutes at 3,600 r.p.m. The hemoglobin in the supernatant fluid was then estimated with the Klett photoelectric colorimeter. The hemoglobin content of the tube containing 0.1 per cent sodium chloride was considered as 100 per cent hemolyzed; the hemoglobin reading of the other tubes was recorded in per cent of this value. In Figure 2 sodium chloride concentration giving 50 per cent hemolysis are plotted against time of storage for the various preservative solutions.

Mean corpuscular volume

For the 5 solutions tested, those with the higher dextrose concentration showed an increasing fluctuation in the values of the mean corpuscular volume. The 2 highest concentrations of dextrose produced an abnormally high mean corpuscular volume of the stored cells. The pattern of variations for each concentration has been found to be fairly constant for blood from the same source (see Figure 1).

Osmotic resistance

For the first 3 weeks of preservation there was little difference between the cells preserved in the various concentrations of dextrose. A slight spread of values occurred after the twenty-first day of storage, the lower concentrations of glucose showing a better osmotic resistance than the higher (see Figure 2).

Hemoglobin concentration in supernatant plasma

There appears to be no difference up to the fourteenth day of storage between erythrocytes in the various concentrations of dextrose. A definite spread of values occurred at the end of the third

[2] Series I and Series II each consist of 10 tubes, each containing 5 ml. of a sodium chloride solution of the following concentration per cent:

Tube No.	Sodium chloride grams per cent Series I	Series II
1	0.100	1.900
2	0.300	1.700
3	0.400	1.600
4	0.450	1.550
5	0.500	1.500
6	0.550	1.450
7	0.600	1.400
8	0.700	1.300
9	0.900	1.100
10	1.000	1.000

Intermediate concentrations are used whenever necessary.

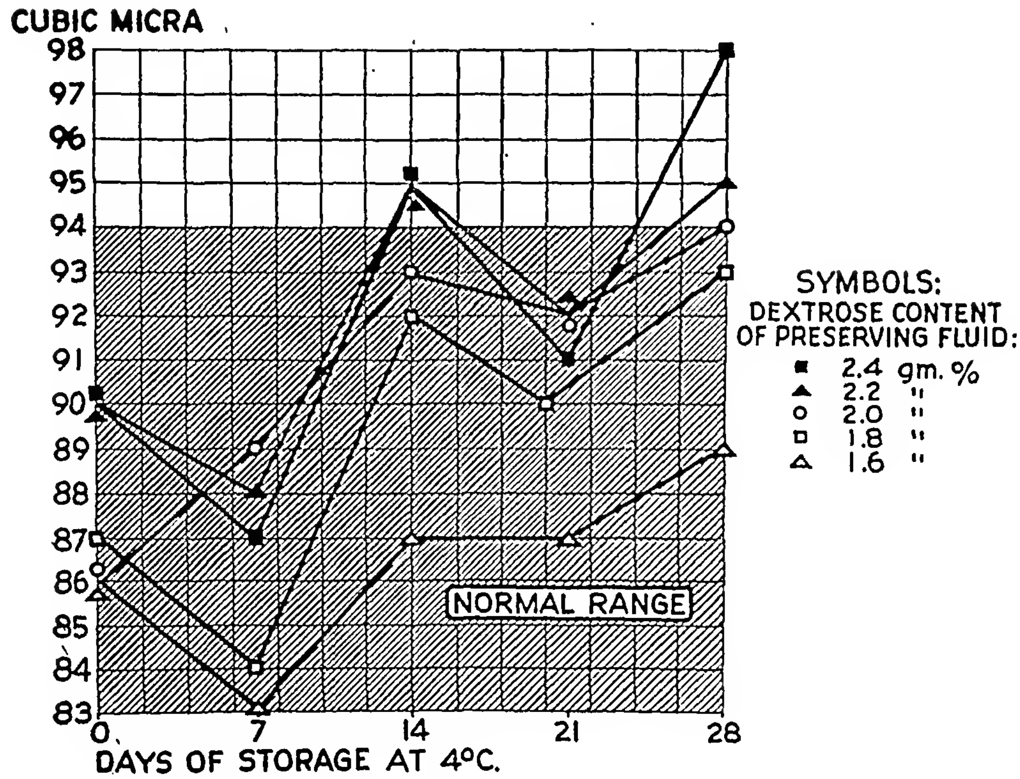

FIG. 1. EFFECT OF DEXTROSE CONCENTRATION ON THE MEAN CORPUSCULAR VOLUME

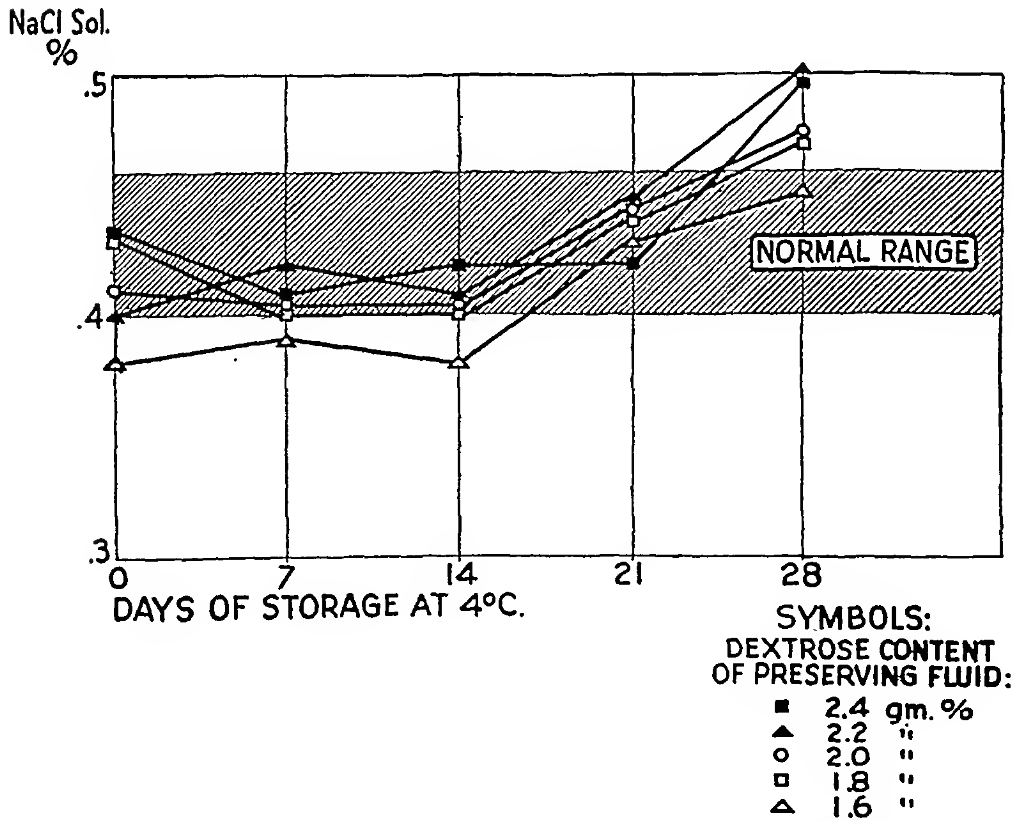

FIG. 2. EFFECT OF DEXTROSE CONCENTRATION ON THE OSMOTIC RESISTANCE OF ERYTHROCYTES (50 PER CENT HEMOLYSIS PLOTTED)

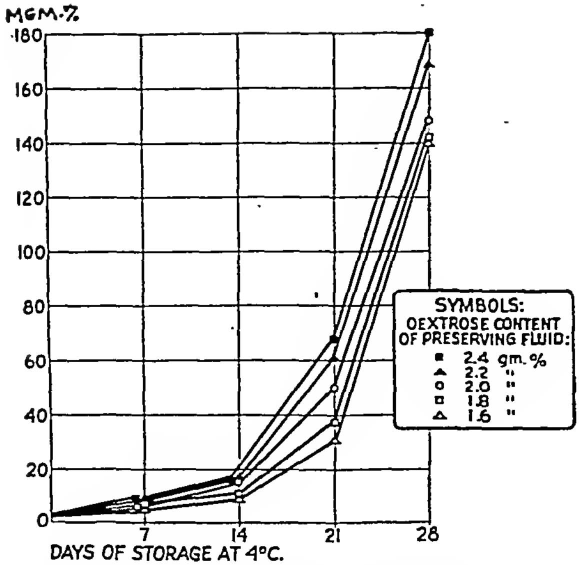

FIG. 3. EFFECT OF DEXTROSE CONCENTRATION ON HEMOGLOBIN IN THE SUPERNATANT PLASMA

week. The higher dextrose concentration showed a greater hemolysis (see Figure 3).

From these studies *in vitro* it was concluded that the amount of dextrose could be profitably reduced. Accordingly the following formula was adopted (February 1945) for further clinical trials:

B.M.H.—A.C.D. No. 3

Sodium citrate (trisodium, dihydric)	1.6 grams
Citric acid (monohydric)	0.56 gram
Dextrose (anhydrous)	1.5 grams
Water	75 ml.

Seventy-five ml. of this solution are placed in each collecting bottle and steam sterilized at 120° C. for 20 minutes. The pH of this solution is 4.8 and the pH of the resulting plasma varied from 7.05 to 7.45 (see Table I).

This formula was compared with the B.M.H.—A.C.D. No. 2 in a series of studies *in vitro*. It was noted that with the B.M. No. 3 the mean corpuscular volume remained within the normal range for at least 28 days, whereas with the B.M. No. 2 the tendency was to swelling beyond normal much sooner.

TABLE I

B.M.H. No. 3

A.C.D. plasma (75 ml.)

No. of bleedings	Pool No.	Days preserv. blood average	Blood average	Hb.	Prothrom. normal	Protein	pH	Turbidity filter 66	Complement titration						
									1/2	1/4	1/8	1/16	1/32	1/64	1/128
			ml.	*mgm. per cent*	*per cent*	*grams per cent*									
12	339A	4.3	454	2.6	78	6.1	7.41	107	−	−	−	±	+	++ ++	++ ++
13	339B	8.8	396	3.8	80	6.4	7.20	72	−	−	−	−	++ +	++ ++	++ ++
12	339D	8.2	430	2.9	80	6.2	7.30	72	−	−	−	−	++ +	++ ++	++ ++
13	341A	8	396	3.4	78	6.1	7.20	76	−	−	−	−	+	++ +	++ ++
11	341B	9.7	436	3.7	72	6.2	7.05	66	−	−	−	−	+	++ ++	++ ++
13	341D	8.5	458	3.0	77	6.2	7.20	69	−	−	−	−	+	++ +	++ ++
11	345A	8	414	3.8	77	6.3	7.40	68	−	−	−	−	+ −	++ +	++ ++
11	345B	10	436	2.9	78	6.4	7.40	63	−	−	−	−	+ −	++ +	++ ++
11	345D	3.2	395	3.9	70	6.2	7.45	69	−	−	−	−	+ −	++ +	++ ++
12	346	8	475	4.0	74	6.1	7.30	67	−	−	−	−	+ −	+	++ ++

A comparison of results of the studies of the osmotic resistance with the 2 solutions shows (see Figure 4) that the blood preserved in the B.M. No. 3 with lower dextrose content, remained within the normal limits for at least 35 days whereas , with the B.M. No. 2, abnormal resistance developed by the eighteenth day.

IN VIVO STUDIES

Radioactive iron

Radioactive iron studies on the survival of transfused erythrocytes after varying lengths of storage at 4° C. in B.M.—A.C.D. No. 3 have been reported elsewhere (2). The study showed optimal preservation up to at least 22 days, the survival of the erythrocytes being 84 per cent, a result better than that obtained with any other preserving fluid tested.

Hyperbilirubinemia

Determinations of the recipient's serum bilirubin level were carried out immediately before and 3 hours after completion of the transfusions. Figure 5 shows the result of such studies in 48 transfusions. The volume of transfusions was 450 to 500 ml. of whole blood (not including the preserving fluid).

While the data are as yet insufficient to allow a definite conclusion to be reached, there appeared to be no increase in the rate of hyperbilirubinemia during the first 21 days of storage.

Clinical observations

From 2/7/45 up to date, 5,010 specimens of blood have been collected in the Bryn Mawr A.C.D. No. 3. Studies of 1,215 whole blood transfusions were made and the reaction rate as well as the expected clinical results have been found to be optimal. No difficulties were encountered in the filtration of blood preserved up to 22 days. A complete description of a type of filter suitable for whole blood is given elsewhere (6). Proper filtration is obtained with finely woven nylon, stainless steel cloth (100 mesh) or multiple layers of more loosely woven gauze. When employing ordinary 40-mesh gauze, it should be used in 4 thicknesses.

To allow rapid filtration of blood, the filtering surface with any of the above mentioned materials should be 30 to 38 sq. cm.

It is essential to maintain the blood in constant slow rotating motion while it is being collected (7) and to mix the blood thoroughly before administration by gently rotating the bottle held at various angles for at least 3 minutes.

An objection was raised concerning the possibility that with lowered dextrose content the glycolytic action of the erythrocytes would deplete the dextrose before the estimated period of maximal

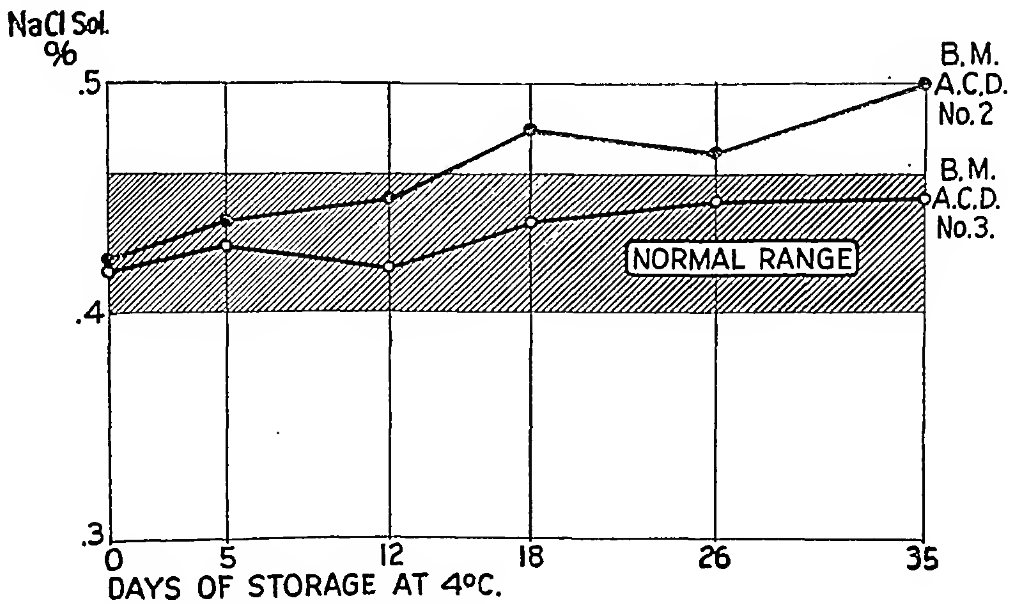

FIG. 4. OSMOTIC RESISTANCE OF ERYTHROCYTES STORED IN BRYN MAWR A.C.D. NO. 2 AND NO. 3

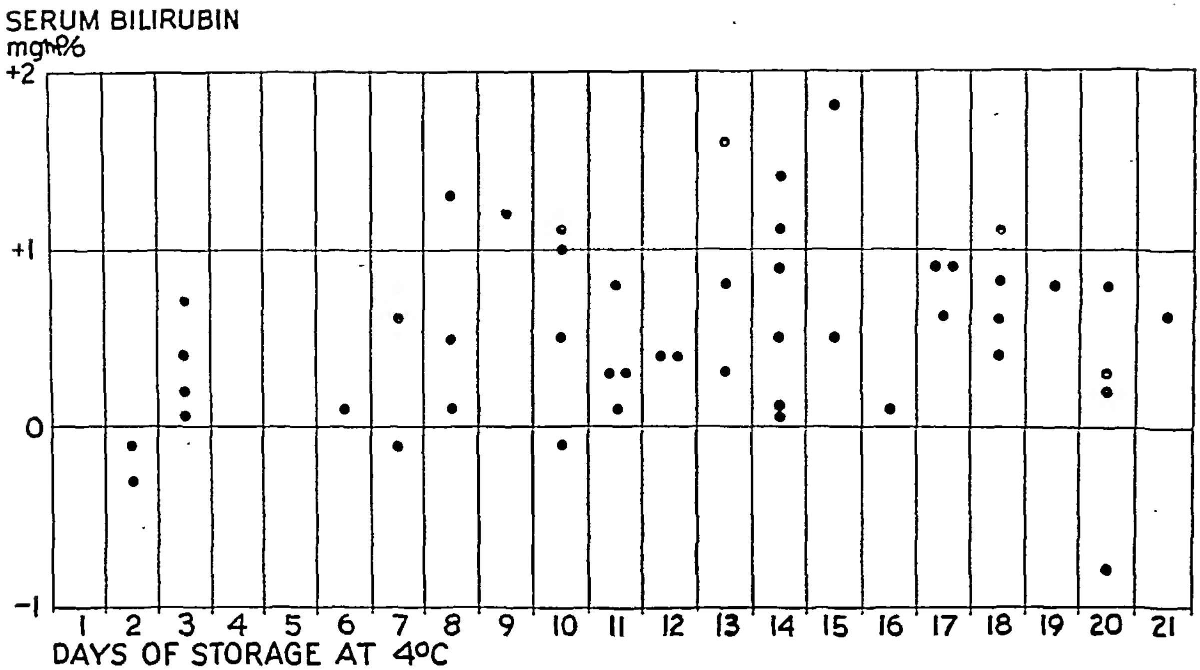

FIG. 5. VARIATIONS IN SERUM BILIRUBIN CONCENTRATION IMMEDIATELY BEFORE AND 3 HOURS AFTER TRANSFUSION OF BLOOD STORED IN A.C.D. B.M. No. 3

preservation of 4 weeks. Repeated studies have shown that such is not the case. For the determination of the dextrose content of whole blood and plasma, samples of blood were taken as described previously. A protein-free filtrate of whole blood and of plasma was prepared by the Folin-Wu technic and the dextrose content was determined by the Benedict method. The dextrose content of the red cells was calculated by differential.

Dextrose appears to be present in optimal concentration in both plasma and erythrocytes for at least 28 days (normal content of dextrose in plasma 95 mgm. per cent and in erythrocytes 66 mgm. [see Figure 6]).

These studies were repeated in a series of random specimens of blood obtained from the blood bank. The data contained in Figure 7 were obtained from determinations done on routine blood bank specimens, varying in volume from 450 to 500 ml. of whole blood. These were collected in the B.M.—A.C.D. No. 3, chilled and preserved undisturbed at 4° C. The dextrose determinations were done on an aliquot of well mixed blood obtained at the time of delivery of blood for administration to patients. The determinations were carried out by the Benedict method.

Figure 7 shows that for preservation up to 21 days at least 190 mgm. or more of dextrose are present.

A.C.D. PLASMA

The general composition of 10 pools of plasma obtained from blood preserved in B.M.—A.C.D. No. 2 were studied. When the findings were compared with similar ones obtained from the study of lots of plasma similarly prepared from plain citrated blood, it was found that the B.M.—A.C.D. No. 2 plasma had a lower hemoglobin content, a lower prothrombin content, a lower complement content, a lower protein content, a lower pH, and a lower turbidity. It is important to keep in mind that the A.C.D. blood was stored before separation of plasma for a period of time comparable to that of the plain citrated blood but that the dilution was somewhat greater. It was also found that the fibrinogen in the A.C.D. No. 2 plasma was definitely more unstable than in the ordinary citrated plasma. Flocculation of fibrinogen occurred more readily in plasma kept in the liquid state or thawed from the frozen state. A very considerable improvement in the quality of plasma was obtained by using the B.M.—A.C.D.

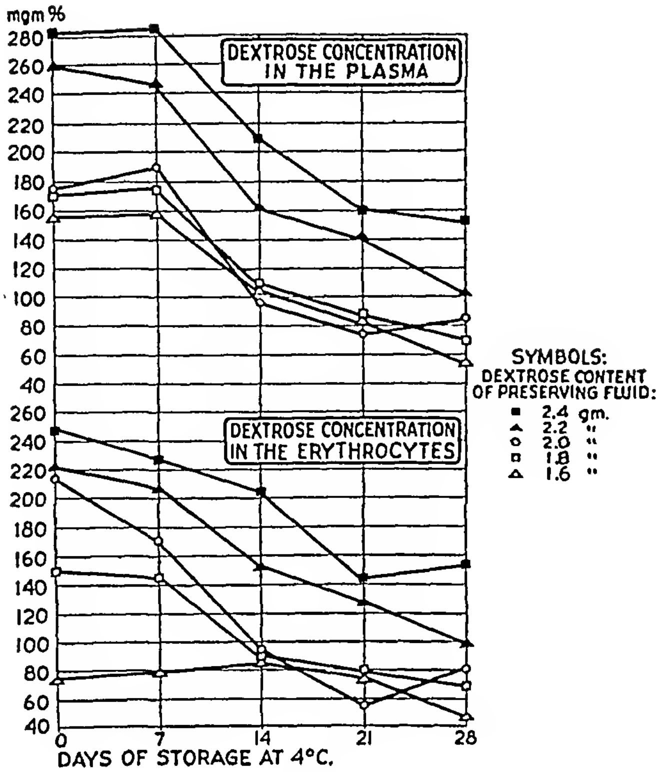

FIG. 6

No. 3 solution for the preparation of plasma. The general composition of 10 pools of such plasma is given in Table I.

When these findings were compared with those from lots of plasma similarly prepared from the B.M.—A.C.D. No. 2 solution (see Table II) it

TABLE II

Comparison of plasma obtained with A.C.D. solutions

	B.M.H. No. 2 A.C.D. sol. 100 *ml.*	B.M.H. No. 3 A.C.D sol. 75 *ml.*
Total no. of bleedings	110	119
Average time of preservation at 4° C., *days*	8.8	8.7
Average volume of bleedings, *ml.*	465	429
Hemoglobin, *mgm. per cent*	5	3.4
Prothrombin, *per cent of normal*	61.5	76.4
Protein, *grams per cent* (actual)	5.2	6.2
Protein, *grams per cent* (calculated)	5.1	5.7
Turbidity filter 66	74.9	72.9
pH	6.84	7.29
Complement titration	Comparable	

was found that the plasma obtained with the B.M. —A.C.D No 3 solution had lower free hemoglobin, substantially higher protein and prothrombin content, and comparable turbidity and complement titration although the average size of the bleeding was 36 ml. (8 per cent) less.

From Table II it is noted that the actual protein concentration is somewhat higher than one calculated from simple dilution factors. This is probably due to the fact that water enters the red cells whereas the protein does not, so that there is some concentration of proteins in the plasma. In other words the increase in concentration of the plasma protein is due to the increased hematocrit of the red cells. The pH of the plasma from the B.M.—A.C.D. No. 3 averages 7.29 instead of 6.85 of the previous solution. This change was responsible for the improved prothrombin preservation. It was also noted that when the plasma obtained with the use of the B.M.—A.C.D. No. 3 was frozen and thawed, according to the proper procedure outlined elsewhere, the fibrinogen was fully as stable as that obtained from the plain citrated blood. This optimal stability of fibrinogen is conditional on proper mixing of the blood and preserving fluid during the collection. The necessity of proper mixing of blood with the preservative solution cannot be sufficiently emphasized. This mixing must be done by a gentle continuous ro-

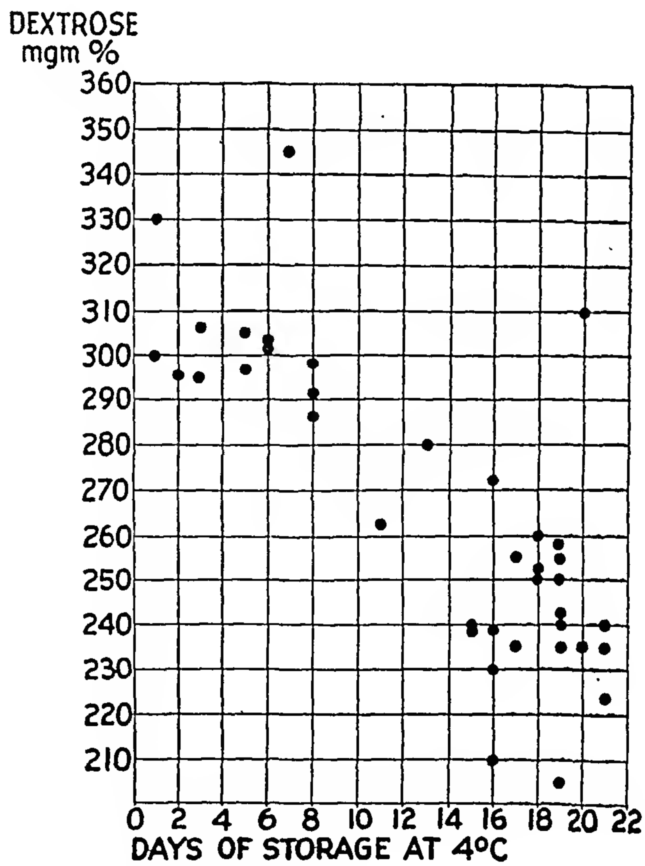

FIG. 7. DEXTROSE CONCENTRATION IN WHOLE BLOOD STORED AT 4° C. IN A.C.D. SOLUTION (B.M. No. 3)

tating motion. This is best accomplished by the use of a mechanical rotator, which does away with the unavoidable irregularities of the hand mixing and with the necessity of having a person in attendance for each patient. The rotators provided by the A. H. Thomas Co. of Philadelphia have been found excellent when fitted with a suitable heavy wooden bottle holder. Extensive studies have shown that the plasma obtained with the B.M.—A.C.D. No. 3 solution can be preserved in the frozen state or dried from the frozen state with results in all ways comparable with those obtained when a plain citrated plasma is used. It is to be noted here that when plasma prepared from whole blood preserved in a solution containing a higher glucose content is dried, the period of drying is lengthened because of the necessity of maintaining the plasma at a lower temperature while the water is being sublimated. When regenerating plasma prepared from A.C.D. blood, the use of a .1 per cent citric acid solution exerts the same beneficial effect in the preservation of prothrombin which has been noted for the plain citrated plasma (8).

CONCLUSIONS

An acid citrate-dextrose solution is proposed which has given good results for preservation of whole blood and yields a good stable plasma. This A.C.D. solution has a smaller volume and a lower dextrose concentration than solutions previously used. This solution has proved entirely satisfactory in practical use in over 5,000 blood collections.

TECHNICAL NOTE

DETERMINATION OF HEMOGLOBIN IN PLASMA (VISUAL COLORIMETRY)

By W. G. Karr and F. W. Chornock

SOLUTIONS:

Acetic acid—10 per cent:

Pipette 10 ml. glacial acetic acid into a 100 ml. volumetric flask and dilute to mark.

Benzidine dihydrochloride:

Dissolve 140 mgm. of benzidine dihydrochloride in about 200 ml. of water with warming. Cool, add 3.3 ml. of 10 per cent acetic acid and dilute to 500 ml. in a volumetric flask. Keep in a brown bottle in the refrigerator. (The acidity of this reagent is correct only for use with plasma as directed below.)

Hydrogen peroxide—1 per cent:

Dilute 0.5 ml. of Merck 30 per cent Superoxol to 15 ml. in a graduate. Prepare this solution just before use.

Artificial standard:

Ferric ammonium sulfate—1 per cent.
Potassium ferrocyanide —1 per cent.
Gum ghatti —1 per cent.

The iron and the ferrocyanide solutions are prepared accurately by careful weighing and dilution in a volumetric flask. Select clean, purple crystals of ferric ammonium sulfate. The gum ghatti is made approximately by suspending 1.5 grams on a wire or cloth gauze in 100 ml. of cold water and allowing it to dissolve overnight. If necessary, filter through cheesecloth to remove particulate matter.

In a liter volumetric flask, pipette exactly 13.0 ml. of the 1 per cent potassium ferrocyanide. Dilute to about 900 ml. Add 10 ml. of 1 per cent gum ghatti.

Add 20 ml. of the 1 per cent ferric ammonium sulfate. Dilute to mark. Mix. Keep in ice box.

Color is equivalent to 25 mgm. Hb per 100 ml. when the color is developed as in Method described below.

Serial standards:

Prepare 250 ml. of each of the following dilute standards by diluting the artificial standard with water as indicated.

Water	Standard	Hb. equiv. (C) mgm. per 100 ml.
0	250	25
50	200	20
100	150	15
150	100	10
200	50	5

Mix and place in 250 ml. bottles. Keep in ice box.

METHOD:

Dilute 1 ml. of plasma to 10 ml. with water. Measure 4 ml. of the dilute plasma into a test tube. Add 15 ml. of the benzidine dihydrochloride reagent. Add 1 ml. of the 1 per cent hydrogen peroxide and mix. Immerse in an ice bath for 35 minutes. At the end of this time select the artificial standard which is nearest the color of the unknown plasma. Pour 20 ml. into a test tube and add 0.4 ml. of the original undiluted plasma. Compare in the colorimeter.

If the blue color developed is appreciably greater than the 25 mgm. standard, the determination should be repeated using 4 ml. of a dilution of plasma greater than 1 to 10. Make appropriate change in the calculation.

CALCULATION:

X = mgm. Hb. per 100 ml. plasma.
S = reading of standard on the right.
U = setting of the unknown on the left.
C = equivalent Hb. concentration of the artificial standard selected for reading.

$X = \frac{S}{U} \times C$. Set U at 10. $X = \frac{S \times C}{10}$.

Blank: 4 ml. diluted plasma plus 15 ml. benzidine reagent plus 1 ml. water in icebath with unknowns.

THE *IN VITRO* PRESERVATION AND POST-TRANSFUSION SURVIVAL OF STORED BLOOD[1]

By J. F. ROSS,[2] C. A. FINCH, W. C. PEACOCK, AND M. E. SAMMONS

(From the Evans Memorial, Massachusetts Memorial Hospitals, the Department of Medicine, Boston University School of Medicine, the Department of Biochemistry, Harvard Medical School, and the Department of Physics, Massachusetts Institute of Technology)

(Received for publication February 17, 1947)

INTRODUCTION

The therapeutic value of blood transfusion is well established and experiences during World War II demonstrated the urgent need for readily available supplies of whole blood. Blood plasma and plasma "substitutes," although effective in combatting shock and in replacing plasma lost into burned and traumatized areas, cannot restore erythrocytes lost from hemorrhage or intravascular destruction (1).

Civilian and military experiences have demonstrated the practicability and value of whole blood stored or "banked" in advance of need, and immediately available for use in any emergency. In civilian practice, the blood bank has greatly facilitated the procedure of blood transfusion and has made feasible the routine use of whole blood transfusion. In military practice, banked blood is an absolute essential since it is impractical to bleed donors for transfusion under combat conditions, but it is under these very conditions that whole blood is most urgently needed.

Although stored blood is highly desirable practically and economically, to be effective, the viability of the erythrocytes must be maintained during the period of storage since the major purpose of transfusing whole blood is to supply the recipient with functional erythrocytes. Erythrocytes destroyed immediately after transfusion not only are valueless to the recipient, but the intravascular liberation of large amounts of hemoglobin from destroyed cells actually is deleterious and dangerous to the recipient. The life span of the erythrocyte *in vivo* is between 100 and 120 days but after removal from the circulation the period of viability is greatly reduced. Unless special precautions are observed, blood is unsatisfactory for transfusion purposes after storage for periods as brief as 3 to 5 days (2).

Attempts to preserve the functional capacity of stored erythrocytes were first made by Rous and Turner in 1916 (3) with considerable success. Robertson, an English army surgeon, using the solution devised by Rous and Turner, made the first successful use of bank blood during the first World War (4). The solution of Rous and Turner had several serious shortcomings, however, and did not receive general use. During the ensuing 20 years various modifications of the Rous and Turner solution were made and many new types of preservative solutions were devised (5 to 11). None of these preservatives was entirely satisfactory, however, and little exact information was presented as to how effective each actually was in maintaining the viability of the stored cells.

Under the stimulus of World War II various English (12 to 16) and Canadian (17, 18) workers reinvestigated the entire subject of blood preservation, and used as the criterion of effective preservation the post-transfusion survival of erythrocytes determined with the differential agglutinating techniques of Ashby (19) and of Wiener (20). These agglutinating techniques allow a qualitative comparison of the effectiveness of various preservatives, and also make possible the determination of the total duration of time that transfused cells survive in the recipient's circulation. As usually performed, however, these methods do not permit an accurate quantitative evaluation of the *immediate* post-transfusion erythrocyte survival; yet it is this immediate survival that is most

[1] The work described in this paper was done under contracts recommended by the Committee on Medical Research between the Office of Scientific Research and Development and the Massachusetts Memorial Hospitals and the Massachusetts Institute of Technology.

[2] Formerly Welch Fellow in Internal Medicine, National Research Council. These investigations were carried on while under tenure of the Welch Fellowship in Internal Medicine.

important in the majority of transfusions. In general, however, the findings and conclusions of the English investigators have been similar or identical to ours which were obtained with a very different, and, we believe, more exact technique.

To determine the most effective method of preserving the viability of erythrocytes in stored blood, we have investigated 16 preservative solutions. We have judged the effectiveness of these solutions from the standpoint of the post-transfusion survival of erythrocytes stored for varying lengths of time in each solution, and we have determined the post-transfusion survival of red blood cells by the radioactively labeled erythrocyte technique previously described by Ross and Chapin (2). In an attempt to determine which factors in the preservative medium promoted cell survival, extensive studies of the changes in physical and chemical properties of the stored blood were made in conjunction with the survival studies. It soon became apparent to us, as it has to others (21, 22), that the *in vitro* characteristics of stored blood are of little value in predicting the suitability of stored blood for transfusions. The really significant criterion of the value of a blood preservative is how well it maintains the viability of the stored erythrocytes, and this attribute can be judged only by studying the survival of the cells after transfusion into a recipient.

PROCEDURES AND METHODS

The radioactively labeled erythrocyte technique of evaluating the survival of erythrocytes following transfusion has been outlined in a previous paper (2). In brief, this method consists of administering orally or parenterally one of the radioactive isotopes of iron to a prospective blood donor whose hematopoietic system incorporates the radioactive iron in the hemoglobin molecules of newly formed erythrocytes. These erythrocytes are thus "labeled," since once an atom of radioactive iron is built into the hemoglobin molecule it does not exchange with the nonradioactive iron of the plasma or tissues. It remains within the erythrocyte during its lifetime and is liberated from the red cell only when the red cell is destroyed (23). Hemoglobin and erythrocytes containing this radioactive material differ in no physiological respect from unlabeled cells, but by appropriate physical techniques (24, 25) they can be accurately detected when present in dilutions as great as 1 in 3,000.

When donor cells labeled with radioactive iron are transfused into compatible recipients, they rapidly mix with the recipient's cells but still can be detected quantitatively in samples of the recipient's blood. If the labeled cells are destroyed after transfusion, there is a decrease in the concentration of radioactivity in the recipient's blood, and samples taken consecutively will reveal the extent and rate of cell destruction. The effectiveness of various blood preservatives can thus be evaluated by observing their influence on the survival of transfused radioactively tagged erythrocytes.

Preparation of donors of radioactively labeled erythrocytes

In evaluating the effectiveness of preservative solutions we believe that considerable importance should be attached to procuring uniformity in the donor blood. Individual variations in the bloods of different donors may markedly influence the storage and transfusion properties of the donor's erythrocytes and give erroneous impressions of the preservative solutions under investigation. To eliminate the factor of donor-cell variation from our studies all bloods used in our experiments were procured from a single blood donor with the exception of a series of control observations when blood was obtained from a second donor. The behavior of the cells of these 2 donors was identical. Both donors were healthy young adult males with normal erythrocyte, hemoglobin, and leukocyte characteristics. The blood of donor I, on whom most of the observations were made, was Group O, Rh factor negative. Donor II provided blood for control observations. His blood was Group O, Rh factor positive.

The radioactive isotope of iron, Fe^{55}, was administered intramuscularly or intravenously in an aqueous solution of iron and ammonium citrate. Donor I received 2 series of injections. In the first series a total of 4.68 mgm. iron with an activity of 7,000,000 counts per minute given in 20 injections during a period of 71 days. second series of injections was administered 8 mon later when 4.36 mgm. of iron with an activity of 6,610,(counts per minute were given over a period of 74 d The activity is expressed as the absolute number of co determined with a beryllium window Geiger-M counter (25). The radioactive iron was rapidly in porated in the newly formed hemoglobin and erythroc of the donors. Although the rate of incorporation i hemoglobin and the percentage utilization of the injec radioactive iron are considered in a separate publicati we may point out that approximately 60 per cent of given dose of injected radioactive iron appeared in the circulating erythrocytes of the donors and that maximum utilization of a single dose was complete in approximately 20 days. The maximum specific radioactivity produced in the donor's blood amounted to 4,180 counts per minute per ml. of erythrocytes, 12,550 counts per minute per gram of hemoglobin, or 3,760 counts per minute per mgm. of hemoglobin iron.

Since the labeling radioactive iron first becomes available to the donor for hemoglobin synthesis at the time of the first injection of the isotope, the maximum age of the donor erythrocytes is determined by the interval of time elapsing between the first injection of radioactive

iron and the times that the donor is venesected and the blood transfused. Thus, it is possible to state definitely that the labeled cells of a given transfusion have a maximum age of 7 days, 30 days, 100 days, etc. As previously described (2), radioactive iron liberated from destroyed radioactively labeled erythrocytes is rapidly reutilized by the body and incorporated into newly formed hemoglobin and erythrocytes. Therefore, 4 to 6 months after the first injections of radioactive iron the labeled cells are representative of the mixed age population of the whole cell mass. These considerations are important in evaluating the behavior of young, old, and mixed age cells during storage and after transfusion.

With the exception of the previously reported (2) observations on blood stored in tri-sodium citrate solutions the donor erythrocytes used for these studies varied in possible maximum age from 80 days to 120 days. The majority of observations were made on bloods in which the radioactive labeled cells were of all ages and were representative of the age distribution of the entire erythrocyte population.

Technique of collection and storage of radioactively labeled donor blood

After a fasting period of at least 12 hours the donors were bled from an antecubital vein through a closed system into the preservative solution under investigation. Except when noted to the contrary, 400 to 500 ml. of blood were drawn into the preservative solution contained in a 600-ml. pyrex Fenwal transfusion bottle, both solution and container previously having been chilled to 4° C. The blood was stored immediately in the dark in a stationary mechanical refrigerator thermostatically regulated 4° to 6° C. until aliquots were removed for transfusion.

Recipients of transfusions

All recipients were normal healthy adult male or female medical students, internes, or hospital technicians. The of normal individuals excluded the uncontrollable factor of effect of disease processes in the recipient on the post-transfusion survival of erythrocytes. All donors and recipients used in these studies were of blood group O. Most of the studies were performed with Rh negative (rh, rh or cde, cde) blood. In experiments in which Rh positive blood was employed, only Rh positive recipients were used. Careful cross-matching with the Landsteiner test tube technique verified complete compatibility between donor and recipient bloods in all cases.

We believe that the use of donor blood of the same blood group as that of the recipient is important in these studies, since it is now well established that the iso-agglutinins contained in transfused blood may destroy the recipient's own erythrocytes (26). If this should occur following a transfusion of radioactively labeled blood the specific radioactivity of the recipient's erythrocytes would be increased and a false impression of the post-transfusion survival would be obtained.

Techniques of transfusion and sampling of recipients

All transfusions were given early in the morning while the recipient was in a fasting state. The recipient remained in bed during the course of the injection of the blood and for 1 hour thereafter, and then resumed full activity.

Aliquots of radioactively labeled blood for transfusion and for hematologic, chemical, and radioactive studies were removed by aspiration from the storage flasks after the cells and plasma had been gently and thoroughly mixed by rotation. The storage flask was then returned to the refrigerator. Immediately after removal from the storage flask a known amount, usually 100 ml., of the chilled blood was injected into the recipient through a No. 18 needle from a calibrated 100-ml. syringe. Two to 4 minutes were required to make the injection. A known amount of the dye T–1824 was then immediately injected through the same needle into the vein of the recipient for purposes of plasma volume determination.

Samples of blood for hematologic study and for radioactivity and T–1824 concentration determinations were subsequently removed through a No. 18 needle in the opposite arm. A portion of the sample was placed in the mixed oxalate of Heller and Paul (27) for hematologic study, and the remainder of the sample was placed in a calibrated conical centrifuge tube and allowed to clot. The serum from the clotted blood was used for spectroscopic study and for determination of T–1824, hemochromogen, and bilirubin concentrations. The red blood cells from a known volume of oxalated and clotted blood were digested for radioactivity determinations as subsequently described. The exact volume of red blood cells and the amount of hemoglobin in each sample were calculated from the volume of blood and the hematocrit and hemoglobin values determined on an aliquot of this blood.

Ninety transfusions of blood were given in this fashion. There were no reactions of any sort in 88 of the subjects. Two subjects experienced a mild febrile reaction which was proved to be caused by the lot of T–1824 dye solution used for the blood volume determination in these 2 subjects.

Radioactivity determinations

The specific radioactivity of the donor's and recipient's whole blood, erythrocytes, hemoglobin, and hemoglobin iron was determined with techniques similar to those described by one of us in previous papers (2, 24), with some modifications (25). In these experiments we have used the radioactive isotope Fe^{55} (half life approximately 5 years) instead of the radioactive isotope Fe^{59} (half life 47 days). The longer half life of Fe^{55} makes this isotope much more satisfactory than Fe^{59} for long-term cell tracing experiments. The radiations from Fe^{55} are low energy x-rays and have necessitated the use of a beryllium window counting tube (25) instead of the thin mica window tube previously used. The preparation of the samples of blood for determination of radioactive con-

tent by acid digestion, neutralization, and precipitation of iron is identical with those previously described (24) with the exception that the iron in the present series of experiments was precipitated as ferric hydroxide instead of ferrous sulfide.

To eliminate variation in self-absorption the iron content of each sample was determined by multiplying the grams of hemoglobin in the sample by 0.00334 (that fraction of hemoglobin which is iron) and then enough non-radioactive iron was added to the sample to make its total iron content 10 mgm.

The iron was electrolytically deposited in a uniform, thin layer on copper discs as previously described (24, 25), but the plating process was carried out from a ferric rather than a ferrous solution. This required a longer period of electroplating than was the case when a ferrous solution was employed but was satisfactory for quantitative removal of the iron.

An aliquot of the donor blood which had been injected into each subject was assayed for radioactivity with the radioactivity determination of each sample of the recipient's blood, thus eliminating the necessity of making corrections for the decay of the radioactive iron, counting tube variations, etc.

Determination of plasma, blood and erythrocyte volumes

The determination of the post-transfusion survival of erythrocytes by any method is no more accurate than the accuracy with which the total circulating erythrocyte volume of the recipient is determined. This is true not only of the radioactively tagged cell method but also of the Ashby (19) and Wiener (20) methods of differential agglutination. The critical significance of the total erythrocyte volume will be evident from consideration of the following formula for calculating the post-transfusion survival of radioactively labeled red blood cells.

$$\left.\begin{array}{c}\text{Per cent of transfused cells}\\ \text{surviving in the recipient's}\\ \text{circulation}\end{array}\right\} = \frac{\begin{array}{c}\text{Radioactivity per}\\ \text{ml. of recipient's}\\ \text{cells}\end{array} \times \begin{array}{c}\text{Recipient's red}\\ \text{blood cell}\\ \text{volume}\end{array} \times 100}{\text{Total radioactivity of transfused blood}}$$

Although the radioactivity concentrations of the recipient's and donor's bloods can be determined with considerable accuracy, the method of determination and interpretation of the recipient's red blood cell volume is the subject of considerable difference of opinion. A discussion of the latter problem is beyond the scope of this paper, but it seems worthwhile to point out that the neglect of the significance of the cell volume, the assumption that it represents a constant per cent of the body weight or surface area, or its estimation purely on the basis of the plasma volume and the uncorrected venous hematocrit will give grossly erroneous values for the survival of transfused cells. In the differential agglutinating technique of Ashby or Wiener, calculations of survival are based on the assumptions that all of the transfused cells are surviving at the conclusion of the transfusion and that the number of non-agglutinated cells present in the recipient's blood at the conclusion of the transfusion represent 100 per cent survival of the transfused cells. This assumption is not valid, since our data indicate that many transfused erythrocytes are removed from the recipient's circulation very rapidly (actually during the course of the transfusion). This is particularly true when bloods with poor survival characteristics are transfused. The poorer the post-transfusion survival of stored blood the more rapidly the non-viable cells are removed from the circulation. Because of this fact most of the studies performed with modifications of the Ashby technique have indicated erroneously high post-transfusion survival.

Calculation of the cell volume from the plasma volume and venous hematocrit repeatedly has been shown to give values 15 to 30 per cent too high, unless correction is made for the error of the hematocrit as determined by centrifugation and for the unequal distribution of plasma and cells throughout the vascular system (28 to 31). Unless allowance is made for these errors, the calculated survival of labeled erythrocytes after transfusion will be 15 to 30 per cent too high.

Realizing that determinations of post-transfusion erythrocyte survival and evaluation of preservative fluids and techniques were so critically affected by the red blood cell volume we have determined this volume in an identical fashion in each recipient and have determined it with a technique which we believe represents a conservative factor in evaluating the post-transfusion erythrocyte survival. Although our method may represent too small a cell volume and, therefore, a low value for post-transfusion survival, it certainly does not give too high a cell volume or indicate too high a post-transfusion survival.

The recipient's red blood cell volume was determined as follows:

1. The plasma volume was determined with the dye T-1824 according to the method of Gibson and Evans (32), samples being taken at 15, 25, 30, 35, and 60 minutes, and the dye concentrations being determined on serum in the micro unit of the Evelyn colorimeter.

The L values obtained at 620 millimicrons were corrected with a reading at 540 millimicrons to correct for the effect of serum hemoglobin (which was present in the serum following transfusion of blood with poor survival characteristics). The L values were also corrected for fluctuation in plasma protein concentration (33, 34). The disappearance curve was extrapolated to the time of injection.

2. The blood volume and cell volume were calculated from the following formula, employing the corrected hematocrit value previously described (28):

$$\text{Blood volume} = \frac{\text{plasma volume}}{1 - (\text{hematocrit} \times 0.92)}$$

$$\text{Cell volume} = \text{blood volume} - \text{plasma volume.}$$

3. The cell volume so determined was corrected to compensate for the error introduced by unequal distribution of erythrocytes and plasma throughout the vascular system (29).

$$\text{Corrected cell volume} = \text{cell volume} \times 0.85.$$

The cell volumes of normal human subjects determined in this fashion compare very closely with the cell volume determined in the same subjects with the use of radioactive tagged cells (31).

We again wish to emphasize the fact that the use of the cell volume determined in this fashion provides a conservative estimate of post-transfusion erythrocyte survival and allows an accurate comparison of various preservative fluids.

Calculation of post-transfusion survival

The radioactivity present in the circulating red blood cell mass of the recipient was determined at various intervals following the transfusion by applying the formula:

$$\left.\begin{array}{c}\text{Per cent of transfused radio-}\\ \text{activity present in the recipient's}\\ \text{circulation}\end{array}\right\} = \frac{\begin{array}{c}\text{Radioactivity per}\\ \text{ml. of recipient's}\\ \text{red blood cells}\end{array} \times \begin{array}{c}\text{Recipient's red}\\ \text{blood cell}\\ \text{volume}\end{array} \times 100}{\text{Total radioactivity of the transfused blood}}$$

The specific radioactivity of the recipient's cells and thus the percent of transfused radioactivity present in the recipient's circulation decreased following the transfusion, the lowest values being reached at the end of approximately 24 or 48 hours. Subsequently, the concentration of radioactivity progressively increased (Figures 1 and 2). We have interpreted the decrease in radioactivity as indicating the removal of the non-viable transfused erythrocytes from the recipient's circulation. The rate of this removal was most rapid in those bloods showing the poorest post-transfusion survival. We have interpreted the increase in radioactive iron in the recipient's circulation as indicating the reutilization of the radioactive iron liberated from the destroyed transfused erythrocytes for the formation of new erythrocytes by the recipient. Support is given to this interpretation by observations of similar buildup curves following infusion of solutions of hemoglobin labeled with radioactive iron (35).

During the first 24 hours following the transfusion the amount of radioactive iron incorporated in newly formed recipient's erythrocytes is too small to contribute significantly to the total radioactivity in the recipient's circulation. Therefore, during this period all of the radioactivity in the recipient's blood can be attributed to the presence of surviving labeled donor red blood cells and indicates post-transfusion survival. After 24 hours, the reutilization of radioactive iron and its incorporation in the recipient's own erythrocytes may occur more rapidly than the removal of the transfused labeled cells and may be great enough to indicate a falsely high post-transfusion survival.

Because of these considerations the minimum specific radioactivity of the recipient's erythrocytes, which usually is reached 24 hours after transfusion, has been adopted as indicating the minimum post-transfusion survival of the labeled donor erythrocytes.

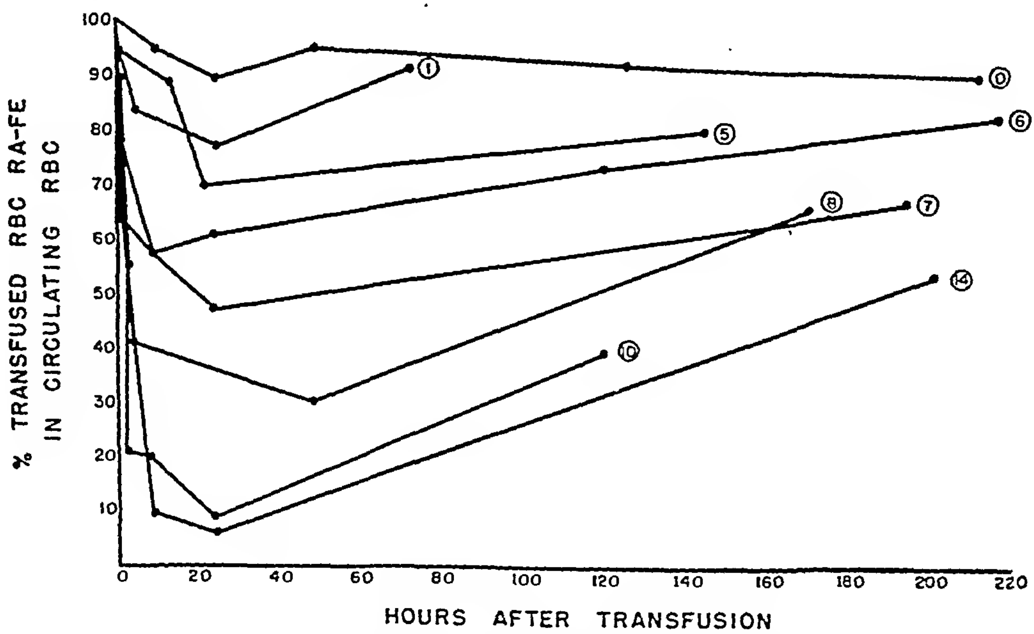

FIG. 1. THE EFFECT OF STORAGE AT 4° C. ON THE POST-TRANSFUSION SURVIVAL OF ERYTHROCYTES OF WHOLE BLOOD STORED IN TRISODIUM CITRATE (SOLUTION NO. 1)

The circled figures indicate the number of days the blood was stored prior to transfusion.

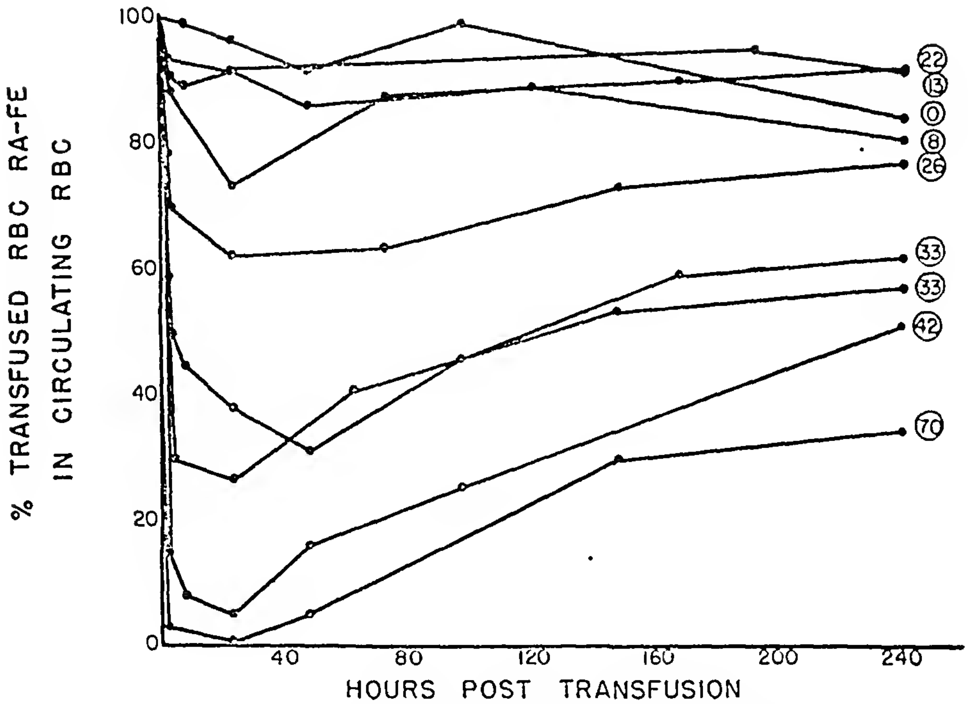

FIG. 2. THE EFFECT OF STORAGE AT 4° C. ON THE POST-TRANSFUSION SURVIVAL OF ERYTHROCYTES OF WHOLE BLOOD STORED IN DENSTEDT'S SOLUTION (SOLUTION No. 2)

The circled figures indicate the number of days the blood was stored prior to transfusion.

This minimum survival has been used as the criterion for evaluating the effectiveness of the blood preservative under consideration.

Preservative fluids studied

All solutions (except the corn syrup and Alsever's solutions which were obtained commercially) were prepared with pyrogen-free, freshly distilled water and reagent chemicals. All glassware and storage bottles (except the Baxter bottles containing Alsever's solution) were pyrex glass. With the exception of a few experiments that were carried out at room temperature, all bloods were drawn into containers and solutions which previously had been chilled to 4° C. and were immedately stored at 4° to 6° C.

The fluids studied may be grouped into those used for the preservation of whole blood and those used for the preservation of erythrocytes separated from blood plasma. A description of the constitution, the methods of preparation, and use of these fluids follows.

A. PRESERVATIVE FLUIDS FOR WHOLE BLOOD

Solution No. 1: Trisodium citrate

Trisodium citrate (2.5 per cent)	50 ml.
pH of solution	7.5
Whole blood	450 ml.
pH citrate blood mixture	7.4

Nineteen transfusions were given of blood stored in this solution 0 to 14 days.

Solution No. 2: Denstedt's or McGill No. II solution

Isotonic sodium citrate (3.2 per cent)	80 ml.
Isotonic dextrose (5.4 per cent)	80 ml.
Isotonic phosphate buffer pH 7.4	40 ml.
Whole blood	400 ml.
pH of solution	7.4
pH solution-blood mixture	7.4

The citrate, dextrose, and buffer solutions were prepared and autoclaved separately, cooled, and mixed with aseptic precautions in sterile Fenwal bottles according to the method described by Denstedt, *et al* (17). Twelve transfusions were given of blood stored in this solution 0 to 70 days.

Solutions No. 3 and 4: Alsever's solutions No I and II[3] *(Baxter No. I and II)*

Solution No. 3—Alsever's solution No. I

Dextrose (U.S.P.)	2.05 per cent	of this solution—500 ml.
Sodium citrate (U.S.P.)	0.80 per cent	
Sodium chloride (U.S.P.)	0.42 per cent	
Citric acid (U.S.P.)	0.04 per cent	
Whole blood		500 ml.
pH of solution		6.78
pH of solution-blood mixture		7.5

[3] These solutions, modifications of the one described by Alsever and Ainsle (11), were prepared and provided by the Baxter Laboratories, Incorporated, through the courtesy of Dr. N. M. Nesset. The formulae given here were provided by the Baxter Laboratories as descriptive of their constitution.

Four transfusions of blood stored in this solution 1 to 36 days were given.

Solution No. 4: Alsever's solution No. II

Dextrose (U.S.P.)	2.05 per cent	of this solution	—500 ml.
Sodium citrate (U.S.P.)	0.80 per cent		
Sodium chloride (U.S.P.)	0.42 per cent		
Citric acid (U.S.P.)	0.055 per cent		
Whole blood			500 ml.
pH of solution			6.0
pH of solution-blood mixture			7.2

Four transfusions were given of blood stored in this solution 7 to 35 days.

Solution No. 5: Acid citrate-dextrose solution of Loutit and Mollison[4]

Disodium citrate (2 per cent)	100 ml.
Dextrose (15 per cent)	20 ml.
Whole blood	430 ml.
pH of solution	5.0
pH of solution-blood mixture	6.8

This solution was prepared according to the method described by Loutit and Mollison (14). Nine transfusions of blood stored in this solution 2 to 34 days were given.

Solution No. 6: Acid citrate-dextrose solution of reduced volume

Trisodium citrate	2.20 grams	of this solution	—75 ml.
Citric acid	0.80 grams		
Dextrose (anhydrous)	2.25 grams		
Water	100 ml.		
pH	5.0		
pH of preservative-blood mixture	6.8		
Whole blood			500 ml.

(15 ml. of this solution used for each 100 ml. of whole blood.)

In the proportions used, this solution provided approximately 2 grams of disodium citrate per 500 ml. of blood, and an eventual 24 millimolar concentration of citrate ion in the supernatant plasma of the preservative-blood mixture. In these respects, and in the pH of the solution and the solution-blood mixture, solutions No. 5 and 6 were identical. The dextrose content of solution No. 6 was approximately ½ that of solution No. 5, however, and the volume of the diluent was 62.5 per cent of solution No. 5.

Four transfusions of blood stored in this solution 6 to 28 days were given.

[4] The disodium citrate used in preparing this solution and others containing disodium citrate was kindly prepared and provided by Dr. Walter Clarke of the Eastman Kodak Company, Rochester, New York. In the event that crystalline disodium citrate should not be available a solution of disodium citrate can readily be prepared as follows:

Trisodium citrate ($Na_3C_6H_5O_7 \cdot 2H_2O$)	1.662 grams
Citric acid ($H_3C_6H_5O_7 \cdot H_2O$)	0.595 grams
Water	100 ml.
pH	5.0

B. PRESERVATIVE FLUIDS FOR ERYTHROCYTES SEPARATED FROM THEIR PLASMA

The separated cells for solutions 7, 8, 9, and 10 were prepared as follows: 450 ml. of donor blood were drawn into 50 ml. of previously chilled 2.5 per cent trisodium citrate solution of pH 7.5. The cells were immediately sedimented by centrifugation at 2,500 r.p.m. for 1 hour, and the plasma then removed by aspiration with aseptic precautions. For the experiments with solutions 11, and 12, 400 ml. of blood were drawn into 100 ml. of 2 per cent disodium citrate solution of pH 5.0. Centrifugation and separation of plasma were carried out as previously described. The cell mass for solution 13 was obtained from defibrinated blood which was centrifuged and separated from its plasma as described above.

A description of the solutions and techniques used in the preservation of erythrocytes separated from their plasma follows:

Solution No. 7: Human albumin solution[5]

Human albumin	6.00 per cent	of this solution	—400 ml.
Dextrose (anhydrous)	1.00 per cent		
Sodium chloride	0.85 per cent		
Phosphate buffer (0.125 molar pH 7.4)	0.07 per cent		
Red blood cell mass			200 ml.
pH of solution			7.35
pH of solution-blood mixture			7.35

The solution was sterilized by passing it through a Seitz filter with pressure. It was chilled to 4° C., and the packed red blood cells were pipetted into it. The cells and preservative were mixed thoroughly then stored at 4° C.

Five transfusions of cells preserved in this fashion were given; the duration of storage varying from 10 to 46 days.

Solution No. 8: Corn syprup

Corn syrup (10 per cent)	200 ml.
Packed blood cells	200 ml.
pH of corn syrup	4.0
pH of corn syrup-blood mixture	6.7

This 10 per cent solution of sterile corn syrup was provided in ampules through the courtesy of Dr. William Thalhimer of New York City. The concentration of the corn syrup before it is diluted is stated to be (36):

Dextrose	17.7 per cent
Maltose	16.8 per cent
Higher sugars	16.2 per cent
Dextrins prosugars	29.6 per cent
Moisture	19.7 per cent

The chilled corn syrup was added to the packed red blood cells, mixed by rotation, and then stored at 4° C.

Seven transfusions of these cells were given after storage for 6 to 22 days.

[5] The human albumin used in this solution was provided through the courtesy of Dr. Edwin Cohn of the Harvard Medical School.

Solutions No. 9, 10, 11, and. 12: Maltose-dextrose solutions

TABLE I

Solution	Name	Disodium citrate	Maltose	Dextrose	NaCl	Vol. of solution	Vol. of packed cells	pH of solution	pH of blood mixture
		per cent	*per cent*	*per cent*	*per cent*		*ml.*		
9	M1	2.0	6.84	0.5	0.85	250	125	4.9	5.7
10	M2	2.0	6.84	0.5	0	250	125	5.0	5.7
11	M3	0.5	6.84	0.75	0	250	125	5.8	5.8
12	M4	0	6.84	0.75	0.43	250	125	6.5	6.7

These chilled solutions were added to packed red blood cells in proportions noted. The cells for solutions No. 9 and 10 were obtained from blood drawn into trisodium citrate solution (solution No. 1). The cells for solutions No. 11 and 12 were drawn into acid citrate dextrose (solution No. 5).

Five transfusions of cells stored 7 to 14 days in these solutions were given.

Solution No. 13: RPA solution [6]

	grams per l.
$MgCl_2$	.095
$CaCl_2$	.056
KCl	.410
NaCl	5.825
Na_2HPO_4	.301
$NaHCO_3$*	2.35
Glucose	2.50
Difco proteose peptone	1.50
Stearns A A**	0.50
Glycerol	0.25
Sodium acetate	0.15
	micrograms per l.
Adenine sulfate	250
Guanine–HCl	250
Thymine	125
Xanthine	250
Uracil	250
Ascorbic acid	5,000
Biotin	16
Choline	500
Cocarboxylase	400
Nicotinic	1,000
Nicotinamide	1,000
d–Ca Pantothenate	500
Pyridoxine	500
Ribose	500
Riboflavin	500
Thiamine	1,000

* Added as Na_2CO_3 and converted to bicarbonate by passing CO_2 gas through the solution.

** Fortified with glycine and histidine.

P-amino benzoic acid is added to conc. 10 gamma per cent.

Medium (complete) is filtered instead of autoclaved.

The solution was added to the red blood cell mass procured from defibrinated blood in amounts sufficient to produce hematocrit values of 27, 37 and 40 per cent. The cells and solution were mixed and the pH adjusted to 7.0 by equilibration with CO_2. The mixture was stored at 4° C.

Solution No. 14: ACD solution 2 per cent

This solution is identical with solution No. 5, but the method of handling the cell-solution mixture differs markedly from that followed with solution No. 5. Four hundred thirty ml. of donor blood were drawn into the chilled solution. The mixture was stored at 4° C. for 24 hours. It was then centrifuged at 2,500 r.p.m. for 1 hour and the supernatant plasma removed aseptically by aspiration. The packed cells were then stored at 4° C. without addition of further diluent until they were transfused. The pH of the cell mass was 6.8. A small amount (equal to 10 per cent of the volume of cells) of 0.85 per cent sodium chloride solution at a temperature of 4° C. was added to the cell mass at the time of transfusion.

Five such transfusions were given of cells stored 11 to 24 days.

Solution No. 15: Acid citrate-dextrose solution 5 per cent

Disodium citrate	(5 per cent)	of this solution	—25 ml.
Dextrose (anhydrous)	(6 per cent)		
Whole blood			250 ml.
pH			5.0
pH of solution-blood mixture			6.8

The blood was drawn into the chilled solution and stored for 24 hours at 4° C. It was then centrifuged at 2,500 r.p.m. for 1 hour and the supernatant plasma removed aseptically by aspiration. The packed cells were stored at 4° C. until transfused and injected without dilution.

Three transfusions were given of cells stored 7 to 22 days.

Solution No. 16: Acid citrate solution 5 per cent

Disodium citrate (5 per cent)	25 ml.
Whole blood	225 ml.
pH of solution	5.0
pH of solution-blood mixture	6.8

The blood was drawn into the chilled solution, stored at 4° C. for 24 hours, centrifuged and the plasma removed as described above. Then 15 ml. of chilled 10 per cent dextrose solution were added to and mixed with the cell mass by rotation of the container. The mixture was stored at 4° C. until transfused and injections were made without dilution, after storage for 9 to 22 days.

Hematologic studies

The following studies were performed on aliquots of donor blood shortly after it was drawn into the preservative solution and at intervals during the period of stor-

[6] This solution was prepared by Dr. Eric Ball of the Harvard Medical School and was identical with the solution used by Ball and his collaborators for the *in vitro* cultivation of malaria parasites (37).

age; they were also performed on aliquots of the samples removed from the recipients before and after the transfusion:

1. Erythrocyte and leukocyte counts were performed in quadruplicate, using 4 pipettes and 4 counting chambers and the average of the 4 counts was used in calculations.
2. Hematocrit determinations were made with the Wintrobe hematocrit tube and with application of a relative centrifugal force of 1,800 for 1 hour.
3. Whole blood hemoglobin concentration was determined by the Evelyn oxyhemoglobin method (38) on the Evelyn photoelectric colorimeter.
4. Erythrocyte indices were calculated according to the method of Wintrobe (39).
5. The concentration of heme pigments in the plasma of the recipient and in the supernatant plasma of the donor blood was determined according to the hemochromogen method of Flink and Watson (40).
6. The plasma bilirubin concentrations of the recipient were determined according to the method of Evelyn and Malloy (41).
7. The whole blood sugar content of the donor blood was determined by the method of Folin and Malmros (42).
8. The pH of the donor blood was determined with the Beckman glass electrode pH meter.
9. The susceptibility of the donor erythrocytes to hemolysis by hypotonic saline solutions ("osmotic fragility") was determined by the method originally suggested by Dacie and Vaughan (43) as modified by Shen, Ham, and Fleming (44).
10. The morphologic characteristics of the donor erythrocytes were observed in wet unstained preparation and in dry Wright stained preparations.
11. Spectroscopic studies were performed on plasma and serum of donor and recipient bloods with the Zeiss hand spectroscope and the Hartridge reversion spectroscope.

OBSERVATIONS

Figures 1 and 2 illustrate the post-transfusion survival of radioactively labeled erythrocytes stored in tridosium citrate (solution No. 1) and in Denstedt's solution (solution No. 2). Following transfusion the non-viable donor cells are destroyed and removed from the recipient's circulation. The number of cells removed and the rapidity with which they are removed increase with increase in the duration of storage.

The majority of the non-viable cells are removed during the first hour or 2 following transfusion and the survival curve then continues to fall more gradually during the next 18 to 20 hours. At the end of 24 hours the minimum post-transfusion survival usually is reached. It is this minimum survival which we have used as the criterion of the effectiveness of the blood preservative, and it is this value which has been used in constructing the curves in Figure 4. After 24 hours newly formed erythrocytes containing reutilized radioactive iron may be liberated in the recipient's circulation more rapidly than the labeled donor cells are removed and consequently the concentration of radioactive iron per unit volume of red cells increases.

Trisodium citrate obviously is a very poor blood preservative (Figure 1). The erythrocytes of stored citrated blood degenerated at a rate of 7 per cent per day and after storage for 7 days only 50 per cent of the transfused cells survived 24 hours (Figures 1 and 4). If we accept as an arbitrary minimum requirement for a satisfactory transfusion the survival of 70 per cent of the transfused cells for at least 24 hours following transfusion, citrated blood can no longer be considered satisfactory for transfusion if stored for longer than 5 days.

Denstedt's solution, in marked contrast to trisodium citrate, is an excellent blood preservative (Figures 2 and 4). Blood stored in this solution for 24 days showed satisfactory post-transfusion survival, and the rate of degeneration of red cells during storage was only approximately 1.4 per cent per day. There was 1 serious drawback to Denstedt's solution, however. The necessity for separately autoclaving the citrate, dextrose, and phosphate solutions and then mixing them with sterile technique made its preparation exceedingly laborious and not very satisfactory for routine use. Since the acid citrate-dextrose solution (solution No. 5) was found to have almost identical preservative powers and was much simpler to prepare, Denstedt's solution does not justify the effort required to prepare it.

The 2 Alsever's solutions studied differed only in their citric acid content and initial pH, and were almost identical in their preservative powers (Figure 3). They were not good preservative solutions, since after storage for only 7 days, less than 70 per cent of the transfused cells survived 24 hours, and the rate of degeneration of the erythrocytes during storage amounted to approximately 3 per cent per day.

Another serious disadvantage of Alsever's solution is the large volume of diluent (500 ml.) required for the preservation of 500 ml. of blood. The addition of this large volume of fluid serves

no useful purpose and is actually contraindicated in many blood transfusions.

The most satisfactory blood preservatives which we studied were the acid citrate-dextrose solutions, either the solution originally described by Loutit and Mollison (14) (solution No. 5) or modifications of this fluid (solutions No. 6, 14, 15, and 16). The acid citrate-dextrose solution of Loutit and Mollison (for convenience called "ACD" throughout the remainder of this paper) was an excellent blood preservative—maintaining satisfactory transfusion properties in blood stored for as long as 23 days (Figure 4) and retarding the rate of degeneration of erythrocytes during storage to only 1.4 per cent per day. In addition to its excellence as a preservative ACD was extremely simple to prepare. The citrate and dextrose solutions were mixed prior to sterilization, and were autoclaved together without caramelization.

The volume of ACD (120 ml.) was not large enough to dilute the blood to any serious degree, but it was believed by the Subcommittee on Blood Substitutes of the National Research Council that a smaller volume preservative might be desirable, since it might make more simple the preparation of desiccated plasma. Therefore, solution No. 6 was devised. Its volume was only 75 ml. but it provided the same amount of disodium citrate per unit volume of blood as solution No. 5; it reduced significantly the amount of dextrose. The preservative properties of this solution were indistinguishable from those of solution No. 5 (Table II).

TABLE II

Survival of erythrocytes of stored whole blood

Preserving solution	Per cent r.b.c. surviving in the recipient's circulation 24° after transfusion of blood stored			
	7 days	14 days	21 days	28 days
1. Trisodium citrate	50	3	0	
2. Denstedt's solution	92	90	73	60
3. Alsever's No. I	67	60	34	13
4. Alsever's No. II	68	60		
5. Acid citrate-dextrose (Loutit and Mollison) ("ACD")	97	92	71	60
6. Acid citrate-dextrose reduced volume	95	92	75	64

Similar observations were obtained with a solution of even smaller volume (50 ml.) (solution No. 15), which was used for preservation of erythrocytes separated from plasma. The post-transfusion survival of the separated cells taken into this solution was almost identical with that of whole blood in 120 ml. volume ACD (solution No. 5) or in the 75 ml. of modified ACD (solu-

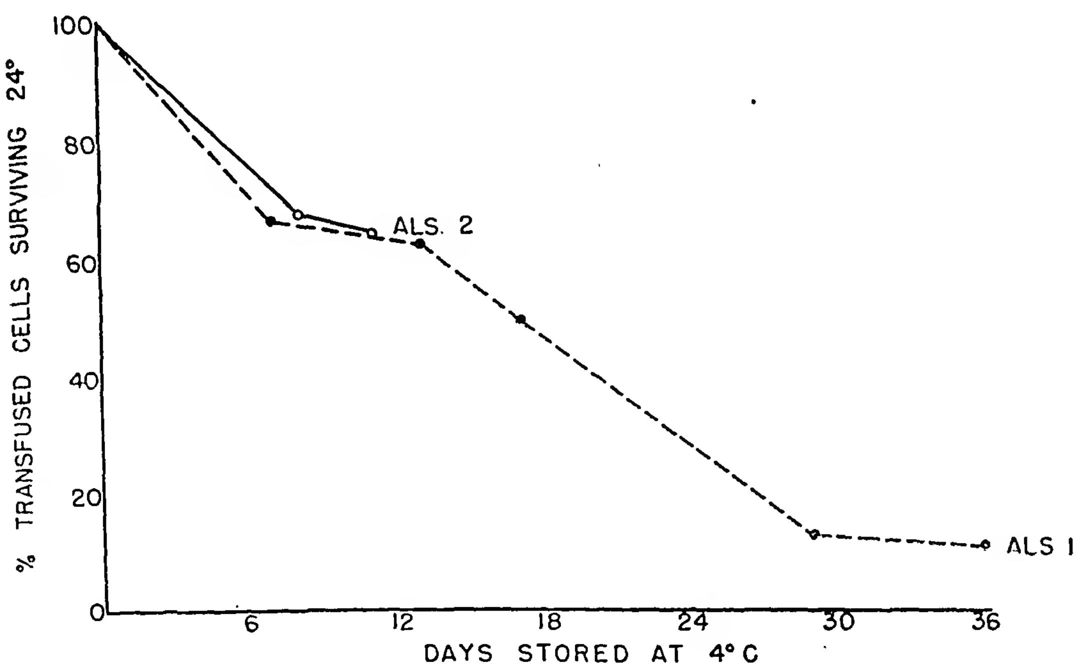

FIG. 3. COMPARISON OF THE EFFECT OF STORAGE OF WHOLE BLOOD IN ALSEVER'S SOLUTIONS NO. 1 AND 2 ON POST-TRANSFUSION SURVIVAL

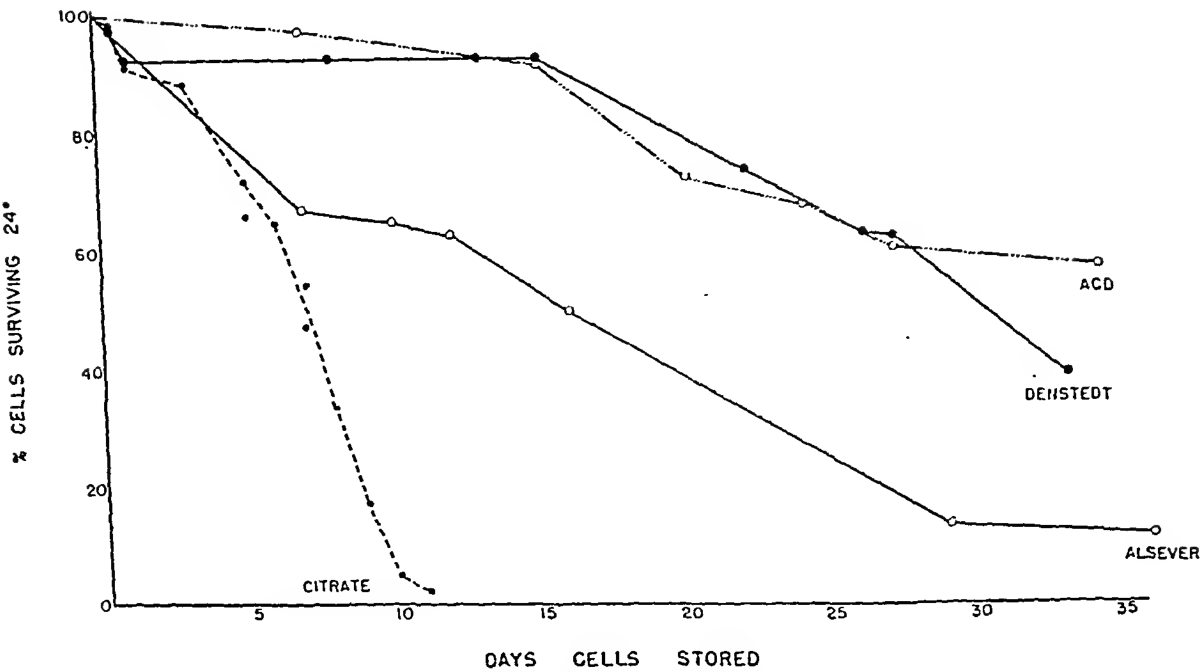

Fig. 4. Comparison of the Survival of the Erythrocytes of Whole Blood Stored at 4° C. in the Acid Citrate-Dextrose Solution of Loutit and Mollison (solution No. 5, "ACD"), Denstedt's Solution (solution No. 2), Alsever's (solution No. 3), and Trisodium Citrate Solution (solution No. 1)

tion No. 6). The volume of the preservative within these limits had little influence on erythrocyte preservation.

Preservation of erythrocytes separated from plasma

Since normal blood contains various hemolytic systems it was believed that erythrocytes might survive better *in vitro* if they could be removed from their plasma and resuspended in some other fluid. Furthermore, if some method of preserving cells separated from plasma could be devised it would salvage tremendous quantities of red blood cells which are discarded in the process of preparing blood plasma and plasma fractions. Such studies were successful in demonstrating a simple yet effective method of preserving red blood cells after separation from plasma.

The studies of Furchgott and Ponder (45) indicated that crystalbumin prevented the development of certain morphologic abnormalities in erythrocytes placed under abnormal conditions *in vitro*. With the hope that human albumin might exert a similar beneficial effect on stored human red cells, we resuspended erythrocytes separated from whole blood in solution No. 7. After storage for 22 days 70 per cent of the transfused cells survived 24 hours (Figure 5), which is good preservation but no better than in several far simpler and less expensive solutions.

This proved to be the case with corn syrup (solution No. 8) which was investigated at the request of the Subcommittee on Blood Substitutes. It maintained satisfactory transfusion properties in resuspended erythrocytes for only 10 days (Figure 5).

In vitro studies indicated that non-diffusible disaccharides might be effective as erythrocyte preservatives; so the maltose-dextrose solutions (solutions No. 9, 10, 11 and 12) were devised to test this possibility. Only solution No. 12 was of any value (Table III).

Ball and his collaborators (37) showed that the malarial parasite could be satisfactorily cultivated in erythrocytes suspended in the complex solution described as "RPA" (solution No. 13). It seemed possible that one of the reasons this solution supported the growth of malarial parasites was because it maintained erythrocyte viability. Therefore, we investigated the preservation of erythrocytes separated from their plasma, resuspended, and stored in this fluid.

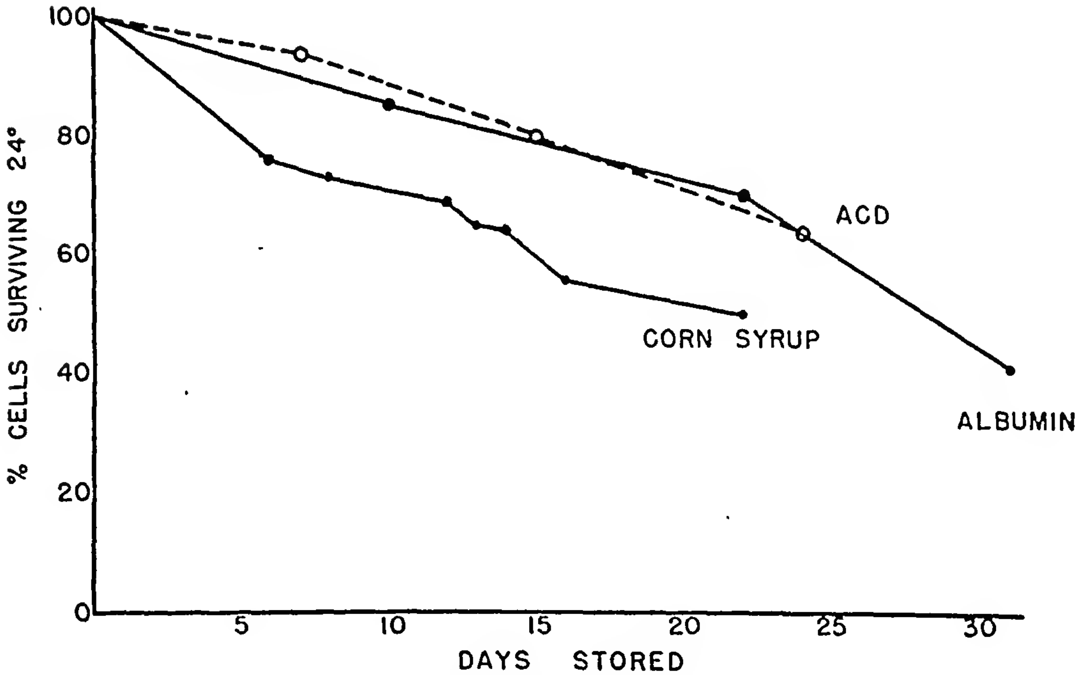

FIG. 5. COMPARISON OF THE POST-TRANSFUSION SURVIVAL OF ERYTHROCYTES SEPARATED FROM PLASMA

ACD represents cells separated from blood drawn into ACD and stored without addition of diluent (solution No. 14). The "albumin" and "corn syrup" cells were resuspended in solutions No. 7 and 8.

The post-transfusion survival of these cells was quite good (Table III), but, as in the case of the albumin solution, corn syrup, and maltose-dextrose solutions, it was not so good as the survival of cells stored in simpler and less expensive preservatives.

The excellence and simplicity of the ACD solutions (solutions No. 5 and 6) as whole blood preservatives and the fact that plasma was not essential to the preservation of erythrocytes (solutions No. 7, 8 and 12) suggested that red blood cells might survive if they were separated from blood drawn into ACD and stored without resuspension (solution No. 14). The survival of cells preserved in this fashion was excellent (Figure 5). A smaller volume ACD (solution No. 15) proved just as effective as solution No. 14 (Figure 6).

TABLE III

The survival of erythrocytes separated from plasma

Resuspending solution or technique	Per cent r.b.c. surviving in the recipient's circulation 24° after transfusion of blood stored		
	7 days	14 days	21 days
7. Human albumin	90	80	72
8. Corn syrup	74	64	51
9. Maltose No. M1	43	25	
10. Maltose No. M2	0		
11. Maltose No. M3		20	
12. Maltose No. M4	81	72	
13. RPA solution	90	80	63
14. ACD (2 per cent solution) packed cells not resuspended	94	80	70
15. ACD (5 per cent solution) packed cells not resuspended	92	78	70
16. AC (5 per cent solution) + dextrose added to packed cells after 24°	97	90	75

In the recovery of plasma it may be desirable in some instances not to add dextrose directly to the preservative solution until the plasma has been removed. To investigate the possibility of preserving the erythrocytes of such blood we carried out the procedure outlined in solution No. 16. Blood was drawn into 5 per cent disodium citrate solution, the plasma was removed the next day, and dextrose solution was added to the cell mass. As summarized in Table III, the survival of these erythrocytes was as good, if not slightly better than the survival of cells drawn directly into ACD.

Influence of storage temperature on post-transfusion erythrocyte survival

Although Rous and Turner (3) in their original observations clearly demonstrated the importance

of refrigeration in the preservation of stored blood, a recent publication questioned its necessity and claimed that certain preservatives were capable of maintaining erythrocyte viability at room temperature (46). Large amounts of unrefrigerated whole blood were being sent to the European Theatre of Operations in 1944, and since poor preservation of this blood might render it potentially dangerous to recipients the question of refrigeration was reinvestigated.

In the first series of observations, donor blood was drawn directly into Alsever's solution (solution No. 4) at room temperature (25° C.) and allowed to remain at room temperature until transfused. As illustrated in Figure 7 the post-transfusion survival of these erythrocytes was extremely poor. After 2 days' storage only 65 per cent of erythrocytes survived 24 hours in the recipient's circulation, and after 4 days, only 25 per cent of the cells survived 24 hours.

When blood was taken into chilled ACD, stored at 4° C. for 3.5 days, and then at room temperature (25° C.) until transfusion, erythrocyte survival was extremely poor, and after 9 days' storage, none of the labeled cells survived (Figure 7).

The adverse effect of warm temperature was not overcome by returning the blood to refrigeration after it had been exposed for relatively brief periods of time to room temperature. Blood drawn into chilled Alsever's solution, refrigerated at 4° C. for 2 days, exposed to room temperature (25° C.) for 24 hours, and then returned to 4° C., showed considerable decrease in post-transfusion survival (Figure 7).

These studies emphasize the necessity for constant refrigeration of whole blood and of erythrocytes during storage and reconfirm the original observations of Rous and Turner.

Practical application of acid citrate-dextrose solutions

The acid citrate-dextrose solution of Loutit and Mollison (solution No. 5) and the small volume ACD (solution No. 15) were given extensive practical trials in the blood bank of the Massachusetts Memorial Hospitals. From September, 1944 until January, 1946 the ACD of Loutit and Mollison (solution No. 5) was used for all routine bleedings in the blood bank. During this period 2,576 bloods were taken into this solution, 1,926 transfusions were given, and 217 pints of pooled, frozen plasma were prepared.

The maximum period of storage of this blood was 21 days although most bloods were transfused within the first 10 days after they were drawn. The therapeutic responses to these transfusions

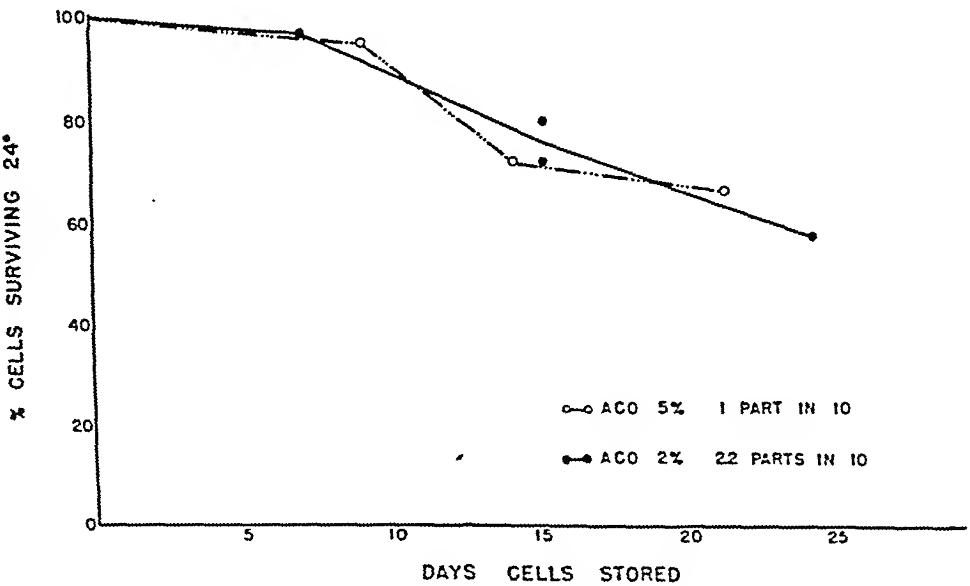

Fig. 6. The Effect of Variation in the Volume of Preservative on the Post-transfusion Survival of Erythrocytes Separated from Plasma

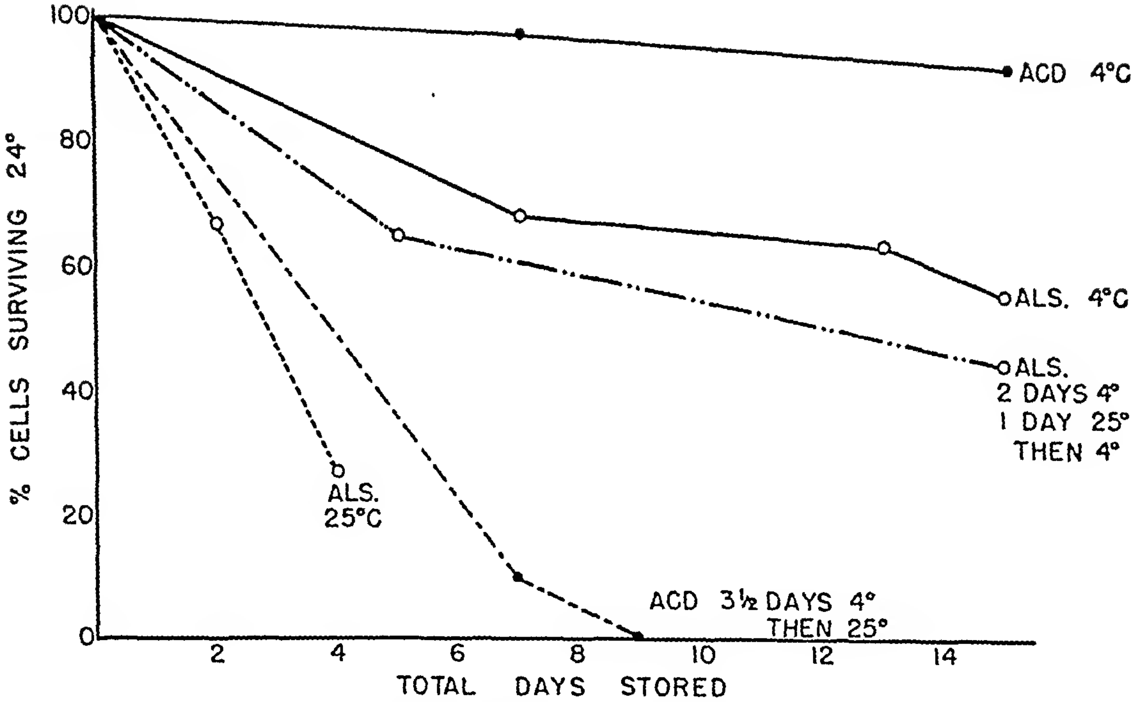

FIG. 7. THE EFFECT OF VARIATION IN STORAGE TEMPERATURE ON THE POST-TRANSFUSION SURVIVAL OF ERYTHROCYTES OF WHOLE BLOOD

were completely satisfactory, and the incidence of reactions was not higher than that usually prevailing in this blood bank.

The concentration of the citrate ion in the supernatant plasma of the ACD blood mixture is approximately 24 millimolars—a value approximately double the concentration needed to prevent coagulation (47). In spite of this fact, however, there is a tendency to clot formation in blood drawn into this solution unless the blood and anticoagulant are thoroughly mixed during the process of venesection. If this precaution is observed, the incidence of clot formation is no higher than with other preservative fluids, and in our experience has presented no serious difficulty.

From January, 1946 to February, 1947 the 50 ml. of 5 per cent ACD solution (solution No. 15) was used for routine bleedings; 2,522 bloods were drawn into this solution, 2,002 transfusions were dispensed, and 181 pints of frozen plasma were prepared. This preservative was in every respect as satisfactory as the larger volume ACD preservative.

Packed red blood cells separated from their plasma were routinely prepared from bloods drawn into each solution as described for solutions No. 14 and 15. They have proven eminently satisfactory therapeutically, and their use in transfusions for the correction of anemia is steadily increasing.

COMMENT

Loss of viability of stored erythrocytes proceeds at a very constant rate in blood stored in any given preservative, suggesting that the degenerative process may be one of aging and similar to the process normally going on in the body. The steadiness of the rate of senescence is well illustrated in Figures 4, 5, and 7 in which it appears that the decrease in viable erythrocytes is a straight line function of time. It is possible to calculate the approximate rate of senescence per day for blood stored in different preservatives and such rates are tabulated in Table IV. The rate is high in poor preservatives and at room temperature, and low in good preservatives and in the cold. In all preservatives studied it is higher than the 0.83 to 1.0 per cent per day rate of degeneration of erythrocytes in the body.

Following injection into a recipient, most of the non-viable erythrocytes are removed from the circulation very rapidly—usually within an hour or two. A smaller number are removed at a less rapid rate during the next 10 to 20 hours (Figures 1 and 2). The cells which are removed rapidly

TABLE IV

Maximum allowable duration of storage of blood and separated erythrocytes in various preservatives

Preservative: Solution no.	Preservative: Name	Maximum duration storage permitting 70 per cent post-transfusion survival	Approximate rate of degeneration of r.b.c. *in vitro*
		days	*per cent per day*
	Whole blood

8	Corn syrup	10	3.0

probably are dead prior to injection; those removed at the slower rate probably have been damaged during storage and become non-viable after injection.

The longer a blood has been stored and the more non-viable erythrocytes there are—the more rapid is the rate at which the non-viable cells are removed. This may be accounted for by progressive changes in the stored erythrocytes after they have become non-viable—a "postmortem degeneration," so to speak. If these changes are extensive enough they may result in actual disintegration of the erythrocytes and be reflected by gross hemolysis in the stored blood. As described in a subsequent paper, however, extensive degenerative changes may occur in erythrocytes stored in some preservatives, without gross hemolysis or other evidence of cell disintegration.

Our studies have been directed primarily at a critical evaluation of the effectiveness of certain selected preservatives, rather than at a general survey of the properties of preservative fluids. However, there are certain important features of blood preservatives which have become apparent in our studies, and these will be commented on briefly. The presence of dextrose in a preservative solution is essential for maintenance of erythrocyte viability. Its actual concentration does not appear to be critical within the range of 0.5 to 2.0 per cent. The initial reaction of the preservative-blood mixture is important and should be between pH 6.8 and 7.0. Certain autolytic or destructive processes probably are retarded at this pH. The degree of dilution of the blood with preservative fluid is not of great importance. The survival of erythrocytes stored in a cell mass with a hematocrit of 88 per cent is little different from the survival of cells stored in a whole blood-preservative mixture with a hematocrit of 30 per cent. The presence of plasma in the preserving medium is not essential for good erythrocyte preservation, and there is some evidence that its removal may improve preservation. The importance of constant refrigeration has already been emphasized. The addition of vitamins, amino acids, and other accessory substances is not essential and does not improve erythrocyte preservation.

In adopting the arbitrary value of 70 per cent post-transfusion survival as a minimum requirement for satisfactory transfusion properties, we do not wish to imply that blood providing cells of this viability is as satisfactory as blood in which a greater percentage or all of the cells are viable. Although blood stored for 3 weeks and providing erythrocytes of 70 per cent viability may be "satisfactory" for transfusion under emergency circumstances, it is not so good as fresh blood or blood stored for a shorter period of time. During the war when large quantities of blood had to be shipped literally to the ends of the earth it was occasionally necessary to use blood stored for 3 weeks, and such blood saved the lives of thousands of American troops. In civilian practice and in most hospital blood banks there is no necessity for using blood stored this long.

From a practical standpoint, however, transfusion of blood stored in ACD, or one of the modifications of ACD, for 7 to 10 days may be considered as satisfactory as fresh blood for the relief of anemia.

SUMMARY

(*1*) The effectiveness of 16 solutions and of various techniques in the preservation of whole

blood, and of erythrocytes separated from plasma have been evaluated with the radioactively tagged erythrocyte technique.

(*2*) The most effective preservative and the simplest to prepare was an acid citrate-dextrose solution.

(*3*) Whole blood drawn into this solution maintained satisfactory transfusion properties during a storage period of 21 days.

(*4*) Erythrocytes separated from blood drawn into this acid citrate-dextrose solution and stored without addition of diluent also maintained satisfactory transfusion properties during a storage period of 21 days.

(*5*) This acid citrate-dextrose solution proved to be very satisfactory in routine hospital blood bank use.

(*6*) Studies of the influence of temperature on the viability of stored erythrocytes emphasized the necessity for constant refrigeration of blood during the entire period of storage.

ACKNOWLEDGMENT

We wish to acknowledge gratefully the willing cooperation of the medical students of the Boston University School of Medicine and the Professional Staff of the Massachusetts Memorial Hospitals who served as subjects for the majority of these studies.

THE MEASUREMENT OF POST-TRANSFUSION SURVIVAL OF PRESERVED STORED HUMAN ERYTHROCYTES BY MEANS OF TWO ISOTOPES OF RADIO-ACTIVE IRON [1]

By JOHN G. GIBSON, 2ND, JOSEPH C. AUB, ROBLEY D. EVANS, WENDELL C. PEACOCK, JOHN W. IRVINE, JR., AND THEODORE SACK

(From the Radioactivity Center, Massachusetts Institute of Technology, Cambridge, Massachusetts; the Medical Clinics of the Peter Bent Brigham and Massachusetts General Hospitals; and the Department of Medicine, Harvard Medical School, Boston, Massachusetts)

(Received for publication August 31, 1946)

The evaluation of the efficacy of whole blood transfusion in augmenting total red cell volume has always been of interest to physicians called upon to care for patients with hemorrhage, burns, blood dyscrasias, or traumatic shock. The establishment of blood banks, resulting in an increasing use of stored blood, has focused more attention on the problem. Military requirements have created a demand for the preservation of whole blood over far longer periods than are required for civilian purposes. The urgent need for better preservative solutions and for the selection of the best conditions for overseas air transport of whole blood for the Armed Forces made it imperative that an accurate method of measuring the post-transfusion survival of stored human erythrocytes be available.

The morphological and chemical changes that take place in red cells during storage have been studied by several laboratory methods. The rate of spontaneous hemolysis, changes in cell dimension, changes in the permeability of the cell membrane, changes in osmotic resistance to hypotonic solutions of NaCl, rate of diffusion of potassium, and disturbances in carbohydrate metabolism have all been proposed as *in vitro* tests for the evaluation of the ability of stored red cells to survive after transfusion.

Each of these tests assays only changes in one functional characteristic of the erythrocyte and it is for this reason that the opinion has been expressed that *in vitro* tests fail as a guide to the viability of stored blood (1). When several of these techniques have been applied in conjunction, they have served a useful purpose in screening suggested preservative solutions for further evaluation. But, until the changes demonstrated by *in vitro* studies are proved to reflect truly the degree of red cell deterioration, the final evaluation of any preservative must be based on the results of *in vivo* post-transfusion survival studies.

The simplest *in vivo* method is the measurement of the recipient's red cell count, hemoglobin, or hematocrit before and after transfusion. In uncomplicated anemia or blood loss this procedure does give some idea of the improvement in red cell volume, but in hemolytic anemias or in the presence of continuing hemorrhage the interpretation of data is difficult or impossible. It has been our experience that the hematocrit and hemoglobin level of venous blood, as well as the red cell count from finger blood, vary greatly in random samples from a given individual, depending upon the degree of venous stasis incident to venipuncture, temperature of extremities, and the general circulatory state of the subject. This variation may be as great as the net increase in hematocrit, hemoglobin, or red count expected to result from a single 500-ml. transfusion.

The increase in circulating red cell volume resulting from one or more transfusions may be measured by the dye-plasma volume hematocrit technic with a fair degree of accuracy. A transfusion of 500 ml. of whole blood contains about 200 ml. of erythrocytes. This quantity is about 10 per cent of the normal human circulating red cell volume (2). In hemorrhage or blood loss the percentage of transfused to recipient circulating red cells varies directly with the degree of cell volume

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts Institute of Technology, in collaboration with the Peter Bent Brigham Hospital, and the Massachusetts General Hospital.

deficit. A single transfusion will rarely represent more than 30 per cent of the pre-transfusion erythrocyte volume.

Plasma volume can be measured by the dye method within ± 5 per cent. An additional error is introduced by unavoidable variations in the hematocrit determination on venous blood samples, upon which the red cell volume is calculated. Circulating red cell volume measured by the dye-plasma volume hematocrit technic is greater than the true volume (3, 4, 5), because the hematocrit of capillary blood is less than that of blood in large vessels (6, 7). This error may be minimized by correcting the calculated cell volume by the factor 0.85. Hence, the intrinsic error of the technic, which is about ± 5 per cent, may be the equivalent of a large fraction of the cells transfused. It is desirable to follow the fate of stored cells at frequent intervals after transfusion, but the dye method gives only data for a single period, and repeated blood volume determinations at short intervals are not always practicable.

The occurrence of hemoglobinuria or hemoglobinemia following a compatible transfusion is, of course, evidence of massive destruction of donor or recipient cells. Hemolysis produces a rise in recipient serum bilirubin levels. Strumia has shown a progressive hyperbilirubinemia with increasing age of stored blood (8). Gilligan and Altschule (9) found large variations in the net rise in plasma hemoglobin levels following the intravenous administration of hemoglobin solutions, indicating wide individual differences in the ability to handle pigments derived from blood. Bilirubin data are misleading in patients with liver disease or hemolytic tendencies. The measurement does not permit quantitative evaluation of cell destruction.

The agglutination method of following the fate of transfused cells was introduced by Ashby in 1919 (10, 11). Whole blood from a group O donor is given to a group A recipient. The transfused O cells are, of course, of all different ages and represent mixed-age cells. Samples of recipient blood are taken and the A cells agglutinated with anti-A typing serum and thrown down by centrifugation. The unagglutinated O cells remaining in suspension are then counted with standard blood counting pipettes and chambers. The count in a sample drawn at the completion of the transfusion or shortly thereafter is usually taken as the quantity of O cells in circulation resulting from complete retention of all the transfused cells. Counts upon subsequent samples are referred to this "100 per cent value" for calculation of the percentage of surviving O cells. The method has been widely used in the study of red cell preservation by Mollison (12), Maizels (13), Denstedt (14), and more recently by Thalhimer (15).

Scrutiny of the results obtained by these workers shows that the non-agglutinable counts on samples taken only a few days apart may vary by as much as 20 per cent (14, 15), even when the greatest possible care is taken. This suggests a large intrinsic probable error in the method.

All workers report that a certain proportion of the recipient A cells are not agglutinated by anti-A sera, even though of very high titre. In practice this non-agglutinable cell count is determined prior to transfusion and subtracted from subsequent counts. The assumption is that this non-agglutinable portion of recipient cells remains a constant throughout the observation period, which in some instances has been as long as 130 days. Such an assumption may or may not be valid.

It is assumed that a complete separation of the unagglutinated O from the agglutinated A cells is effected by the addition of serum and subsequent shaking and centrifugation. It is, however, possible that numbers of the O cells may become enmeshed in the large A agglutinates and carried down therewith in centrifuging.

It has been suggested (14) that in instances in which there is an abrupt rise in cell count from the previously prevailing slope of cell disappearance, some of the transfused cells may have been temporarily withdrawn from circulation (in the spleen or liver), and later have re-entered the circulation. This hardly seems likely, since it is improbable that there are any great "depots" of red cells in the body but rather that in the normal state practically all the erythrocytes are in active circulation at all times (7).

The agglutination technic permits one to follow the presence of transfused O cells throughout their entire life span in the recipient, information that cannot be obtained by the radioactive technic.

A method of measuring post-transfusion survival of human erythrocytes by means of radioactive isotopes of iron was first described by Ross and Chapin in 1943 (16). The modifications de-

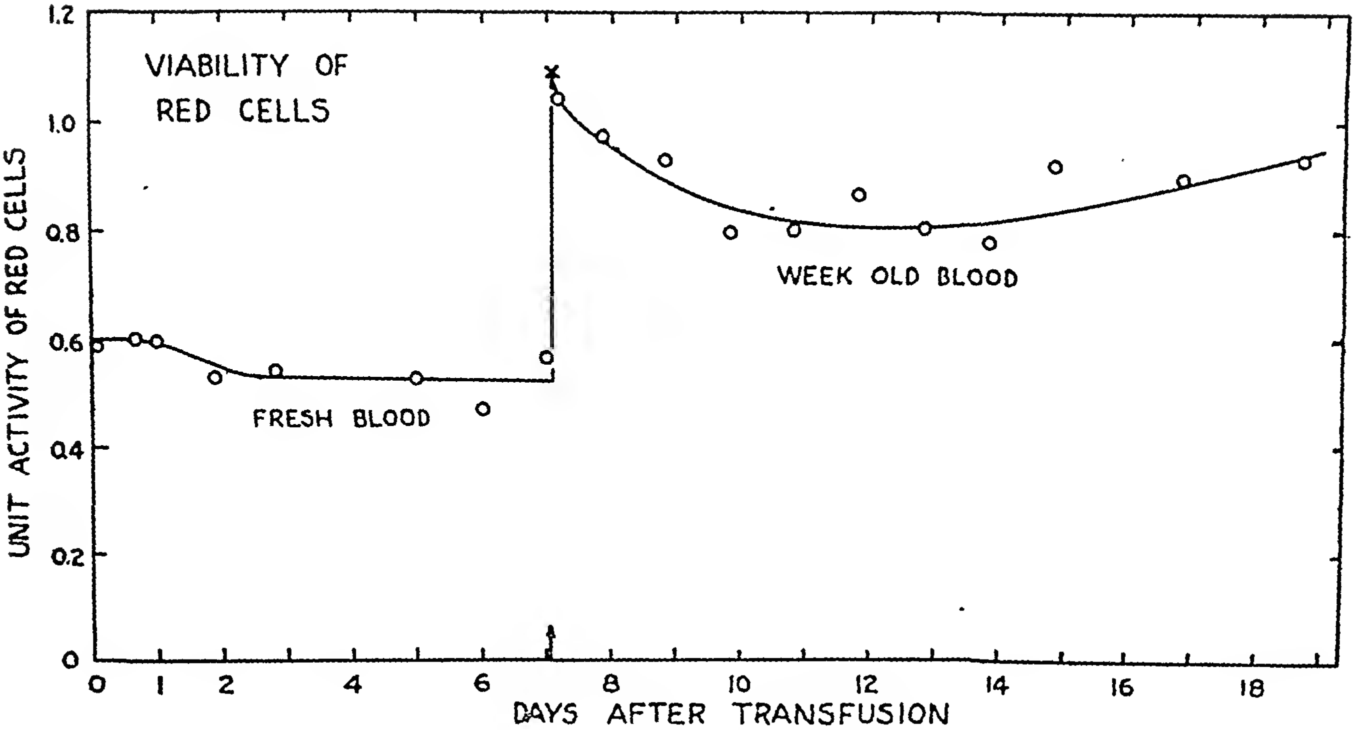

FIG. 1. VIABILITY OF HUMAN ERYTHROCYTES STORED AS WHOLE BLOOD IN 4 PER CENT SODIUM CITRATE

Five hundred ml. of whole blood from a radioactive donor was taken in 4 per cent sodium citrate and divided into 2 equal parts. One aliquot was transfused on the day drawn, and the other given to the same recipient after refrigerated storage for 7 days. The Ua of the recipient's red cells following the first transfusion indicates good retention of the tagged cells for 1 day and a slight loss on the second day. After the second transfusion the recipient Ua rose, but not to twice the level resulting from the first transfusion. Since both aliquots contained the same amount of radioactivity, some of the tagged cells from the second transfusion disappeared from the circulation during the administration of the blood. Only about ½ of the 7-day old cells were viable as shown by the fall in recipient Ua through the twelfth day. The subsequent rise in Ua is due to re-utilization of iron from non-viable cells in hemoglobin synthesis.

scribed herein were developed from our studies in measuring circulating red cell volume in shock. The physical principles involved, the characteristics of the iron isotopes used, the apparatus for radioactivity detection, as well as the experimental techniques of using tagged human erythrocytes for cell volume determination have been described previously (17, 18). For the purposes of this study a brief resumé will suffice.

When small amounts of radioactive ferric ammonium citrate (0.5 to 1.5 mgm.) are given intravenously, the salt is rapidly removed from plasma and deposited in body iron stores (18). In the process of erythrocyte formation in the marrow, some of the iron atoms that become incorporated in the hemoglobin molecule of developing cells are radioactive. Since hemoglobin does not escape from the healthy erythrocyte, it follows that as long as the tagged red cells remain intact, their presence may be detected in the blood stream. If these cells are destroyed, the released radioactive iron returns from the plasma to the iron stores, and eventually is re-utilized and resynthetized into hemoglobin, again appearing in new red cells in the blood stream. Thus the immediate retention (24 to 48 hours) of stored tagged cells can be determined, and the eventual utilization of the iron from those cells that did not survive can subsequently be measured.

Data obtained in the first experiment of this type which we carried out are shown in Figure 1. Following a transfusion of fresh radioactive whole blood (drawn in 4 per cent sodium citrate), the recipient's cell Unit Activity (Ua) [2] remained constant for 24 hours, followed by a slight fall from

[2] Defined as counts per minute (cpm) per ml. of red cells referred to cpm of a radioactive iron standard measured at the same time, and therefore independent of the rate of radioactive decay of the active isotope and counter variability.

the initial level, indicating that about 90 per cent of the transfused cells were retained. On the eighth day a transfusion of week-old cells from the same blood donor, and equal in amount to the first, was given. There was a rise Ua to almost, but not quite, twice that resulting from the first infusion. During the next 5 days Ua progressively dropped, leveling off at a value corresponding to a retention of about 50 per cent of the cells given in the second transfusion. Thereafter Ua rose to about 75 per cent of the original level. Since the only source of radioactive iron in the subject was the transfused red cells, it follows that about ½ of the iron released from destroyed cells was re-utilized by the end of the observation period.

This experiment brings out a fact of importance. The level to which Ua rose immediately following the second transfusion was less than twice the level following the first transfusion even though both contained an equal amount of radioactivity. It is, therefore, evident that the initial post-transfusion activity level following the second transfusion did not correspond to 100 per cent retention, but that some of the tagged cells were withdrawn from circulation *while the blood was being administered.* Thus it is essential to supplement this simple procedure with an independent method of determining the radioactivity level corresponding to 100 per cent retention of the transfused tagged red cells.

It is therefore necessary to determine the recipient's circulating cell volume at the time the transfusion is given. In some of our experiments this was determined by the dye-plasma volume hematocrit technic. The calculated cell volume was corrected by the factor 0.85 which we have found to be the average ratio of the values for the true cell volume measured by radio-iron and the cell volume calculated from the dye-plasma-hematocrit (5). Post-transfusion survivals calculated upon these values probably are accurate to within ± 5 per cent.

In many experiments, the recipient's pre-transfusion red cell volume was more accurately measured by a small infusion of fresh group O cells tagged with Fe^{59}. The preserved transfused cells were tagged with Fe^{55}. Both isotopes can be measured in the same blood sample (17).

The transfused quantity of preserved stored cells tagged with Fe^{55} and the radioactivity of those cells is measured. Knowing the recipient's red cell volume the radioactivity level corresponding to 100 per cent retention of the transfused cells is calculated by the equation

$$Ua_T = \frac{C \times UaD}{Vrr_1 + Vrr_2}$$

where

Ua_T is the 100 per cent value of the unit activity Ua.

C is the quantity of cells transfused in ml.

UaD is the unit activity of those cells, and

Vrr_1 is the recipient's pre-transfusion red cell volume in ml. as measured by Fe^{59}.

Vrr_2 is the quantity of stored cells transfused.

The percentage of radioactive cells in the recipient's circulation at any time in terms of the quantity transfused therefore is

$$\frac{UaR \times 100}{UaT},$$

where UaR is the recipient's red cell radioactivity level.

A typical experiment in which recipient cell volume was measured by radio-iron is shown in Figure 2. The subject was a normal 22-year-old male, blood group A, who had been bled 1 day prior to transfusion. On the morning of the experiment plasma volume was determined by the dye method. At the same time, radio-iron red cell volume was determined, the subject receiving 44.8 ml. of cells drawn as whole citrated blood from a group O donor who had been built up with Fe^{59}. Three venous blood samples were drawn at 10-minute intervals after the injection of dye and tagged cells for measurement of plasma dye concentration and red cell radioactivity. Four hours later the subject received 160 ml. of cells tagged with Fe^{55}, drawn as whole blood in Alsever's solution and stored 19 days.

Venous blood samples were then drawn at 20 minutes and approximately 1, 4, and 8 hours after the end of the transfusion of stored blood. Two blood samples were taken on both the first and second day, and 1 sample on the third, fourth, and fifth day after transfusion, and a final sample was taken on the twenty-eighth day. All of these samples were analyzed for both Fe^{59} and Fe^{55}. Data obtained are given in Protocol GR–78 and are plotted in Figure 2.

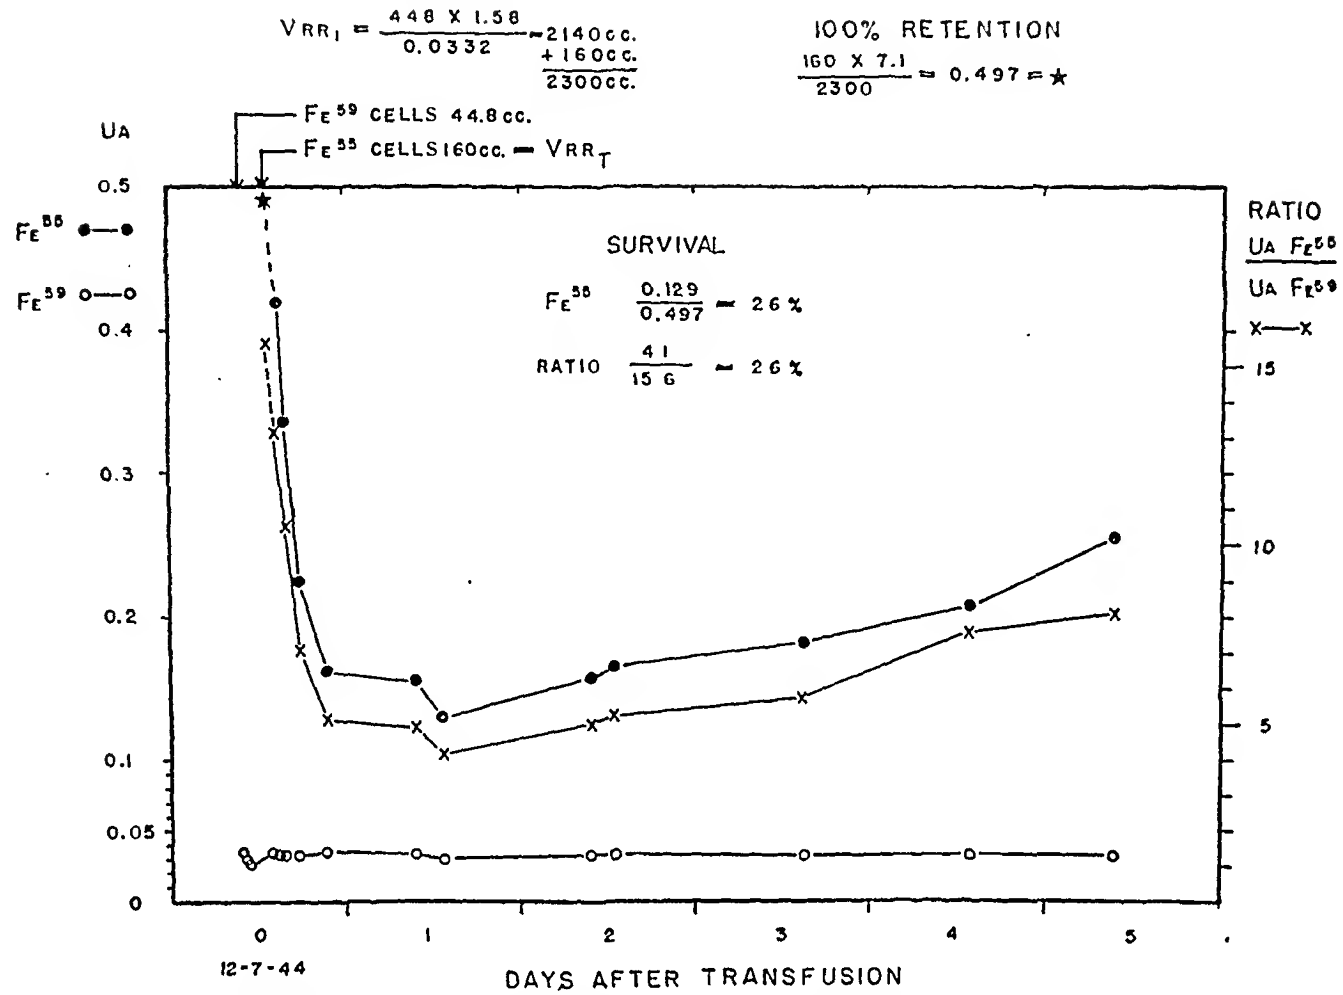

Fig. 2. Method of Measuring Post-transfusion Survival of Stored Human Erythrocytes by means of 2 Isotopes of Radioactive Iron

The recipient's pre-transfusion circulating red cell volume was determined by giving 44.8 ml. of freshly drawn group O cells tagged with Fe^{59} and found to be 2,140 ml. Then 160 ml. of group O cells tagged with Fe^{55} and stored 19 days were given. The resultant expected red cell volume was 2,300 ml. The theoretical recipient red cell Ua corresponding to 100 per cent retention of the Fe^{55} cells was 0.497. The lowest recipient Fe^{55} Ua value was 0.129, and survival was computed at 26 per cent.

Recipient's pre-transfusion red cell volume computed from the quantity of Fe^{59} cells given, the Ua thereof, and the average Fe^{59} Ua value of the first 4 recipient's blood samples, is

$$\frac{44.8 \times \text{Ua Fe}^{59}\ (1.58)}{0.0332} = 2{,}140 \text{ ml.}$$

This agrees well with the calculated corrected dye-plasma-hematocrit red cell volume of 2,110 ml.

The total quantity of recipient circulating red cells is equal to the red cell volume plus the amount of cells transfused, or 2,140 ml. + 160 ml. =2,300 ml.

The recipient's 100 per cent retention value Fe^{55} Ua then becomes

$$\frac{160 \times \text{Ua Fe}^{55}\ (7.1)}{2{,}300} = 0.497.$$

This value, 0.497, is higher than that of the first post-transfusion sample, 0.418, indicating a loss of about 16 per cent of the transfused cells in the 50-minute interval between starting the transfusion and drawing the first sample.

The lowest recipient Fe^{55} red cell Ua [3] during the first post-transfusion day is used for calculating percentage survival, which is

$$\frac{0.129}{0.497} = 26 \text{ per cent.}$$

It will be noted that the Fe^{59} Ua values of the

[3] No correction for blood loss in sampling was made since the total whole blood drawn, after the transfusion of stored cells, was about 150 ml. or about 3 per cent of the recipient's total blood volume, an average of less than 1 per cent per day.

Protocol Exp. No. GR-78 December 7, 1944

POST-TRANSFUSION SURVIVAL OF WHOLE BLOOD IN ALSEVER'S SOLUTION TRANSFUSED 19 DAYS AFTER DRAWING

** Ua Fe^{59} is average of values for samples e–o, incl., omitting sample j.

recipient red cells remained constant, within the limit of error of the technic, throughout the first 5 days of the experiment, indicating virtually complete retention of these group O tagged cells. The slight fall in Ua samples d and e is to be explained by the additional dilution of the Fe^{59} tagged cells by the transfused Fe^{55} cells.

The ratio of Ua Fe^{55} to Ua Fe^{59} falls progressively during the first 24-hour post-transfusion period and thereafter rises. Since this ratio is an expression of the proportion of Fe^{55} to Fe^{59} tagged cells in the circulation and since virtually all of the Fe^{59} tagged cells were retained, this ratio can also be used for computing percentage of survival.

$$\text{Thus,} \quad \frac{4.1}{15.6} = 26.2 \text{ per cent.}$$

The rise of the ratio after the first post-transfusion day is due to the presence of radio-iron derived from non-viable transfused cells tagged with Fe^{55}.

Figure 3 shows the course of the radioactive red cell level of a subject receiving "tagged" whole blood in McGill II solution, stored under refrigeration for 29 days prior to transfusion. Unit activity data are expressed in terms of percentage of total cells transfuesd Ua/Ua_T. A large proportion of the cells had deteriorated during storage and their removal from the blood stream was reflected by a sharp decline in recipient red cell radioactivity in the first few hours after transfusion, falling to about $\frac{1}{5}$ of the calculated 100 per cent retention value. During the following day this level was unchanged, but thereafter successive samples showed a rise in radioactivity, at first rapid, but leveling off at about 70 per cent of the 100 per cent value.

The question arises as to whether or not those cells which were not rapidly removed from circulation were normally functioning cells with normal life expectancy and remained in circulation throughout the observation period. Denstedt (14) and more recently Thalhimer (15) have shown that when the post-transfusion course of stored cells is followed by the agglutination technic there may be an initial abrupt fall in the recipient's group O cell count, followed by a decreased rate of disappearance, the slope of which closely ap-

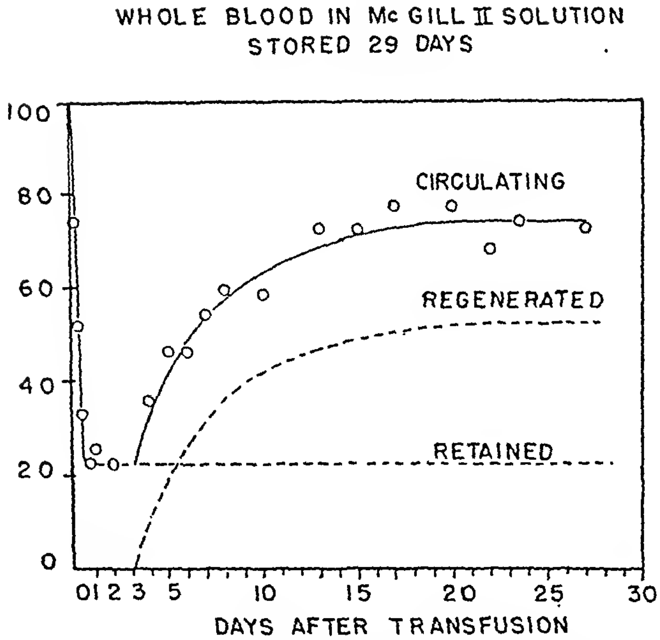

FIG. 3. RE-UTILIZATION OF RADIO-IRON DERIVED FROM NON-VIABLE TRANSFUSED STORED CELLS IN SYNTHESIS OF HEMOGLOBIN

About 80 per cent of the tagged stored cells were rapidly withdrawn from circulation; and the radio-iron contained in these non-viable cells may be considered as available for blood-iron need. For reasons given in the text, it is assumed that those cells not immediately destroyed retain full functional capacity and are retained. Hence, about 20 per cent of the recipient red cell radioactivity is accounted for by these viable cells, and the remainder of the radioactivity, indicated by the broken line, is due to resynthesis into hemoglobin of radio-iron; so about 5/8 of the radio-iron available was re-utilized. From the third post-transfusion day on, the percentage of circulating tagged cells rose, leveling off about the twentieth day at about 75 per cent of the original value.

proximates that obtained for transfused fresh group O cells, somewhere in the neighborhood of 1 per cent per day. This conclusion was confirmed by 2 experiments in which the fate of group O cells tagged with radioactive iron (Fe^{55}) transfused into group A recipients was followed by both the agglutination and radio-iron techniques.

Two such experiments, in which equal aliquots of blood drawn from the same donor into De Gowin's solution were transfused into individual recipients, one on the day of collecting, and the other after storage for 24 days, are illustrated in Figure 4.[4]

Following the transfusion of fresh blood, a prompt initial loss of about 10 per cent of the cells was demonstrated by both methods. Thereafter the number of radioactive cells in circulation increased, reaching the 100 per cent value on the thirtieth post-transfusion day, whereas the count of non-agglutinable cells progressively fell until, the sixtieth day, somewhat less than 40 per cent were detectable in the blood stream. A much greater initial loss occurred in the subject receiving the 24-day-old blood. The immediate (24 to 48 hour) survival was about 40 per cent by the radio-iron and about 70 per cent by the agglutination technic. This discrepancy is probably to be accounted for by a considerable destruction of cells during the interval between the beginning of the transfusion and the taking of the first blood sample for non-agglutinable count. Radioactivity data revealed that 60 per cent of cells had disappeared from the circulation in the first 6 hours after transfusion started. Since the initial post-transfusion count was used as the denominator in calculating percentage of transfused cells remaining in circulation, the computed immediate survival was falsely high.

After the initial loss, a continuous rise in the recipient's red cell radioactivity occurred, reaching a level of about 90 per cent of the 100 per cent value on the fortieth post-transfusion day. During this period the percentage of non-agglutinable cells fell at a rather constant rate.

In the case of both the fresh and the deteriorated blood, however, after the initial drop, the non-agglutinable cells disappeared at a rate of about one per cent per day, or at a mortality rate equal to that of normal cells.

The increase in radioactivity of recipient's cells after the initial decline is due to the presence of tagged cells newly developed since the transfusion. About 80 per cent of the transfused cells were destroyed and their contained iron may be considered as available for re-utilization. The curve of regeneration flattens out at about 50 per cent of the quantity of radioactive cells destroyed during the first day, and hence it is concluded that 5/8 of the total radio-iron from destroyed cells was eventually re-utilized and the remainder either excreted or stored.

The assumption that the retained cells accounted for an almost constant portion of the total recipient cell radioactivity appears to be warranted in this particular experiment, because only young red

[4] These experiments were carried out in collaboration with Dr. Orville Denstedt, McGill University.

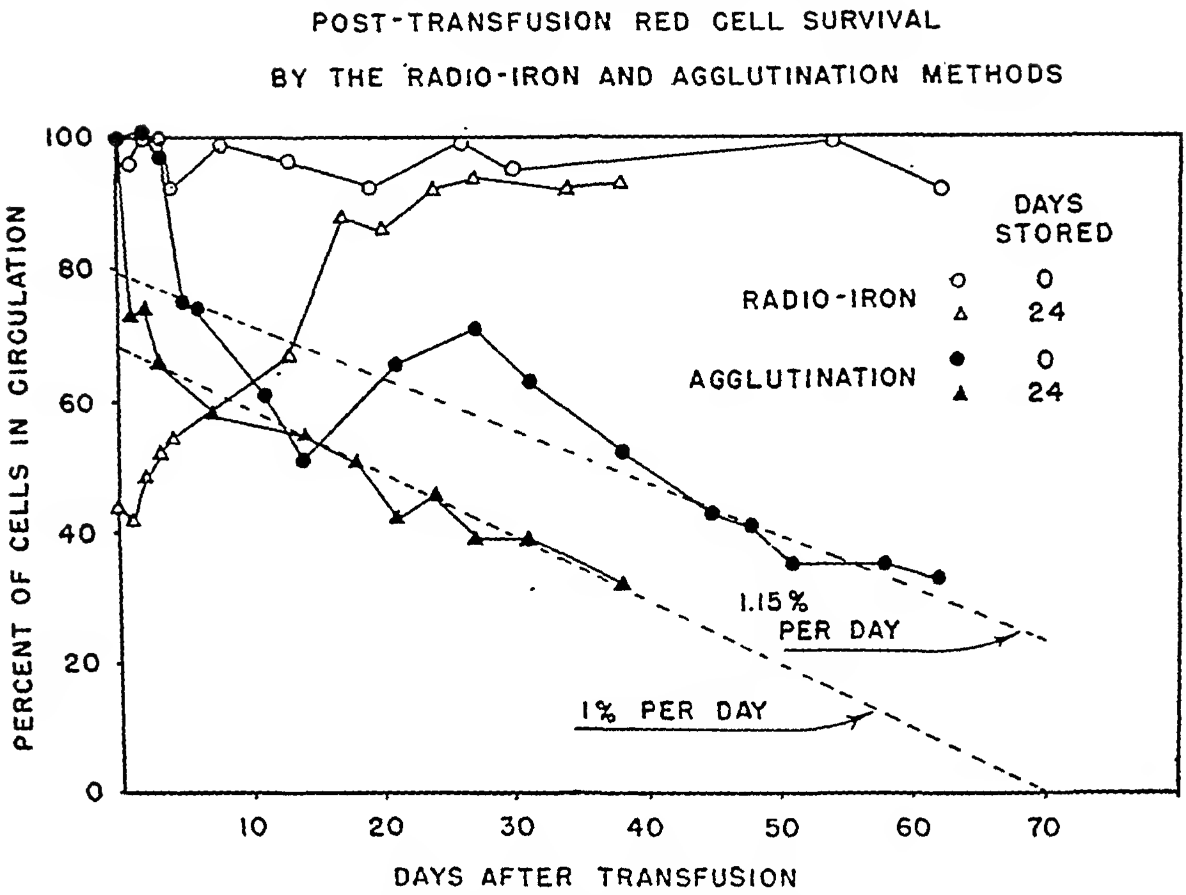

FIG. 4. THE POST-TRANSFUSION SURVIVAL OF GROUP O BLOOD TRANSFUSED FRESH AND AFTER 24 DAYS OF STORAGE INTO AN A RECIPIENT, MEASURED BY BOTH THE RADIO-IRON AND AGGLUTINATION TECHNIQUES

Radioactivity levels clearly show the initial loss of cells and subsequent re-utilization of hemoglobin-derived iron. Non-agglutinable cell counts show an initial loss of non-viable group O cells, and thereafter a continued loss, the rate of which closely approximates the normal red cell mortality rate.

cells had been tagged. The donor blood was drawn 28 days after the donor received his initial injection of radio-iron, and since the blood was stored 29 days, the oldest radio-iron tagged cells were approximately 57 days old when transfused. The normal life span of the adult human erythrocyte is considered to be at least 100 days (19, 20). Hence, the residual cells would remain in circulation during the remaining 27 days of the experiment.

It is important to ascertain whether the behavior of all donor cells, ranging in age from newborn to senescent, was similar during storage. The work of Denstedt (21) and Thalhimer (15), in whose studies the survival of cells representing the entire age population of donor erythrocytes was measured, indicates that the percentage of non-viable cells is roughly proportional to the number of days elapsing between drawing and transfusion. It was therefore necessary to distinguish, radioactively, between young cells and cells that were known to be of mixed age. The known fact of re-utilization of hemoglobin-derived iron was used to advantage to tag differentially young and mixed-age cells.

For example, one donor received the first injection of 5-year iron at 133 days and the last injection 95 days prior to bleeding. He had also received 47-day iron, the first injection 28 days and the last injection 5 days prior to bleeding. Thus, all of the donor's cells tagged with Fe^{59} were young cells, whereas the cells tagged with Fe^{55} were representative of the entire cell population.

Blood from another donor prepared in a similar manner was drawn into acid-citrate-dextrose, and equal aliquots were transfused into 3 recipients after storage for 15, 29, and 41 days, respectively.

Blood from this donor was drawn into ACD, the plasma was removed and the cells resuspended in an acid-citrate-dextrose medium. Aliquots were transfused into 4 recipients after 3, 10, 16, and 30 days' storage at 4° C.

Red cell volume for determination of the 100 per cent retention value was calculated from plasma volume and hematocrit, and percentages of survival were calculated from both the Fe^{55} and Fe^{59} recipient blood levels. In both experiments, as shown in Table I, the survival of the young (Fe^{59}) cells was consistently better than that of the mixed-age (Fe^{55}) cells. The ratio of Fe^{55} to Fe^{59} radioactivities of recipient's cells in relation to the ratio of corresponding radioactivities of the donor's cells was about 0.9, and varied little with the length of storage period.

TABLE I

The comparative survival of young and mixed-age red cells tagged with radio-iron

Days of storage	Day since donor received radio-iron				Percentage survival		Relative retention of mixed-age to young cells*
	Fe^{55}		Fe^{59}		Mixed-age (Fe^{55})	Young (Fe^{59})	
	First	Last	First	Last			
Whole blood in acid-citrate-dextrose

* The ratio of Fe^{55} to Fe^{59} radioactivities (Ua) of recipient's cells in relation to the ratio of the same isotopes in a sample of the donor cells transfused.

These experiments indicate that when blood is obtained from donors who have been freshly prepared with radioactive iron, the survival of those cells on storage is proportional to the survival of all the cells, tagged and not tagged. Therefore, a comparison of red cell survival in various preservatives, based on blood from freshly built up donors, truly reflects differences in the value of different solutions.

The use of 2 tracers also permits, under selected conditions, of measurements of changes in the recipient's own cells. In the experiment described in Figure 5, the recipient, blood group A, received 560 ml. of group O blood (220 ml. of cells) of high "anti-A" titre (1/400). Fe^{59} tagged group O cells for cell volume determination were given shortly before, and the value obtained agreed very closely with that calculated from the Fe^{55} recipient levels. During the next 7 days the recipient Fe^{55} and Fe^{59} levels both rose progressively and to about the same degree. At the same time the venous hematocrit progressively fell. It is clear that the proportion of the recipient's cells that were radioactive became greater. Since both lots of group O cells were well retained, as evidenced by the constancy of the ratio of the 2 isotopes, it follows that the rise in radioactivity was due only to destruction of the recipient's own A cells. Calculations based on the original cell volume and the changes in Fe^{55} levels showed a loss of about 700 ml. of A cells. (Calculations based on hematocrit changes showed a loss of only 500 ml.) During the remainder of the observation period the hematocrit rose, and both radioactivity levels declined to almost the original levels, but the ratio of the two isotopes again remained constant. These later changes reflect the regeneration of recipient A cells.

We have applied the method described to the study of a large number of solutions, recommended both for the preservation of erythrocytes as whole blood and as red cell resuspensions after removal of plasma. Results will be reported in subsequent communications.

The method has also been placed at the disposal of several collaborators working in the field of blood preservation. They have built up their own donors with radio-iron prepared in the M.I.T. cyclotron, and donor and recipient blood samples, forwarded by mail, have been chemically prepared and analyzed for radioactivity in our laboratories. Since the cells are destroyed in wet-ashing, the packed cells can be laked prior to shipping. Time in transit or temperature changes do not affect the accuracy of radioactivity measurements.

A standard system of mnemonic symbols for samples of donors' stored and recipients' bloods was developed to facilitate reporting of data to

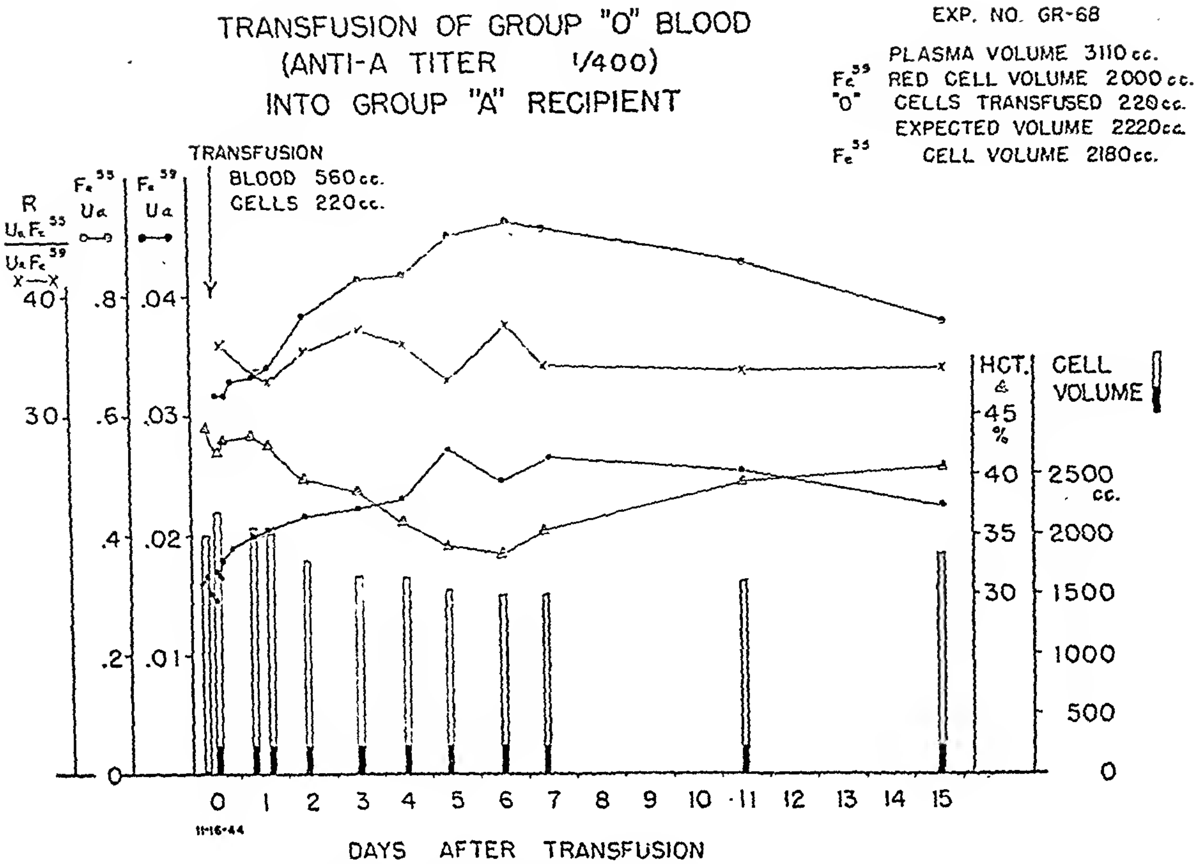

FIG. 5. TRANSFUSION OF HIGH-TITRE ANTI-A GROUP O BLOOD INTO GROUP A RECIPIENT

Recipient's pre-transfusion cell volume as determined by the injection of O cells tagged with Fe^{59} was 2,000 ml., and 220 ml. of stored O cells with Fe^{55} were given. Thereafter the radioactivity level of both isotopes in the recipient's cells rose progressively for 6 days, exceeding the initial post-transfusion values. The ratio of the 2 isotopes, however, remained constant, indicating that both the fresh and stored O cells were all retained. The rise in radioactivity of both isotopes was therefore due to the progressive loss of the recipient's A cells. The recipient's hematocrit fell from an initial value of 43 to a low of 33 in 6 days, and his red cell volume, calculated from Fe^{55} activities, diminished by 700 ml. As recovery occurred, radioactivity levels of both isotopes fell, the hematocrit rose, and red cell volume rose to nearly pre-transfusion level.

collaborators. Because all workers used a common technic, differences in method were reduced to a minimum, and results obtained have been truly comparable.

CONCLUSIONS

(*1*) A method of measuring the post-transfusion survival of preserved stored human erythrocytes by means of 2 radioactive isotopes of iron is described.

(*2*) The method is specific in that only intact circulating cells containing radioactive iron bound in the hemoglobin molecule are detected.

(*3*) The determination of the recipient's pre-transfusion circulating red cell volume by means of fresh group O cells tagged with Fe^{59} permits of accurate calculation of recipient post-transfusion red cell radioactivity level corresponding to 100 per cent retention of transfused stored cells tagged with Fe^{55}. This is important in the study of deteriorated bloods in which red cells may be withdrawn from circulation in the interval between starting the transfusion and obtaining the first post-transfusion blood sample.

(*4*) The extent to which iron derived from non-viable transfused stored cells is re-utilized in the synthesis of new hemoglobin can be measured.

(*5*) The destruction of the homologous cells of patients of group A and B by high anti-A or anti-B titre donor bloods of group O is discussed.

THE POST-TRANSFUSION SURVIVAL OF PRESERVED HUMAN ERYTHROCYTES STORED AS WHOLE BLOOD OR IN RESUSPENSION, AFTER REMOVAL OF PLASMA, BY MEANS OF TWO ISOTOPES OF RADIOACTIVE IRON [1]

By JOHN G. GIBSON, 2ND, ROBLEY D. EVANS, JOSEPH C. AUB, THEODORE SACK, and WENDELL C. PEACOCK

(From the Radioactivity Center, Massachusetts Institute of Technology, Cambridge, Massachusetts; the Medical Clinic of the Peter Bent Brigham and Massachusetts General Hospitals; and the Department of Medicine, Harvard Medical School, Boston, Massachusetts)

(Received for publication August 31, 1946)

The modern era of blood transfusions was ushered in by the discovery of human red cell groups by Shattock (1) in 1900 and Landsteiner (2) in 1901. Grouping was later systematized by Jansky (3) and Moss (4). In the course of a few years the paraffined tube method of Kimpton-Brown (5), the multiple syringe technic of Lindeman (6) and the 4-way stopcock apparatus of Unger (7) came into general use in hospitals for direct transfusions. All of these methods required speed in transferring blood from donor to recipient because of the dangers of clotting.

Agote (8) and Lewisohn (9) introduced sodium citrate as an anticoagulant. This avoided the hazards of clotting in the interval between drawing and administering blood and yet permitted the observance of aseptic precautions. The procedure was much simpler than the direct methods which required surgical teams and operating room technic.

The citrate method came into favor very slowly. Early apparatus described by Hoffman (10) and Brines (11) involved suction for collecting and positive air pressure for injecting. Reactions were common. A review of transfusion procedure by Herr as late as 1925 (12) indicated that the direct was still preferred to the citrate method.

The first successful preservation of human whole blood was accomplished in 1916 by Rous and Turner (13) by the addition of dextrose to a sodium citrate anticoagulant. This solution was used to a limited extent in World War I by Robertson (14). Since the ratio of diluent to cells was high, and the amount of citrate large, the supernatant fluid was removed and the cells given in suspension in Locke's solution. This procedure was complicated and laborious and did not come into general use.

A survey of transfusion practice in common use up to 1938 was made by Levine (15). Sodium citrate was the most widely used anticoagulant and blood was discarded after from 5 to 7 days. Little if any use was made of blood preservatives.

There is now little doubt that many reactions attributed to citrate may have been due to pyrogenic contamination of solutions or apparatus. Wechselmann (16) reported febrile reactions following intravenous therapy in 1911, and Seibert in 1923 (17) showed them to be of bacterial origin. Banks (18) demonstrated that pyrogens could be destroyed by autoclaving. Removal of pyrogens by Seitz filtration was reported by Co Tui (19), and by adsorption on charcoal by Lees (20). The control of pyrogens by simple procedures made possible the development of methods for preparing safe intravenous solutions (21) and blood transfusion apparatus (22).

Further knowledge of blood groups (23) tended to reduce reaction rates. The discovery of the significance of the Rh factor by Landsteiner and Wiener (24) explained many untoward transfusion effects.

The advent of economical mechanical refrigerators opened the way for the establishment of blood banks, the first of which, in the U. S. A., was established in 1937 by Fantus (25); others followed promptly (26, 27).

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts Institute of Technology, in collaboration with the Peter Bent Brigham Hospital and the Massachusetts General Hospital.

Interest in better blood preservation was awakened by rumors of World War II and greatly accelerated by the actual advent of hostilities in 1939.

De Gowin and his associates modified the original Rous-Turner solution and studied rates of hemolysis (28), potassium diffusion (29), fragility changes (30), and the effect of temperature (31). They made a clinical study of reactions (32) but did not study post-transfusion survival.

Since then numerous reports on survival as measured by the Ashby agglutination technic (33) have appeared in the literature. Wiener and Schaefer (34) concluded that citrated blood survived poorly after 7 days of storage. Preservation for as long as 18 days was obtained with dextrose-saline-citrate solution studied by Mollison and Young (35). These solutions were difficult to prepare since the dextrose caramelized during autoclaving. This was overcome by acidifying the solution with citric acid. In spite of the very low pH, cell preservation was improved (36).

While the beneficial effect of added dextrose was recognized, the necessary facts upon which to base a military overseas blood program were, in the main, not widely known in 1940. The rate at which cells deteriorated during storage even in the best solutions had not been satisfactorily determined. The rate at which these deteriorated cells broke down in the recipient was not known, and the degree of hemoglobinemia to be expected to follow a transfusion of blood of a given age was a matter of conjecture. The ability of the individual to handle large amounts of plasma hemoglobin was an uncertainty, although the association of hemoglobinuria and renal damage was recognized. There was little knowledge of the degree of normal functional activity retained by those cells not rapidly eliminated after transfusion, nor was it known to what extent the blood-building substance of the destroyed cells would be utilized.

The effect on preservation of mechanical agitation incident to transportation on survival of cells was unknown although De Gowin (37) had shown that spontaneous hemolysis was not increased by shipment by automobile or airplane under refrigeration. Refrigeration was considered necessary, but optimal storage temperatures had not been determined.

Changes in the chemical behavior of the cell during storage in varying concentrations of citrate, saline, and dextrose, at varying hydrogen ion concentrations and temperatures, had not been systematically studied, nor had the effect of these variables on the cell membrane been observed. Various *in vitro* tests had been applied but there was general disagreement as to whether observed *in vitro* behavior bore any relation to the extent to which these changes were reversible when the cell was returned to the blood stream.

In short, the degree to which cells would remain viable in any solution for a given time, under given conditions of transportation and refrigeration, was unknown. And finally, no one could say how bad a transfusion a normal, or more important, a seriously wounded human could withstand. Therefore, the standards of acceptable transfusion of stored blood, or the maximum safe period of storage, could not be defined.

The purpose of the study reported in this and subsequent papers was to investigate the many solutions recommended as preservatives for human erythrocytes, both as whole blood and in resuspension after aspiration of plasma, to ascertain:

(*1*) The percentage of survival of red cells, both as whole blood and in resuspension, after refrigerated storage for varying periods;

(*2*) The rate at which non-viable stored cells are removed from the blood stream and the extent of re-utilization of iron contained in those cells;

(*3*) The effect on survival of depot storage at temperatures ranging from − 4° to + 40° C.; and of transportation by land, sea, and air, with and without controlled refrigeration.

METHODS

The method used in these studies for measuring post-transfusion survival of stored cells by means of 2 radioactive isotopes of iron has been described in previous communications (38, 39, 40). Donor red cells are tagged by the intravenous administration of radioactive iron (Fe^{55}). Since the radioactive iron atoms are firmly bound in the hemoglobin molecule, the presence of donor cells in the recipient's blood stream may be detected as long as the cell remains intact and in circulation. The techniques developed afford high accuracy of measurement. The re-utilization of radio-iron from destroyed cells in new circulating red cells can also be measured. Both the percentage of survival and the rate at which deteriorated cells leave the blood stream in the immediate post-transfusion period can be accurately measured, and hence the method offers a basis for the comparison of preservative solutions.

Recipient pre-transfusion red cell volume was directly measured by transfusion of fresh red cells tagged with Fe^{59} (39), or by the dye method (41). The radioactive blood used was drawn from the donors into ACD–1 from 1 to 48 hours before it was injected, and was refrigerated from the time of the bleeding to shortly before administration. Whole blood containing 25 to 100 ml. of cells (by hematocrit) was aspirated from the collecting bottle with a calibrated syringe and infused directly therefrom. A sample for radioactivity measurement was taken just before administration. The procedure was carried out within a few hours of the receipt of the main transfusion of stored cells.

Experimental subjects[2]

With few exceptions, as noted, all donors and recipients were young male volunteers 18 to 25 years of age. Only donors with negative Wassermann reactions and no history of malaria, jaundice, or other recent infectious disease were used. Donors were of Group O and A, and recipients were of all groups. All recipients and most donors were Rh positive. Donors whose bloods were to be preserved were built up with Fe^{55}; those whose cells were used for recipient red cell volume determinations, with Fe^{59}.

The level of radioactivity induced in individual donors was governed to a great extent by the type of experiments for which their blood was to be used. Thus, if small blood aliquots were to be given, the donor levels were higher, proportionately, than if half or full transfusions were given. Iron dosage was estimated from the nomograms shown in a previous communication (39), so as to yield a minimum of 250 c.p.m. per ml. of recipient's blood. Booster doses were required to maintain adequate levels in donors receiving Fe^{59} (47-day half life).

Many donors were bled repeatedly, but at not less than 8-week intervals. Donors prepared with Fe^{55} (half-life 5 years) maintained the radioactivity red cell level resulting from the initial series of injections for long periods.

Blood collection

Blood was collected either by gravity or in vacuum bottles. During every bleeding, the collecting bottle was gently and continuously agitated. A small sample "pilot tube" of clotted donor blood was obtained at the time of bleeding for cross-matching, checking of blood group, and serologic testing.

Recipients were of all 4 blood groups, but all were Rh positive. Typings were twice checked. In all transfusions of group A blood and in many group O bloods, donor cells were cross-matched with the recipient's serum. When small transfusions were given no preliminary bleeding was done; when the transfusions were large (over 75 ml. of cells) the recipients were usually pre-bled an amount of whole blood at least equal to the quantity they were to receive. Each recipient was used for only 1 transfusion.

Gravity method

Blood from donors whose cells were tagged with Fe^{55} was collected into 500-ml. Fenwal blood bottles containing the anti-coagulant solution. Blood from donors, used for red cell volume measurements, whose cells were tagged with Fe^{59}, was collected into 300-ml. Fenwal blood bottles containing ACD–1 solution.

Vacuum method

Commercially prepared, evacuated bottles of 600 ml. or 1,000-ml. capacity containing sterile, pyrogen-free anti-coagulant, were used.[3] The collecting bottle was inverted during the bleeding so that the blood was drawn up through the anticoagulant solution, and the rate of flow was regulated by means of a screw clamp on the rubber tube, keeping it slow enough to reduce foaming to a minimum.

Subdivision

When aliquots of whole blood from one donor were given to several recipients the subdivision was made shortly after bleeding, portions being transferred from the collecting to smaller storage bottles by gentle suction. Subdivision of all resuspensions was done in like manner, after thorough mixing of cells and diluent. In a few instances multiple aliquots were obtained by bleeding a single donor into several collecting bottles (4 and 6 in Table I).

Resuspension of erythrocytes

In all red cell resuspension experiments the blood was collected by gravity into 500-ml. Fenwal bottles. The period between bleeding and centrifugation varied from 1 to 26 hours. Centrifugation was carried out in the collecting bottle in an unrefrigerated International Model F. centrifuge for 35 minutes at 1,800 to 2,000 r.p.m., and the plasma was removed by suction immediately after centrifugation. In some instances most of the "buffy coat" was removed with the plasma. The resuspension solution was added to the packed cells from ½ to 27 hours after plasma aspiration. During all these time intervals, except during centrifugation, the blood or packed cells were refrigerated. Resuspension solutions were usually chilled before being added to cold packed cells.

All these procedures were carried out in an essentially dust-free room, on a porcelain-topped table, under ultraviolet radiation.

Storage

Whole blood and cell resuspensions were stored at 4 to 6° C. The constancy of the refrigerator temperature range was carefully checked by means of a recording thermometer. Except when briefly removed for culturing, they remained undisturbed until transfused.

Bacteriologic control

Four to 5 days before transfusion, 10 ml. of the whole blood or cell resuspension were aseptically aspirated

[2] Students enrolled in Army A.S.T.P. and Navy V–12 programs and civilian students at Harvard Medical School.

from the storage bottle. Of this, 2 ml. were inoculated into each of 2 tubes of thioglycolate broth (for both aerobes and anaerobes), and 3 tubes of tryptose phosphate broth (for aerobes). One tube of thioglycolate and one of tryptose broth were incubated at 37° C. in air, one of each at room temperature in air, and the third tryptose tube in 10 per cent CO_2 at 37° C. After 2 to 3 days they were subcultured to similar media and to blood agar plates, and maintained at both body and room temperatures. Examination by smearing and gram staining was done at from 2 to 5 days of incubation.

Transfusion of stored blood

In all experiments, the storage bottle was removed from the refrigerator ½ to 3 hours before the transfusion and *thoroughly mixed* by gentle rotation.

(1) OPEN BURETTE METHOD. All of the blood but 10 or 15 ml. was decanted through 4 layers of cotton gauze into a graduated 300-ml. salvarsan burette, the delivery tube of which had previously been filled with sterile physiologic saline. The 10 or 15 ml. remaining in the storage bottle was used as a representative aliquot for radioactivity measurements and *in vitro* tests.

(2) TRANSFUSION FROM STORAGE BOTTLE. After standard Army expendable recipient sets[4] became available, all transfusions were given directly from the storage bottle. These sets, which were designed for use with the standard vacuum bottle, were easily adapted for use with Fenwal bottles by means of a short length of rubber tubing and a glass vent tube. A representative aliquot of filtered blood for radioactivity and *in vitro* determinations was obtained directly from the delivery tube just prior to the transfusion. The volume administered was determined by water calibration of the collecting bottle.

Radioactivity sampling

TECHNIC. Fifteen ml. recipient blood samples for radioactivity analysis were taken, with a minimum of stasis, into round bottomed graduated 15-ml. hematocrit tubes, using heparin as an anticoagulant. These were spun, stoppered, at 300 r.p.m. for 30 minutes.

SAMPLING SCHEDULES. The recipient samples following transfusion were analyzed for radioactivity of both isotopes of iron. On the day of the tansfusion, samples were obtained 20 minutes, 1 to 1½ hours, and about 4 hours after the transfusion. On the day following the transfusion 2 recipient samples were drawn, several hours apart. In the earlier experiments sampling was carried out to the eighteenth and in some instances to the thirtieth post-transfusion day, a single daily sample being taken for 5 or 6 days after transfusion, followed by triweekly samples. In the later experiments, two samples were obtained on the first and second post-transfusion day, and single daily samples for the next three days, for a total sampling period of six days.

[4] Supplied by Walter Reed Hospital and American Red Cross Blood Donor Service.

Experiments on whole blood anticoagulant-preservatives

The following solutions, the compositions of which are given in Table I, have been studied. (*1*) Four per cent sodium citrate; (*2*) McGill solution, developed and studied by Denstedt (42); (*3*) a modification of the original Rous-Turner solution reported on by De Gowin (43); (*4*) Alsever's citrate-saline-dextrose solution (27); (*5*) a phosphate-buffered citrate-dextrose solution recommended by Parpart (44); (*6*) "ACD–1," and (*7*) ACD–G, modifications of the Loutit-Mollison acid-citrate-dextrose solution studied by Rapoport (45); (*8, 9*) 2 citrate-dextrose solutions routinely supplied to the European Theatre of Operations (Mediterranean Theatre), and (*10, 11*) 2 acidified modifications of the E. T. O. solutions.

In the following description of procedures, "blood" always means blood drawn from a donor previously prepared with radioactive iron (Fe^{55}). Each blood, or blood aliquot, was transfused into an individual who had never before received radioactive iron in any form. All bloods, or aliquots, were stored at 4 to 6° C.

(1) SODIUM CITRATE. OPEN BURETTE METHOD

Experiment Nos. A, B, C, D. Five hundred ml. of blood were taken into 50 ml. of 4 per cent sodium citrate at room temperature from each of 2 donors. One subject received ½ of the blood from the first donor the day it was drawn, and the remainder after storage for 7 days. The blood from the second donor was stored for 7 days, when it was divided into 2 equal portions and transfused. All bloods were prefiltered just prior to administration. The recipients were bled amounts equal to the quantity of citrated blood given just prior to transfusion.

Experiments Nos. 22 through 24. Three hundred ml. of blood were drawn into 30 ml. of 4 per cent sodium citrate from a donor who had received both isotopes of iron. The donor had received his first injection of Fe^{55} 121 days, and of Fe^{59} 24 days prior to bleeding; thus all Fe^{59} tagged cells were young cells. Three aliquots of about 100 ml. each were transfused after storage for 1, 5, and 8 days.

(2) MCGILL SOLUTION. OPEN BURETTE METHOD

Experiments Nos. 1 through 5. The 3 components of the solution were sterilized separately and mixed aseptically just prior to taking the blood. Five hundred fifty ml. of blood were taken at room temperature into 275 ml. of the solution in a Fenwal 1-litre flask, and the total was divided into 5 equal portions. The aliquots were transfused into 5 individuals after storage for 0, 10, 14, 21, and 29 days.

(3) DE GOWIN'S SOLUTION. OPEN BURETTE METHOD

Experiments Nos. 18 through 21. The sodium citrate and dextrose solutions were autoclaved separately and mixed just prior to the taking of blood. Three hundred ml. of blood were drawn into 450 ml. of the solution in a Fenwal 1-litre flask. The entire bleeding was then divided into 4 approximately equal aliquots. The collection and subdivision of blood were carried out at a tempera-

ture not over 6° C. The aliquots were transfused after storage for 0, 13, 23, and 36 days.

(4) ALSEVER'S SOLUTION. OPEN BURETTE METHOD

Experiments Nos. 51, 53, 55. Five hundred ml. of blood were drawn into 500 ml. of Alsever's solution, pH 6.8, in a 1,000-ml. vacuum bottle, and subdivided by gravity into 5 aliquots of about 200 ml. each. Three of these were stored in individual bottles and transfused at 4, 12, and 21 days after drawing. The 2 other aliquots (Experiments Nos. 52 and 54) were used for refrigeration studies, to be reported elsewhere.

(5) WHOLE BLOOD IN BUFFERED CITRATE-DEXTROSE, PH 7.1 (PARPART). OPEN BURETTE METHOD

Experiments Nos. 25 through 27. The citrate and dextrose were autoclaved dry and the phosphate buffer in aqueous solution, in separate containers. Three hundred ml. of blood were drawn by gravity into the dry citrate in a standard collecting bottle. The dextrose was dissolved by adding 130 ml. of the buffer and the dextrose-buffer was then added to the whole blood. After thorough mixing, the entire bleeding was divided into 3 approximately equal aliquots. The taking and subdividing of the blood was carried out at room temperature. Hemolysis of the supernatant plasma was observed on the day after the blood was taken but apparently did not increase on storage. The aliquots were transfused after storage for 0, 14, and 27 days.

(6) ACID-CITRATE-DEXTROSE (ACD–1). OPEN BURETTE METHOD

Experiments Nos. 10 through 13. All 3 components of the solution were dissolved together and autoclaved in a Fenwal blood collecting bottle. Three hundred ml. of blood were drawn by gravity into 75 ml. of the solution, and the total amount was divided into 4 approximately equal aliquots. The collection and subdivision were carried out at not over 10° C. The aliquots were transfused after storage for 2, 11, 20, and 39 days.

Experiments Nos. 32 through 34. The donor from whom this blood was drawn received the first injection of Fe^{55} 133 days and his first injection of Fe^{59} 16 days prior to bleeding. Five hundred ml. of blood were collected into 125 ml. of ACD–1 at room temperature, and divided into 4 approximately equal aliquots, 3 of which were transfused after 15, 29, and 41 days of storage. The fourth aliquot, stored 61 days, was not transfused and became hemolyzed.

(7) ACID-CITRATE-DEXTROSE (ACD-G). STORAGE BOTTLE METHOD

Experiments Nos. 159, 161, 163. Five hundred ml. of blood from each of 3 donors were drawn into 75 ml. of the chilled solution, and, after mixing, each blood was divided into 2 aliquots. One aliquot from each donor was stored as whole blood, the other as packed cells (see Experiments Nos. 160, 162, 164). The whole blood aliquots were transfused at 6, 15, and 22 days after drawing.

Experiments Nos. 165, 167, 169. Five hundred ml. of blood were drawn from each of 3 donors into 75 ml. of the chilled solution, thoroughly mixed, stored at 4° C., and transfused at 12, 19, and 27 days after transfusion. The recipient of the 19-day-old blood was bled 500 ml. prior to transfusion; the other recipients were not bled.

(4 AND 6) COMPARISON OF ACD–1 AND ALSEVER'S SOLUTION PH 6.8. STORAGE BOTTLE METHOD

Experiments Nos. 56, 58, 60 (ACD–1); 57, 59, 61 (Alsever's). The ACD–1 solution was prepared in our laboratories; and sterilized in the collecting bottles. The Alsever's solution was received from Walter Reed Hospital,[5] transferred to the collecting bottles, and then re-sterilized. Six hundred ml. of blood were drawn by gravity from 1 donor; 100 ml. into each of three 200-ml. bottles containing 25 ml. of ACD–1, and 100 ml. into each of 3 bottles containing 100 ml. of Alsever's solution. These aliquots of blood in each solution were transfused after storage for 11, 15, and 21 days.

MODIFICATION OF CITRATE AND CITRATE-DEXTROSE SOLUTIONS USED IN E.T.O. STORAGE BOTTLE METHOD

At the time these experiments were undertaken, 2 citrate solutions were in routine use in E.T.O. (Mediterranean Theatre) for the collecting of 500 ml. of blood: (*1*) 50 ml. of 4 per cent sodium citrate, and (*2*) 70 ml. of 2.5 per cent sodium citrate in 0.85 per cent sodium chloride. It was the practice in E.T.O. to add 30 to 40 ml. of 5 per cent dextrose in isotonic saline to the bottles, after 500 ml. of blood had been drawn into them. The solutions used in our experiments were commercially prepared in vacuum bottles. All recipients were bled 500 ml. within 72 hours prior to transfusion.

(8) E.T.O. CITRATE-DEXTROSE. *Experiments Nos. 101, 103, 113*

(9) E.T.O. CITRATE-SALINE-DEXTROSE. *Experiments Nos. 102, 104, 114*

Five hundred ml. of blood were drawn by vacuum from each of 6 donors; each of 3 bleedings into 50 ml. of 4 per cent sodium citrate; and each of 3 bleedings into 70 ml. of 2.5 per cent sodium citrate in saline. Thirty ml. of 5 per cent dextrose in 0.85 per cent sodium chloride solution were then added with a syringe to each bottle. The bloods in the citrate-dextrose solution were transfused after 4, 9, and 14 days, and those in the citrate-saline-dextrose solution after 4, 9, and 14 days of storage. The 9-day-old blood was placed in a water bath at about 45° C. for 15 minutes before being transfused.

(10) E.T.O. MODIFICATION A. *Experiments Nos. 95, 97, 99*

(11) E.T.O. MODIFICATION B. *Experiments Nos. 96, 98, 100*

Two modifications of the above routine technic were tested. A stock solution of acidified dextrose-saline was prepared, having the following composition:

[5] Through the courtesy of Captain John Reichel, M.C. A.U.S.

	Grams per 100 ml.
Dextrose anhydrous	5.0
NaCl	0.85
1 N HCl	1.0 ml.

This solution had a pH of 4.7, and was autoclaved without caramelization. It was prepared by adding 10 ml. of 1 N hydrochloric acid to 1 litre of the saline dextrose solution in a vacuum bottle.

Modification A. Seventy ml. of the stock solution were added by vacuum to 50 ml. of 4 per cent sodium citrate in the original bottle, with sterile precautions.

Modification B. Fifty ml. of the stock solution were added by vacuum to the 70 ml. of 2.5 per cent sodium citrate in 0.85 per cent sodium chloride in the original bottle, with sterile precautions.

Three full bleedings were taken by vacuum from individual donors into Modification A, and 3 into Modifica-

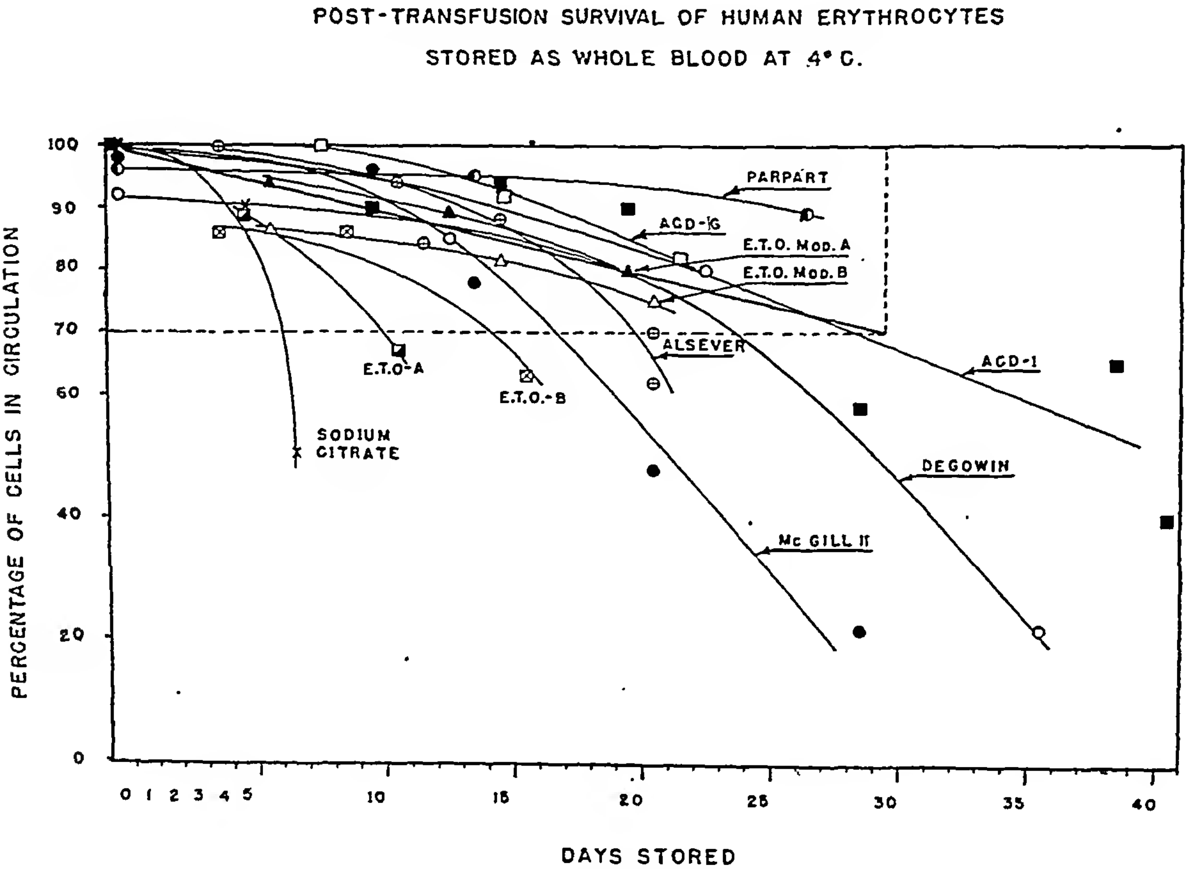

FIG. 1. POST-TRANSFUSION SURVIVAL OF HUMAN ERYTHROCYTES STORED AS WHOLE BLOOD AT 4° C.

In Figures 1, 2 and 3, the solid line represents the normal death rate of live red cells in circulation, approximating one per cent per day. The "zone of safe transfusion" within which 70 per cent or more of the transfused cells are viable is indicated by the broken line rectangle.

Symbols refer to the following solutions:

tion B. After the addition of the stock solution, it was still possible to draw about 480 ml. of blood into the bottle without re-evacuation. The bloods in Modification A were transfused after 6, 13, and 20 days of storage, and those in Modification B after 7, 14, and 21 days of storage.

The post-transfusion survival of erythrocytes, preserved as whole blood as described above, is given in Table III and Figure 1.

Experiments on preservative solutions for resuspending red cells after removal of plasma

The composition of the resuspension fluids studied is given in Table I. Except as noted, all red cell resuspensions were from whole blood drawn by gravity into 4 per cent sodium citrate at a 10 to 1 ratio. Bottles were centrifuged at 1,900 r.p.m. for 30 minutes. The quantity of resuspension fluid added to the packed red cells was approximately equal to the amount of plasma removed, except in the case of the modified acid citrate (Washington Conference—Experiments Nos. 120 through 123).

Two types of fluids were used: (*1*) solutions of electrolytes with and without dextrose, and (*2*) electrolyte-dextrose solutions to which human serum protein fractions had been added. All donors were blood group O.

Electrolyte solutions

(12) ISOTONIC (0.85 PER CENT) SODIUM CHLORIDE. OPEN BURETTE METHOD

Experiments Nos. 6 through 8. Five hundred ml. of citrated blood were centrifuged, and the cells were resuspended in 0.85 per cent sodium chloride, within 2 hours of the time of collection. All procedures were carried out at room temperature. This cell resuspension was divided into 3 equal portions and transfused after 0, 3, and 10 days' storage.

(13) TEN PER CENT CORN SYRUP. OPEN BURETTE METHOD

Experiments Nos. 14 through 17. The corn syrup used was supplied by Dr. Thalhimer[6] (46). Three hundred fifty ml. of whole blood were drawn into 35 ml. of 3.2 per cent sodium citrate and centrifuged in a refrigerated centrifuge. The plasma was removed, and an equal volume of corn syrup was added to the cells, within 2 hours of the time of blood collection. The entire procedure was carried out at not over 10° C. After thorough mixing, the cell resuspension was divided into 4 equal aliquots, and these were transfused after storage at 4° C. for 0, 5, 12, and 21 days.

[6] The composition is said to be as follows:

	Grams per 100 ml.
Dextrose	17.7
Maltose	16.8
Higher sugars	16.2
Dextrins	29.6
Moisture	19.7
The pH of this solution is	4.6

STORAGE BOTTLE METHOD

Experiments Nos. 140 through 147. A more extensive series of experiments was conducted in collaboration with Dr. Thalhimer and Lt. H. Blake, M.C., U.S.N.R. Full bleedings were taken by gravity from each of 8 donors, the plasma was removed, and the cells were resuspended in chilled 10 per cent corn syrup within 24 hours of collection. The bottles were shipped in a portable refrigerator by truck to New York City. They were stored in the refrigerator of the New York Red Cross Blood Donor Center. These cell resuspensions were transfused into selected patients on the wards of the New York Hospital at 9, 11, 12, 13, 14, 15, 18, and 20 days after drawing.

(14) PHOSPHATE-BUFFERED CITRATE-DEXTROSE SOLUTION, PH 6.8 (HUGHES). OPEN BURETTE METHOD

Experiments Nos. 28 through 31. The red cells from 320 ml. of whole citrated blood were resuspended, at room temperature, at about 20 hours after the blood was drawn. After thorough mixing, the entire cell resuspension was divided into 4 approximately equal aliquots, which were transfused after storage for 2, 6, 11, and 20 days.

(15) PHOSPHATE-BUFFERED DEXTROSE SOLUTION. PH 6.0 (HUGHES). OPEN BURETTE METHOD

Experiments Nos. 42 through 45. The donor from whom this blood was drawn received the first injection of Fe^{55} 133 days and his last injection of Fe^{55} 95 days prior to the bleeding for this experiment. His first and last injections of Fe^{59} were 16 and 5 days, respectively, prior to bleeding.

Five hundred ml. of blood were collected into 125 ml. of ACD–1 at room temperature. This was stored for about 40 hours at 4° C., and the cells were then resuspended. This cell resuspension was divided into 4 approximately equal aliquots, which were transfused at 3, 10, 16, and 30 days of storage.

(16) CITRATE-BUFFERED CITRATE-DEXTROSE SOLUTION, PH 5.0 (HUGHES). STORAGE BOTTLE METHOD. (This series was for a direct comparison with 10 per cent corn syrup, Experiments Nos. 140 through 147)

Experiments Nos. 132 through 139. The red cells from eight 500-ml. bleedings were resuspended in the chilled solution about 24 hours after collection. The bottles were shipped to New York in the same portable refrigerator used for the cells resuspended in 10 per cent corn syrup (Experiments Nos. 140 through 147), and stored under identical conditions. These resuspensions were transfused into ward patients at the New York Hospital after 10, 11, 13, 14, 15 (2), 18, and 20 days after drawing.

(17) CITRATE-BUFFERED CITRATE-DEXTROSE SOLUTION, PH 3.8 (HUGHES). COLLECTING BOTTLE METHOD

Experiments Nos. 89, 91, 93, 105, 107. Three full bleedings were taken from each of 3 donors, the cells were resuspended in the chilled solution within 24 hours

and transfused after 10, 18 and 22 days of storage. One full bleeding from a fourth donor was resuspended, mixed, and subdivided into 2 aliquots which were transfused after 32 and 39 days of storage.

Experiments Nos. 109 through 112. Five hundred ml. of blood, drawn in equal amounts into 2 collecting bottles, were taken from 2 donors, and the cells were resuspended in the collecting bottles within 2½ hours from the time of bleeding. The solution was at room temperature. Two aliquots from one donor were transfused after 8 and 21 days, and the aliquots from the other donor after 15 and 28 days of storage.

(18 AND 19) MODIFIED ACD (RAPOPORT C_2A, C_2A^1). OPEN BURETTE METHOD

Experiments Nos. 46 through 49. Five hundred ml. of citrated blood from 1 donor were divided into 2 equal aliquots. Each of these was in turn divided into 2 equal aliquots, centrifuged, and the cells resuspended, 2 in C_2A and two in C_2A^1. The aliquots resuspended in C_2A were transfused after 13 and 20 days, and those resuspended in C_2A^1 were transfused after 13 and 22 days of storage.

(20) MODIFIED ACID CITRATE.[7] STORAGE BOTTLE METHOD

Experiments Nos. 120 through 123. Five hundred ml. of blood were taken by gravity from 2 donors into sodium citrate. The blood from each donor was drawn into 2 Fenwal collecting bottles, so that each bottle contained 250 ml. of blood. Within 24 hours from the time of collection, the cells in each bottle were resuspended in only 50 ml. of the solution, which was pre-chilled. These resuspensions were transfused after 6, 10, 16, and 21 days of storage. The tagged cells in the 6- and 10-day stored resuspension were no more than 46 days old, while those in the 16- and 21-day stored resuspensions were of mixed age, on the day of transfusion.

(21) BICARBONATE-BUFFERED CITRATE-DEXTROSE, PH 6.5 (HUGHES). STORAGE BOTTLE METHOD

Experiments Nos. 155 through 158. Five hundred ml. of whole blood were taken from each of 2 donors into 125 ml. of ACD–1. About 20 hours after collection, bloods were centrifuged and plasma removed in the usual manner, the packed cells being refrigerated for 4 hours. Three hundred ml. of chilled diluent were then added to each, by siphonage (to prevent escape of CO_2). Each cell resuspension was then divided into 2 aliquots, by gentle suction. The aliquots were transfused after 6, 13, and 21 days of storage at 4° C.

The results of these experiments are summarized in Table III and Figure 2.

(22) PACKED CELLS FROM WHOLE BLOOD IN ACD–1. STORAGE BOTTLE METHOD

Experiments Nos. 115 through 119. Five hundred ml. of blood were taken from each of 5 donors into 125 ml. of cold ACD–1 by gravity. After 24 hours of refrigeration, the bottles were centrifuged, the plasma removed, and the bottles placed in storage. The packed cells were transfused after storage for 9, 14, 15, 16, and 21 days. The cells stored 15 days (No 115) were transfused as packed cells, without the addition of saline. In the other 4 experiments, 125 ml. of sterile normal saline were added ½ hour before the blood was transfused. The cells were thoroughly mixed with the diluent before administration.

(23) PACKED CELLS IN ACD–G. COLLECTING BOTTLE METHOD

Experiments Nos. 160, 162, 164. No added diluent. Five hundred ml. of blood were taken by gravity from 1 donor, and subdivided as in Experiments Nos. 159, 161, and 163, [see (7) above]. The collecting bottles were centrifuged, the plasma was withdrawn, and the packed cells were transfused after 7, 14, and 21 days of storage, without the addition of any diluent.

Experiments Nos. 166, 168, 170. Diluent added at time of transfusion. Five hundred ml. of blood were taken from each of 3 donors. The collecting bottles were centrifuged, the plasma was withdrawn, and the packed cells were transfused after 12, 19, and 27 days of storage. One hundred twenty-five ml. of 0.85 per cent NaCl were added just prior to transfusion.

Experiments Nos. 176 and 175. 0.86 per cent NaCl + 0.5 per cent dextrose. Two hundred fifty ml. of blood were taken from each of 2 donors. One hundred ml. of diluent were added. The resuspensions were transfused after storage for 14 and 20 days. Hematocrits were 50.5 and 56.4. Survival was 95 and 84 per cent.

Experiments Nos. 171 and 172. 1.0 per cent NaCl. Two hundred fifty ml. of blood were taken from each of 2 donors. One hundred ml. of diluent were added. The resuspensions were transfused after storage for 13 and 21 days. Hematocrits were 47 and 50. Survival was 100 and 86 per cent.

Experiments Nos. 173 and 174. 1.0 per cent NaCl + 0.5 per cent dextrose. Two hundred fifty ml. of blood were taken from each of 2 donors. One hundred ml. of diluent were added. The resuspensions were transfused after 14 and 20 days of storage. Hematocrits were 48 in both instances. Survival was 100 and 73 per cent.

Experiments Nos. 178 and 177. 10 per cent corn syrup. Two hundred fifty ml. of whole blood were taken from each of 2 donors. One hundred ml. of diluent were added. The resuspensions were transfused after 14 and 21 days of storage. Hematocrits were 53.5 and 64.5. Survival was 64 and 81 per cent.

Experiments Nos. 180 and 181. Stored with diluent added. *1.1 per cent NaCl + 0.5 per cent dextrose.* Two hundred fifty ml. of blood were taken into each of 2 bottles from the same donor. One hundred ml. of diluent were added immediately after removal of plasma. The resuspensions were transfused after 12 and 19 days of storage.

Experiments Nos. 182 and 183. Stored with diluent added. *0.85 per cent NaCl + 0.5 per cent dextrose.* Two

[7] Solution recommended for trial at Conference on Resuspended Blood Cells, of C.M.R., at Washington, D. C., 5/18/45.

per cent citric acid. Two hundred fifty ml. of blood were taken into each of 2 bottles from the same donor. One hundred ml. of diluent were added immediately after removal of plasma. The resuspensions were transfused after 14 and 21 days of storage.

The results of experiments on packed cells are summarized in Table IV and shown in Figures 2 and 4.

Experiments on electrolyte solutions with added human serum protein fractions[8]

The albumin used, Fraction V, was the commercial product supplied to the U. S. Navy. The globulins, Frac-

[8] The human serum proteins were obtained through the courtesy of Dr. E. J. Cohn.

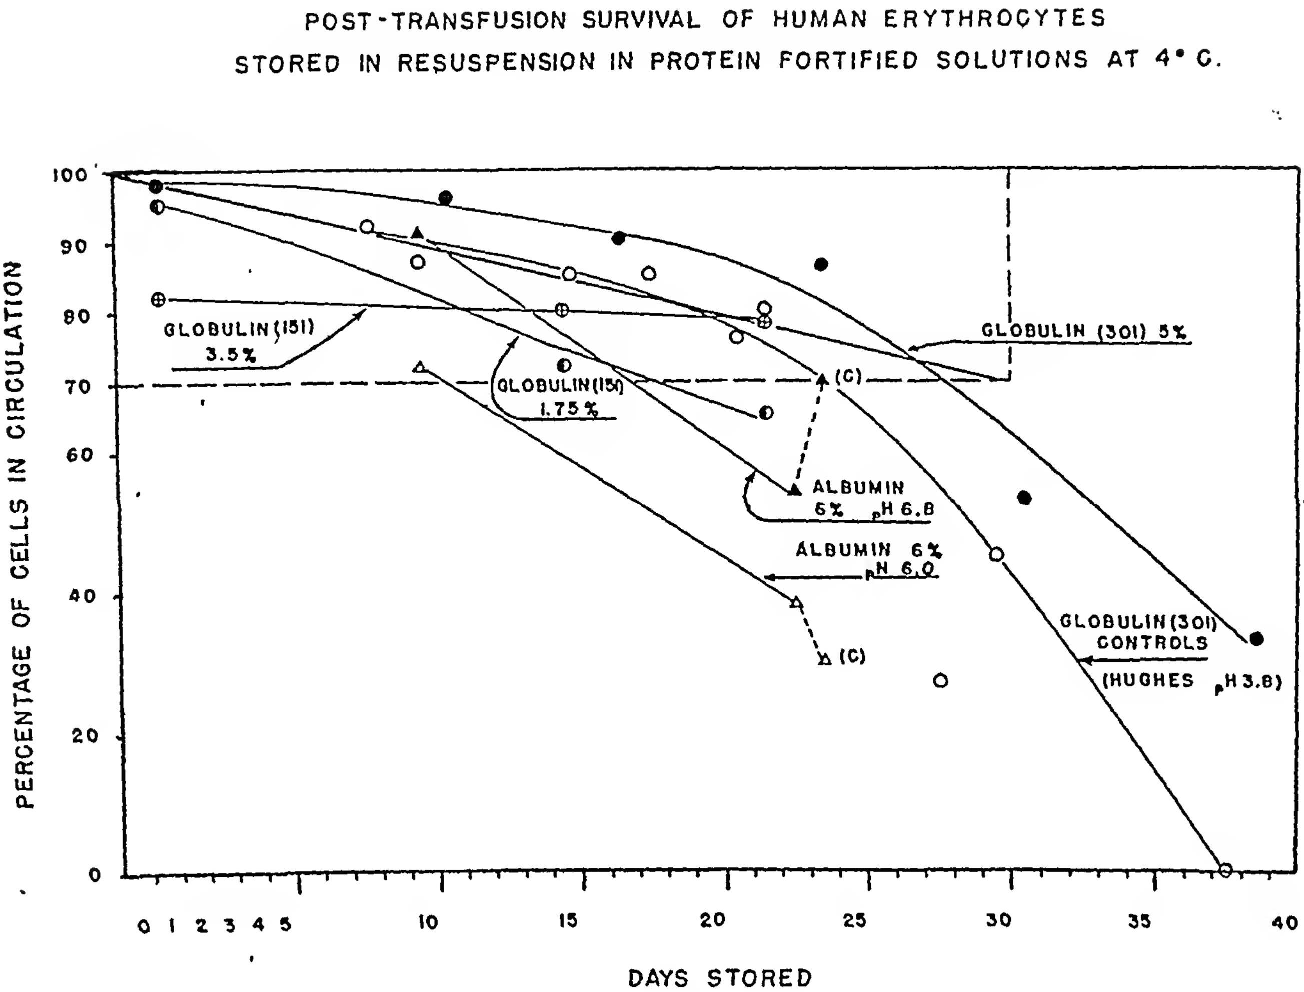

Fig. 3. Post-Transfusion Survival of Human Erythrocytes Stored in Resuspension in Protein-Fortified Solutions at 4° C.

The symbols refer to the following solutions:

▲ = Human serum albumin added to phosphate-buffered citrate-dextrose at pH 6.8.

△ = Human serum albumin added to phosphate-buffered citrate-dextrose at pH 6.0.

⊕ ◐ = Human serum globulin (Lot 151) added to citrate-buffered citrate-dextrose, pH 7.0.

● = Human serum globulin (Lot 301) added to citrate-buffered citrate-dextrose, pH 3.8.

○ = The globulin-free controls for globulin 301.

tion IV-3, 4,[9] were prepared in the pilot plant of the Department of Physical Chemistry, Harvard Medical School. Red cells resuspended in a solution, of the same composition as that to which the proteins were added, were used for control transfusions.

(24 AND 25) HUMAN SERUM ALBUMIN (FRACTION V) IN PHOSPHATE-BUFFERED CITRATE-DEXTROSE SOLUTIONS AT PH 6.8 AND 6.0. OPEN BURETTE METHOD

Experiments Nos. 36, 37 (6.8), Experiments Nos. 39, 40 (6.0), and Experiments Nos. 38 and 41 (controls). With venesection the donor was bled into four 250-ml. storage bottles, designated as bottles (a), (b), (c), and (d). Bottles (a) and (b) each contained 20 ml. of 4 per cent sodium citrate solution, and each received 200 ml.

[9] Safety tests on Fraction IV-3, 4 were carried out by Dr. O. Krayer, in animals, and by Dr. C. A. Janeway, in humans.

of donor blood. Bottles (c) and (d) each contained 10 ml. of 4 per cent sodium citrate solution, and each of these received 100 ml. of the blood. These were stored at 4° C. over night, and then all 4 bottles were centrifuged, and the plasma was removed. To each bottle of packed cells was added a volume of resuspension solution approximately equal to the volume of plasma withdrawn. Bottle (a) received albumin solution buffered to a pH of 6.8. Bottle

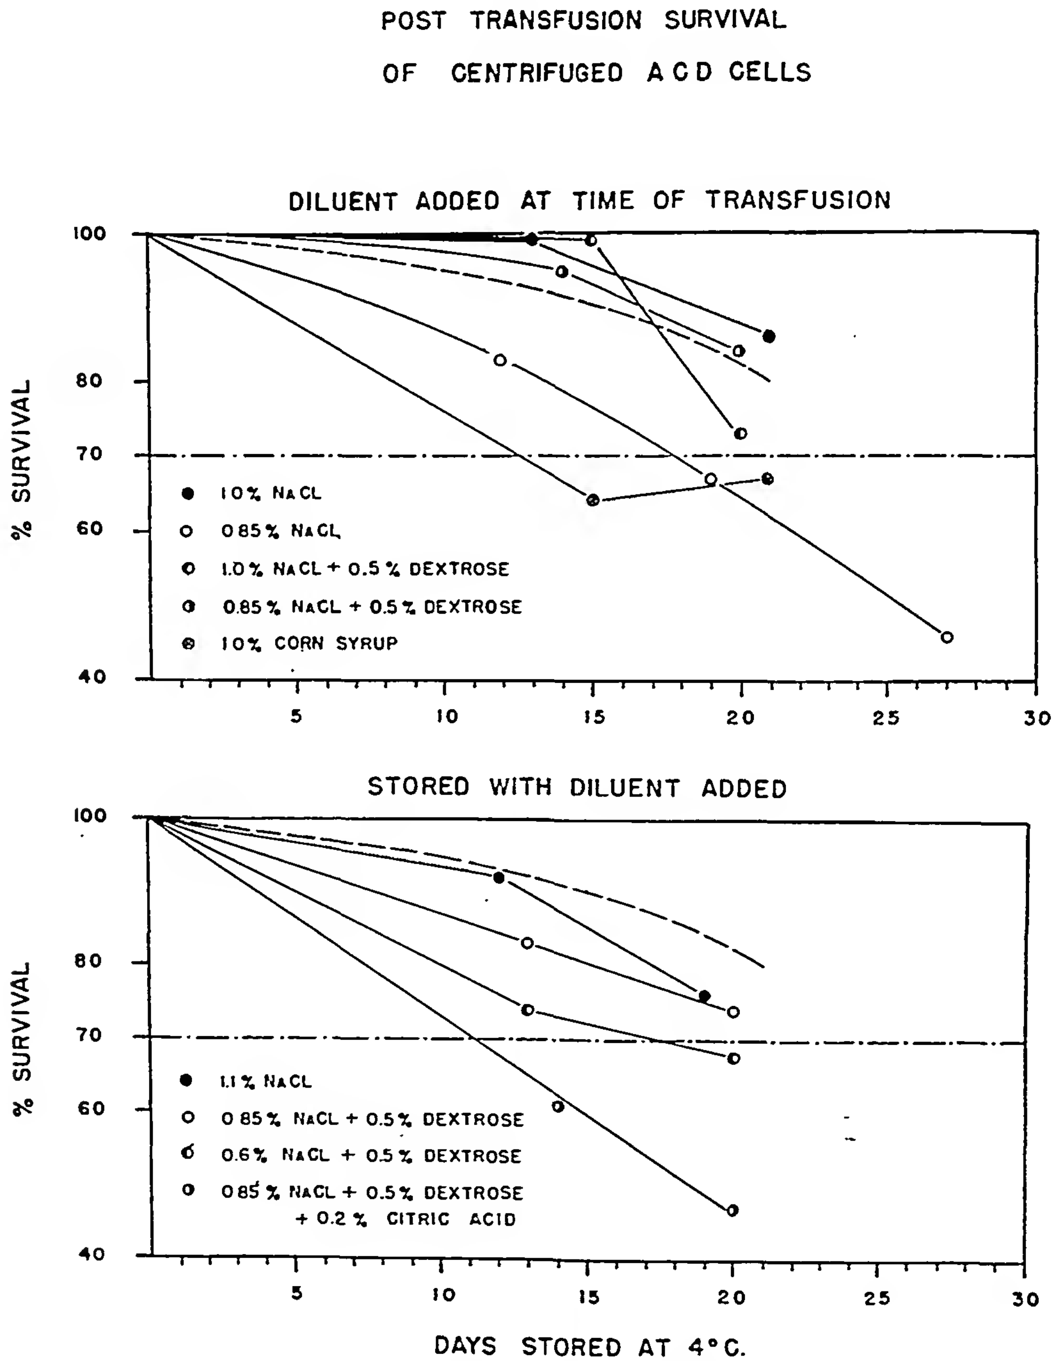

FIG. 4. POST-TRANSFUSION SURVIVAL OF CENTRIFUGED ACD CELLS

The addition of a slightly hypertonic saline solution just prior to transfusion does not decrease the viability of packed red cells drawn as whole blood in ACD. Storage in these same diluents increases the rate of deterioration.

(b) received albumin solution buffered to a pH of 6.0. Bottle (c) received albumin-free solution buffered to a pH of 6.8, and bottle (d) received albumin-free solution buffered to a pH of 6.0. Bottles (a) and (b) were each subdivided into 2 equal aliquots. The entire procedure was carried out at room temperature. After 10 days of storage, an aliquot of cells resuspended in albumin pH 6.8 and one of cells resuspended in albumin pH 6.0 were transfused. After 23 storage days the 2 remaining albumin-containing aliquots were transfused. The control aliquots, that is, *cell resuspended in a solution buffered to 6.8 and 6.0 (no albumin)*, were both transfused after 24 days of storage.

(26) α AND β GLOBULINS (FRACTION IV–3, 4, LOT 151) IN ACIDIFIED-CITRATE-DEXTROSE (HUGHES PH 3.8)

Experiments Nos. 82 through 87. The globulin was dissolved in the electrolyte solution, in 2 portions, the final concentration of protein being 1.75 and 3.50 grams per 100 ml. Five hundred ml. of blood from each of 2 donors were drawn into 4 per cent sodium citrate at room temperature. The blood was centrifuged within 24 hours, and the plasma was withdrawn. To 1 bottle was added the 1.75 per cent globulin solution and to the other, the 3.50 per cent globulin solution. The globulin solution was cold. After thorough mixing, 3 equal aliquots of each were transferred to storage bottles. Each aliquot was transfused after storage for 1, 15, and 22 days respectively.

(27) α AND β GLOBULINS (FRACTION IV–3, 4, LOT 301)

Experiments Nos. 88, 90, 92, 94, 106, 108. (Controls 89, 91, 93, 105, 107, 109, 110 through 112 are described above.) Three grams of the globulin were dissolved in 100 ml. of the electrolyte solution. Two series of experiments were carried out, in one of which each test and control transfusion was a full bleeding, in the other of which each was a half-size bleeding. Resuspension was completed within 18 hours of drawing the blood. All solutions were cold and the packed cells were refrigerated.

Test transfusions were given 1, 11, 17, 24, 32, and 39 days, and control transfusions, 8, 10, 15, 18, 21, 22, 28, 31, and 38 days after bleeding.

The results of these experiments are summarized in Table V and Figure 3.

RESULTS

Whole blood

The poorest survival of whole blood was obtained with 4 per cent sodium citrate (No. 1). After 4 days of storage, 90 per cent of the cells were viable, but thereafter deterioration was precipitous.

All of the other solutions contained dextrose. The simplest of these, citrate and dextrose, was

TABLE V

Post-transfusion survival of human erythrocytes drawn as whole blood in 4 per cent sodium citrate and stored at 4° C. after resuspension in human serum protein-fortified electrolyte solutions

Solution	Transfusion no.	Days stored	Recip. blood group	Transfused volume: Total	Transfused volume: Cells	Age of tagged cells*	Clots	Reactions (febrile)	Survival

* Days between last injection of radioactive iron and day of bleeding.

De Gowin's solution (No. 3). Although there seemed to be some immediate cell damage, subsequent deterioration proceeded at a rate of less than 1 per cent a day up to about 20 days of storage, at which period 80 per cent of the cells proved to be viable. Thereafter, the survival curve broke sharply.

The 2 unmodified E.T.O. A and B solutions (Nos. 8 and 9) were fortified with dextrose, solution B also containing sodium chloride. Survival in both solutions was considerably better than in plain citrate, the 70 per cent levels being reached in about 11 and 15 days respectively.

Two solutions were buffered with phosphates, at 7.4 (McGill II) (No. 2), and at 7.1 (Parpart's) (No. 5). Survival in McGill II solution was about 90 per cent at 10 days of storage, but thereafter the rate of deterioration increased rapidly, the 70 per cent level coming on the sixteenth day. Very good preservation was obtained with Parpart's solution, even though some initial hemolysis may have been caused by taking the blood over dry citrate. During 26 days of storage, only about 10 per cent of the cells became nonviable.

The pH of Alsever's solution (No. 4) was adjusted to 6.8 with citric acid. Deterioration was fairly constant up to about 15 days of storage, when about 80 per cent of the cells were viable, the 70 per cent level being reached on the twentieth day.

Four solutions were adjusted to a pH of 5.0: E.T.O. Modifications A and B (Nos. 10 and 11) by hydrochloric acid, and ACD-1 (No. 6) and ACD-G (No. 7) by citric acid. Bloods in both of the modified E.T.O. solutions showed a constant rate of deterioration approximating 1 per cent per day, the 80 per cent level being reached in 20 and 16 days, respectively. This series was not followed down to the 70 per cent survival level. Both the ACD solutions gave very satisfactory preservation. Blood in ACD-1 deteriorated at less than 1 per cent per day for 25 days, and in ACD-G for 22 days, at which survival in both solutions was at least 80 per cent.

Deterioration of red cells resuspended in normal saline (No. 12) was rapid, the 90 per cent level being reached in 3 days, and practically no cells being viable after 10 days of storage.

Survival in the first series of cells in corn syrup (No. 13) was poor, the 70 per cent level being reached in about 4 days, but was considerably better in the second series. A wide scatter in survival was found in this series, in which the subjects were hospitalized patients, but it is evident that preservation was satisfactory for at least 10 days.

Both the phosphate-buffered solutions (Nos. 14 and 15) gave good preservation.

Surivival of cells in the pH 6.8 solution was better than 80 per cent up to the longest storage period studied, 20 days; and the survival of cells in the pH 6.0 solution was 70 per cent at 22 days.

The citrate-buffered solution adjusted to pH 3.8 with HCl (No. 27, controls[10]) was better than that adjusted to pH 5.1 (No. 16), the 70 per cent survival levels being reached in 20 and 14 days respectively.

Two other citrate-buffered solutions, C_2A (No. 18) and C_2A^1 (No. 19), gave fairly good preservation, the 70 per cent levels being reached at 21 and 18 days respectively.

The low volume citrate-buffered solution (No. 20) gave poor preservation, the survival level having fallen to about 10 days, and to less than 60 per cent after 16 days of storage.

Survival of cells in the bicarbonate-buffered solution (No. 21) was 70 per cent after 20 days but only about 40 per cent after 26 days of storage.

Packed red cells

Red cells drawn into ACD-G, stored as centrifuged cells with the plasma removed, and transfused up to 21 days of storage without the addition of any diluent, survived as well as whole blood in the same solution. The addition of 0.85 per cent NaCl; 1.1 per cent, 0.85 per cent and 0.6 per cent NaCl plus 0.5 per cent of dextrose; and of 0.85 per cent NaCl plus 0.5 per cent dextrose and 0.2 per cent citric acid decreased the viability of the cells as compared to whole blood, the 70 per cent level being reached at from 12 to 18 days.

The addition just prior to transfusion of 1.0 per cent NaCl; of 1.0 per cent NaCl plus 0.5 per cent dextrose; and of 0.85 per cent NaCl plus 0.5 per cent dextrose did not increase the viability of the cells as compared with whole blood. Results with the addition of 10 per cent corn syrup were equivocal.

[10] Illustrated in Figure 3.

Solutions with added human serum protein fractions.

Human serum albumin (Nos. 24 and 25) did not increase the preservative quality of the electrolyte solution in which it was added (Nos. 14 and 15). Fraction IV–3, 4, composed of α and β globulins and albumin, apparently had a beneficial effect. With one lot of globulin (No. 26) survival of better than 70 per cent was obtained for 15 days. With the other lot (No. 27) survival of cells in the globulin-containing solution was better than 80 per cent for 24 days of storage, but survival of the cells in the control solution had fallen to 71 per cent over a similar storage period.

DISCUSSION

Most of the experimental subjects were normal ambulatory males. In the series of cells resuspended in corn syrup (Experiments Nos. 140 through 147), and Hughes pH 5.1 solution (Experiments Nos. 132 through 139), hospitalized patients were used. It will be noted in Figure 2 that the scatter in percentage of survival throughout the period of observation (9 to 20 days) was much greater in both series than that seen in the normal recipients. Most of these patients were anemic, some were mildly febrile, some had gastrointestinal lesions, others were postoperative, and one under daily X-ray therapy for carcinomatosis. Similar observations on survival of radioactively tagged stored red cells are reported by Denstedt (47) in mental cases and by Strumia (48) in hospital ward patients. Accordingly, the survival in normals may be regarded as the best experimental basis for the comparative evaluation of viability of blood stored in various solutions.

The size of transfusions given varied from full bleedings (150 to 250 ml. of cells) to small aliquots (25 to 100 ml. of cells). Thus, the amounts transfused represented variable percentages of the recipient's pre-transfusion red cell volume. Since the recipients' red cell volumes ranged from about 1,800 to 2,500 ml., the transfusions ranged from 1 to 15 per cent of total red cell volume. The time in which the transfusion was given, and hence the average rate of flow, also varied.

The absolute quantities of non-viable cells varied, in these experiments, with the size of the transfusion and the percentage of survival. While these factors might well influence the *rate* at which non-viable cells or hemoglobin were removed from circulation, it is hardly to be expected that many non-viable cells, even in a badly deteriorated blood, would remain in active circulation for any considerable period of time. Thus the accuracy with which the proportion of non-viable to viable transfused cells was measured was not affected by the size of the transfusion.

In the paper in which the radioactive iron method of measuring post-transfusion survival of transfused red cells (40) was described, the percentage of survival, that is, the percentage of transfused cells found viable, was based upon the lowest radioactivity value of the recipient's red cells found during the observation period. This low point occurred within the first 24 hours after transfusion in the majority of cases, and seldom beyond the first 48 hours after transfusion.

Recipient radioactivity levels after 48 hours constitute the sum of radioactivity of retained donor cells and of new cells containing re-utilized radio-iron. Thus the method does not measure the continued longest period of survival of viable donor cells in the recipient's blood stream. However, the chief danger from the transfusion of stored blood lies in the extent of breakdown of donor cells, and hence the *immediate* survival of the transfused cells becomes a factor of paramount importance in evaluating preservative solutions.

The limit of error of the technic was defined as ± 5 per cent. In those cases in which the loss of cells was considerable, it is possible that some re-utilization of liberated radio-iron had already occurred at the time that the lowest recipient radioactivity value was obtained. If such were the case, the extreme loss of transfused cells might not have been detected, and the computed survival may have been falsely high. In all probability this potential error is not significant in the results obtained on bloods showing better than 60 per cent survival.

It should be clearly understood that only radioactively tagged erythrocytes are detected by the analytic procedures employed. The exact percentage of tagged cells of given ages in the blood of any donor cannot be calculated from the data available, since the quantity of the radio-iron in the individual corpuscles was not measured, nor is it certain that radio-iron is evenly distributed in all developing cells. The time elapsed between the

first exposure of a donor to radio-iron and the drawing of blood from that donor is known and is listed for each transfusion in Tables II through V. Thus it is possible to consider donors as having predominantly young, middle-aged, or old tagged cells. Those donors in whom the time interval between administration of radio-iron and drawing of blood exceeded the normal life span of the red cell (about 100 days) may be considered as having, to an unknown extent, a mixed-age cell population. The longer the time interval, the more closely would the age distribution of the tagged cells approach the age distribution of all the circulating cells.

It was also stated (40) that the age of the radioactively tagged cells at the time the blood was drawn was a factor in the rate of deterioration of the cells during storage; that very young cells survived about 10 per cent better during storage than did cells of advanced age. In those experiments in which only young tagged cells were given, the survival percentages might therefore be expected to be somewhat better than if tagged cells of ages more nearly representative of the whole red cell population had ben used.

Thus, the survival of tagged cells from any donor could be expected to be best when all cells are young and to become progressively poorer as they approach the end of their life span. After that time, survival would be improved due to the presence of new cells tagged with re-utilized radio-iron. This phenomenon would continue until all ages of cells were represented by tagged cells, and the measured survival of the radioactive cells would be truly representative of the survival of the blood as a whole.

The maximum differential in survival of young and old cells is 10 per cent, and the degree of this error will tend to diminish the more closely the age distribution of the tagged cells approaches that of a truly mixed-age red cell population. This factor, slight as it is, has been taken into consideration in the final evaluation of the preservative solutions studied.

In general, evidence, by the radioactive method, of good preservation is slightly more significant when the transfusion contained predominantly old or mixed-age tagged cells, than when the tagged cells were young. Conversely, evidence of poor preservation is more significant when the transfusion contained young tagged cells, than when the tagged cells were of mixed or advanced age.

Studies by Shemin and Rittenberg, employing N^{15}, have demonstrated that the normal life span of human erythrocytes is from 100 to 120 days (33). It can therefore be assumed that red cells normally die off at the rate of about one per cent a day in the body. It follows that if cells deteriorate at a similar rate during storage, as determined by post-transfusion survival, preservation *in vitro* has been as good as if they had remained in circulation in the body.

Survival at a rate equivalent to the post-transfusion loss of not more than 1 per cent of the transfused cells per day of storage would therefore seem a reasonable standard for "satisfactory" preservation. The slope of this rate of survival is plotted in broken lines in Figures 1, 2, 3.

This does not imply that blood showing higher rates of deterioration cannot be safely transfused. As will be shown in a subsequent communication (49), the normal reticulo-endothelial and erythropoietic system is capable of disposing of red cell breakdown products up to 30 per cent of a 500 ml. transfusion without marked hemoglobinemia or hemoglobinuria. One important factor is, therefore, the storage period at which not less than 70 per cent of transfused cells survive. With what we have defined above as "satisfactory" preservation, survival would decline to this level in 30 days. This "zone of safe transfusion" is indicated by the dotted rectangle in Figures 1 through 3.

Inspection of the time-survival curves in these figures reveals that the initial rate of deterioration remains fairly constant throughout the observation period, but in others becomes accelerated at some point during continued storage.

This constant rate of deterioration is illustrated in Figure 1 by the time-survival curves of Parpart's solution, ACD–1 and ACD–G, and E.T.O. Modification A. The acceleration in rate of deterioration is illustrated by the time-survival curves in Figure 1 of citrated blood, McGill II, De Gowin's and Alsever's solution, and in Figure 3, by the curves of cells resuspended in the globulin-fortified (301) acid-citrate dextrose solution, and the pH 3.8 controls. The preservative showing a low and constant rate of deterioration over substantial periods would appear to be superior to one in which an abrupt change was observed.

Both of those characteristics must be considered in determining the longest permissible dating period of blood stored in any preservative.

The storage period at which the rate of deterioration began to exceed 1 per cent per day, and at which the smoothed time survival curves intersect the 70 per cent survival abscissa, is shown in Table VI for each solution studied. In those series in which survival did not fall below 70 per cent, the percentage of survival obtained on the longest observed storage period is listed. Also given in the table are "dating periods"—the longest permissible safe periods of refrigerated storage.

Any dating period is at best an approximation. Blood from individual donors presents one variable, and the state of health of recipients many more variables. The manner in which blood is drawn, and its subsequent handling also may affect behavior during storage. The determination of upper limits of storage should be based on conservative rather than optimistic considerations.

It is recognized that the ability of the human body to dispose of red cell breakdown products is extremely variable and may be far greater than hitherto believed. In the opinion of the authors, safe practice would appear to be to give the patient, not the preservative solution, the benefit of the doubt.

These values have been arrived at by considering the characteristics of the time-survival curves: the storage period at which the rate of deterioration began to exceed 1 per cent per day and the survival had dropped off to 70 per cent (where observed). The age of the tagged cells was also considered according to the general statement made above.

There are obviously wide differences in the preservative qualities of the solutions studied. They may be grouped according to dating period somewhat as shown in Table VII.

In light of the data presented, it can be empirically stated that maximal preservation of cells stored as whole blood is obtained with a solution in which

(a) the ratio of whole blood to diluent is not less than 4 to 1;

(b) the concentration of citrate in diluted plasma is between 0.4 and 0.6 grams per 100 ml. (about 1.0 gram per 100 ml. of packed cells);

TABLE VI

Storage periods at which rate of deterioration begins to exceed 1 per cent per day, at which the 70 per cent survival level is reached, and approximate "dating periods"

* Added just prior to transfusion.

enough so that the buffering action of plasma proteins and hemoglobin will not raise the pH of the diluted plasma above 7.0, or of the cells above 6.8.

These conclusions are in keeping with those of Mollison (35), Loutit (36), and Altmann and Watson (50).

The specifications of the optimal resuspension fluid are, however, less clear.

Since the cells were drawn as whole blood into 4 per cent sodium citrate, some initial damage may have occurred before resuspension.

The addition of dextrose and the maintenance of a slight acidity of the diluent *during storage* appear to be as important for resuspended cells as for whole blood. No significant hemolysis was produced by the addition of even the most acid fluids.

These observations do not apply to fluids used for resuspension of cells drawn as whole blood into ACD-1 or ACD-G.

Slightly hypertonic solutions of NaCl with or without low concentrations of dextrose can be safely used for diluting packed ACD red cells provided the diluent is added just prior to transfusions. No electrolyte diluent was found in which packed cells could be stored without increasing their rate of deterioration.

The formation of fibrin clots occurred in more or less degree in all stored blood and resuspended cells. They varied in character from very fine, pale particles to larger, tenacious, gelatinous masses. They were roughly quantitated by inspection of filters and bottles at the end of transfusion. The relative amounts of clot noted are listed in Tables I to IV. Those clots quantitated as 1 + or 2 + did not interfere with administration of blood through a cylindrical, metal, 100-mesh screen filter with a 20 sq. cm. surface area. Those indicated as 3 + were in sufficient quantity to slow down the speed of transfusion but not stop flow. The small particles cause obstruction by coating

the filter surface and are of more significance than the large, stringy masses which might possibly block the outlet from the bottle, although this has not occurred in our experience.

The amount of clot in any given solution tended, in general, to increase on storage at optimal temperature, the oldest bloods showing the largest amounts. The degree of clot formation on storage showed no relationship to ratio of volume of whole blood to anticoagulant used. There was generally less clot present in stored cell resuspensions than in stored whole blood. Albumin solution and saline resuspensions were notable exceptions, both showing relatively large amounts of clot of the stringy, gelatinous type. In stored packed ACD-1 and ACD-G cells, there was much less clot formation than in the same solutions stored as whole blood. None of the solutions studied entirely prevented the formation of clots.

The reactions tabulated in Tables II to V refer only to those of the febrile type and were probably due to accidental pyrogenic contamination of some part of the collecting, resuspending or transfusion apparatus, or of the solution used, rather than to the breakdown of cells. In many instances there was donor cell destruction equivalent to or greater than that occurring in subjects having a rise in temperature, with no symptoms or fever. In no instance of febrile reaction was bacterial contamination demonstrated. In every case where there was a rise in temperature, there were also malaise and other related symptoms.

In 52 transfusions of whole blood, there were 3 very mild reactions with a maximum temperature rise of 1.5° F., with no chill, and 1 with a maximum rise of 3.1° F., with a slight chill. In 81 transfusions of resuspended or packed cells, there were 7 very mild reactions, with a temperature rise of less than 1.0° F., 5 with a 1.0 to 1.5° F. temperature rise; and 2 with a temperature rise of 3.1 and 4.4° F., respectively, and these 2 subjects experienced chills.

There were about twice as many reactions in bloods stored 15 days or less than in those stored more than 15 days. Hence prolonged storage did not increase the incidence of pyrogen reactions.

It is felt that the information obtained from this admittedly small series of well controlled experimental transfusions offers a better basis for evaluating preservatives than observations obtained by less accurate clinical laboratory tests in larger series of observations.

The practical worth of any preservative must finally rest on long-range clinical experience. The conclusions reached herein are set forth as a guide to clinical usage: for the selection of solutions to meet specific requirements and for the establishment of safe storage limits.

CONCLUSIONS

(*1*) The post-transfusion survival of preserved human erythrocytes, stored under refrigeration for varying periods of time, has been determined by means of the radioactive iron technic.

(*2*) Studies were made of 11 preservative solutions for whole blood, of 10 electrolyte solutions for resuspensions of centrifuged cells, of 2 electrolyte resuspension fluids to which human serum protein fractions were added, and of packed cells stored without resuspension after the removal of plasma.

(*3*) The longest period of time at which cells stored under refrigeration can be safely transfused has been determined for every solution investigated. This "dating period" is based upon the observed rate of deterioration of the red cells during storage.

(*4*) Refrigeration, the addition of dextrose to the citrate anticoagulant, the maintenance of a slightly acid reaction of the diluted plasma or resuspension fluid, and optimal dilution are essentials for prolonged preservation.

(*5*) Whole blood can be preserved up to 70 per cent viability for at least 21 days in acid-citrate (ACD-1 and ACD-G), and for at least 15 days in De Gowin's, Alsever's, and McGill solutions.

(*6*) Red cells drawn as whole blood into sodium citrate can be preserved by resuspension in citrate-buffered citrate-dextrose solution for from 10 to 15 days.

(*7*) Packed red cells from blood drawn into acid-citrate-dextrose may be safely transfused both without the addition of diluent, and with a slightly hypertonic saline diluent added just prior to transfusion, up to 21 days of storage.

ACKNOWLEDGMENTS

The authors wish to express their appreciation for the devoted assistance of Miss Florence Tytell, Mrs. Virginia Bryant, Miss Eleanor Ryan, Miss Barbara Clapp, and Mrs. Rose Clopman.

The authors wish to extend their thanks to Dr. Ralph G. Stillman of the New York Hospital, to Maj. Henry Tisdall, M.C., A.U.S., Lt. Henry S. Blake, U.S.N.R., and Dr. William Thalhimer, for their cooperation in the series of experiments conducted at the New York Hospital.

THE RATE OF POST-TRANSFUSION LOSS OF NON-VIABLE STORED HUMAN ERYTHROCYTES AND THE RE-UTILIZATION OF HEMOGLOBIN-DERIVED RADIO-ACTIVE IRON [1]

By JOHN G. GIBSON, 2ND, WENDELL C. PEACOCK, ROBLEY D. EVANS, THEODORE SACK, AND JOSEPH C. AUB

(From the Radioactivity Center, Massachusetts Institute of Technology, Cambridge, Massachusetts; the Medical Clinics of the Peter Bent Brigham and Massachusetts General Hospitals; and the Department of Medicine, Harvard Medical School, Boston, Massachusetts)

(Received for publication August 31, 1946)

When human erythrocytes are transfused within a few hours of taking in citrate solution, practically all of them remain intact in the recipient's blood stream (1). Thereafter, they disappear from the circulation at a rate of about one per cent per day (2, 3), and it is generally believed that this is the normal death rate of homologous erythrocytes.

Chemico-physical changes occur in red cells during storage *in vitro*. Depending upon the preservative value of the anticoagulant used, deteriorative changes may occur gradually and proceed at relatively constant rates for considerable periods, or they may be initiated early in storage and proceed at accelerated rates. Post-transfusion viability of preserved cells is a function of the length of storage (1).

Thus, the transfusion of stored blood, which always contains a certain quantity of cells in which irreversible changes have occurred, necessitates the removal of those dead or dying red cells from the circulation. These cells may rupture in the blood stream and, through release of hemoglobin, give rise to hemoglobinemia. It is also possible that they may be removed, with membranes relatively intact, by phagocytosis, or segregation in the spleen (4), and subsequently destroyed. In either event a load is imposed upon the mechanism for scavenging the blood stream and for the handling of hemoglobin-derived pigments: the reticulo-endothelial and the erythropoietic systems. Hemoglobinemia also involves renal function since there is a plasma level for hemoglobin above which hemoglobinuria occurs. The degree of this burden will be determined by the quantity of mortally damaged cells transfused (which will in turn depend upon the size of the transfusion, and, for any given preservative solution, the length and conditions of storage prior to transfusion), and the rate at which the blood is transfused.

In previous communications (5) it was concluded that the greater part of the non-viable cells are completely removed from active circulation, usually within 24 hours after transfusion, and that the remainder of the transfused cells resume normal functional capacity and enjoy a sojourn in the body equivalent to the remainder of their normal life expectancy. It is therefore only the non-viable portion of the transfused red cells that need be considered in the study of the effects of the transfusion of stored blood.

In a number of experiments in which blood, the cells of which were tagged with radioactive iron, was transfused, the initial recipient blood sample was taken within 60 minutes, and several subsequent samples within the first 14 hours of the beginning of the transfusion. Since little if any re-utilization of hemoglobin-derived radio-iron can be expected to occur in this period, the radioactivity of those blood samples accurately measured the quantity of transfused cells removed from the blood stream. These values may be expressed in terms of the percentage of total cells transfused or of the contained quantities of hemoglobin or of iron.

Such data were obtained in 9 transfusions of stored whole blood and in 15 transfusions of stored resuspended cells. The whole bloods were drawn into ACD-1 and Alsever's solution; they were transfused from 8 to 26 days after collecting.

Five of the bloods in ACD-1 had been transported, by

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts Institute of Technology, in collaboration with the Peter Bent Brigham Hospital, and the Massachusetts General Hospital.

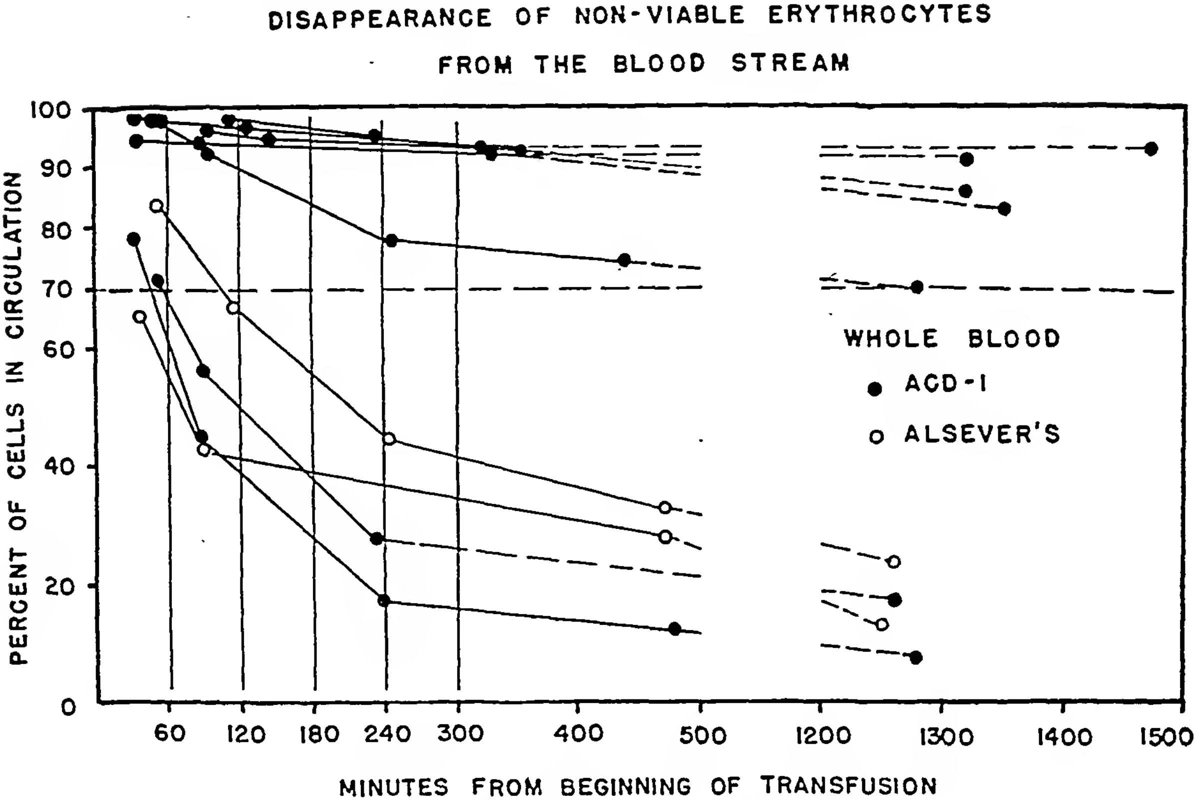

FIG. 1. DISAPPEARANCE OF NON-VIABLE ERYTHROCYTES FROM THE BLOOD STREAM

The percentage of total transfused tagged cells stored as whole blood in ACD-1 and Alsever's solution remaining in circulation during the first 1,500 minutes after beginning transfusion.

air, under constant refrigeration, from Boston, Massachusetts to Oakland, California, and back (5 days elapsed), and subsequently were stored at 4° C. Two bloods in ACD-1 and 3 in Alsever's solution had been transported by air, without constant refrigeration, from Boston to Paris, France (11 days elapsed), and subsequently were stored at 4° C.

The packed cells were resuspended in: a 10 per cent corn syrup; a citrate-buffered citrate-dextrose solution of pH 5.0; and a citrate-buffered citrate-dextrose solution containing 3 per cent Fraction IV-3, 4, Lot 301[2] (α and β globulin). The cells in the globulin-fortified solution had been in depot storage at 4° C. until transfused. The cells in corn syrup and in the acidified-citrate-dextrose solution were transported by truck, under controlled refrigeration (4 to 10° C.), from Boston to New York, and transfused into patients on the wards of the New York Hospital.[3]

[2] Prepared in the Pilot Plant of the Department of Physical Chemistry, Harvard Medical School, under the direction of Dr. E. J. Cohn.

[3] These experiments were carried out, under request from medical authorities of the U. S. Navy, represented by Lt. (s.g.) Henry Blake, U.S.N.R., in collaboration with Dr. Ralph G. Stillman, of the New York Hospital, and Dr. William Thalhimer.

The transfused quantities of whole blood in ACD and Alsever's solution ranged from 315 to 525 ml. (121 to 253 ml. of cells); cell resuspensions in corn syrup and in the citrate-buffered citrate-dextrose ranged from 315 to 520 ml. (147 to 256 ml. of cells); and cell resuspensions in the globulin-fortified resuspension solution, from 420 to 505 ml. (171 to 215 ml. of cells). The average of the 24 transfusions was 194 ml. Time required for transfusion varied from 13 to 65 minutes, and the rate of flow from 8 ml. to 36 ml. per minute, averaging 18 ml. per minute. The hematocrits of whole blood were from 28 to 46; and of cell resuspensions from 34.7 to 50.5; the average hematocrit of all the transfusions was 42.7. Survival during the first 24 post-transfusion hours ranged from 92 to 8 per cent for whole bloods and from 95 to 32 per cent for the cell resuspensions.

These quantities of whole blood and cells are well within the ranges encountered in single clinical transfusions; hence the data may be treated as a whole in applying the findings to transfusion practice. The average rate of inflow, 18 ml. per minute, is perhaps more rapid than that of the usual routine transfusion.

The quantity of whole blood or resuspension cells transfused, rate of inflow, and percentage of total transfused cells lost from circulation at suc-

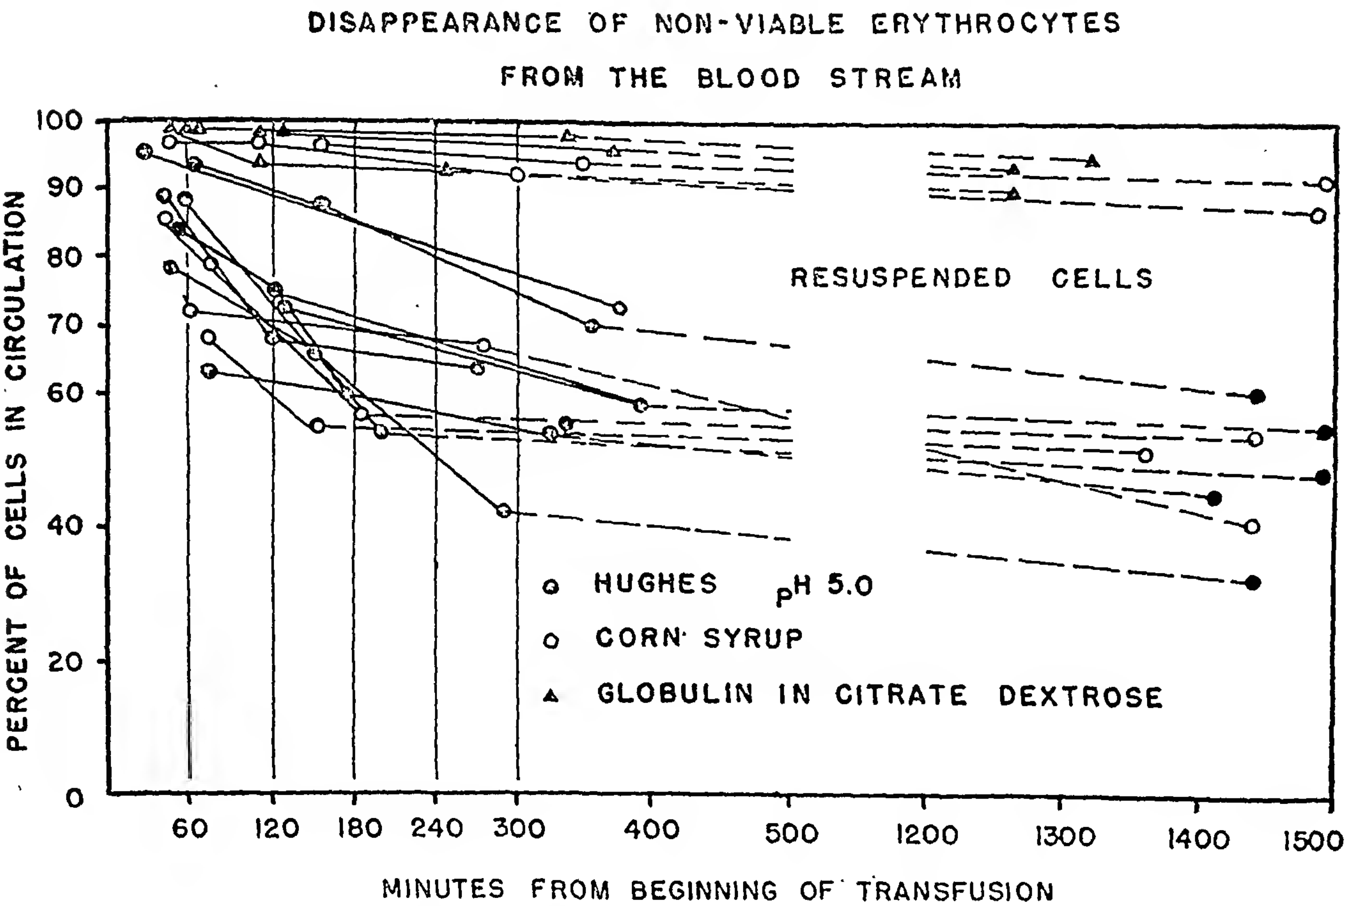

FIG. 2. DISAPPEARANCE OF NON-VIABLE ERYTHROCYTES FROM THE BLOOD STREAM

The percentage of total transfused tagged cells drawn as whole blood in 4 per cent sodium citrate and resuspended in 3 preservative solutions, remaining in circulation during the first 1,500 minutes after beginning transfusion.

cessive intervals from the beginning of the transfusion are shown in Table I. The percentages of cells remaining in circulation at intervals up to 1,500 minutes after transfusion are shown in Figures 1 and 2.

The post-transfusion behavior of both the cells stored as whole blood and the cells in resuspension was similar. The rate of loss of non-viable cells from transfusions in which the eventual survival was better than 80 per cent was slow and relatively constant. At 80 per cent survival, or better, the greater part of the loss occurred during the first 300 to 500 minutes from the start of the transfusion, there being, in general, little further loss during the remainder of the first 24 hours.

In transfusions, the survival of which was less than 80 per cent, the rate of loss of non-viable cells was rapid and tended to vary directly with the eventual survival. The rate of loss was greatest during the first 60-minute period, becoming progressively less during the next 24 hours. The

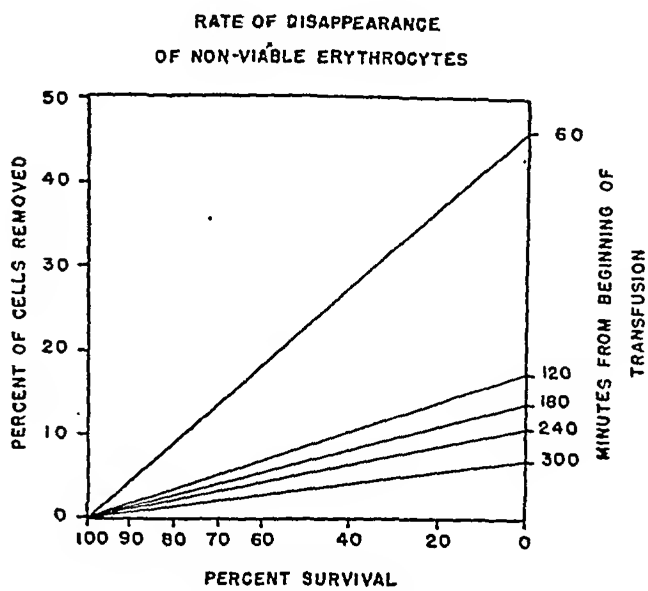

FIG. 3. RATE OF DISAPPEARANCE OF NON-VIABLE ERYTHROCYTES

The average percentages of total transfused tagged red cells removed from circulation during successive 60-minute intervals from beginning of transfusion, in relation to the percentage of survival.

maximum loss was not reached during the first 5 hours, but the rate of loss during the ensuing 19 hours was considerably less than during the first 5-hour period. It should be emphasized that even in the poorest transfusions the 24-hour data still measure disappearance uncomplicated by cell regeneration.

It is therefore apparent that the rate of disappearance of non-viable cells is a function of percentage of survival, which in turn is a function of time of storage.

It is possible, from the time survival curves presented in Figures 1 and 2, to determine, for the entire series of experiments, the average rate of disappearance of cells at given intervals after the beginning of transfusion for any percentage of eventual survival. The family of curves representing these rates at 60-minute intervals up to 5 hours after transfusion are shown, in relation to survival, in Figure 3.

It is evident that the loss of non-viable cells begins very soon after the administration of blood and, in badly deteriorated bloods, may begin during administration. Regardless of the survival, the rate of loss is most rapid during the first 60 minutes' post-transfusion period and decreases considerably during the ensuing four 60-minute periods.

This fact is more clearly evident in Figure 4, in which the average rates of loss of non-viable cells during the first 5 hours after the beginning of transfusion, expressed as per cent of cells lost per minute, are shown for transfusions ranging from 100 to 50 per cent survival.

In the same figure, the total quantity of hemoglobin that would be obtained from *immediate*

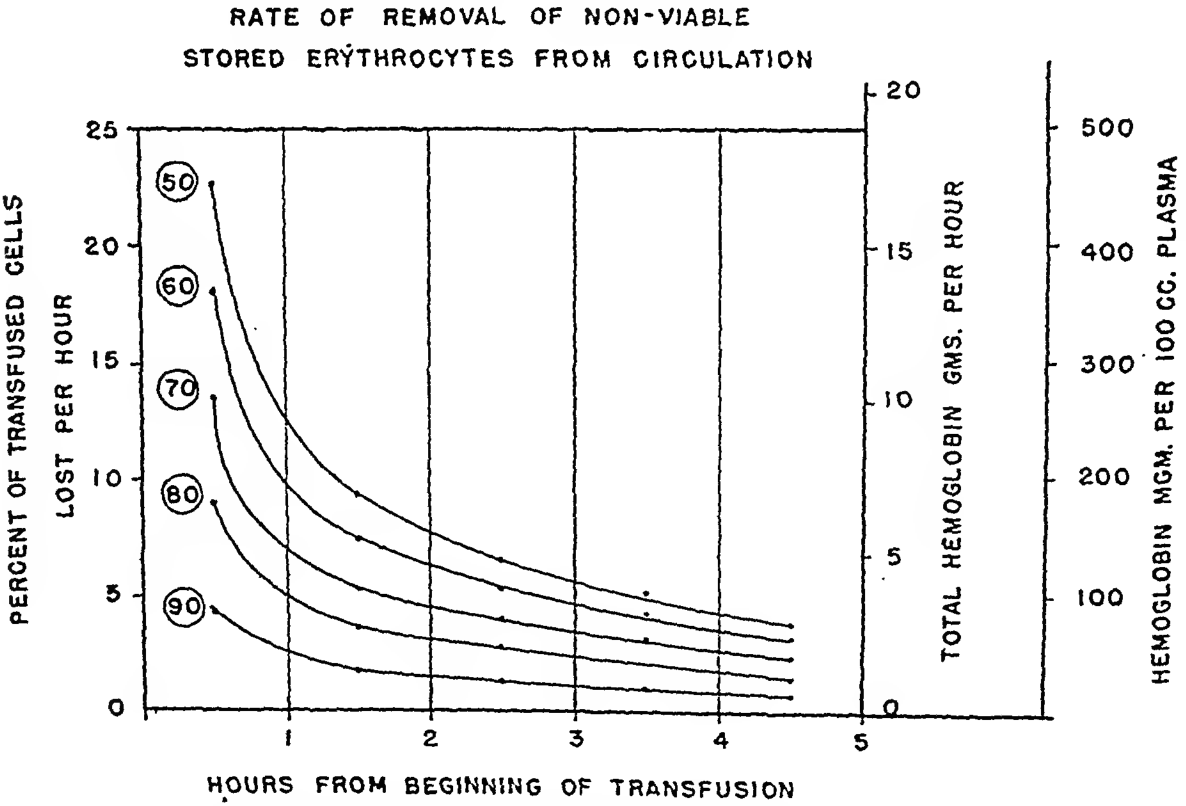

FIG. 4. RATE OF REMOVAL OF NON-VIABLE STORED ERYTHROCYTES FROM CIRCULATION

The average percentages of loss of the total transfused tagged red cells per hour during the first 5 hours from beginning transfusion, in bloods ranging from 50 to 100 per cent survival (indicated by figures in circles). The total amount of hemoglobin, in grams per hour (assuming immediate and complete intravascular hemolysis occurs), liberated from non-viable red cells following transfusion of blood surviving from 50 to 100 per cent, is shown in the first column on the right. The theoretical plasma hemoglobin level, in an individual with a plasma volume of 3,500 ml. resulting from complete retention of the liberated hemoglobin, is shown in the column on the extreme right.

intravascular hemolysis of non-viable cells is shown in relation to the per cent of transfused cells destroyed. These quantities are also plotted as mgm. of hemoglobin liberated per hour per 100 ml. of plasma, in an individual with a plasma volume of 3,500 ml.

Hemoglobinuria was observed only in those of our subjects who received full-sized transfusions of blood the survival of which was less than 50 per cent, and then was a transient affair, the urine being clear within a few hours after transfusion. Even in these subjects the rise in serum total bilirubin did not exceed 2 mgm. per 100 ml. of plasma. It is clear that many dead cells must be removed relatively intact from the blood stream. The role of the spleen in this regard is too well known to elaborate on.

The greatest burden of disposing of cell breakdown products is imposed within the first 2 hours after transfusion has begun. The extent of this load will vary inversely with the size of the transfusion, percentage of non-viable cells, and speed of inflow.

It would appear to be safe practice to set the lower limit of acceptable stored blood at 70 per cent post-transfusion survival. This certainly provides a margin of safety which might not be present were a less good survival accepted.

This concept affords a basis for the assignment of upper dating limit of bloods in the several solutions at present in use in certain blood banks.

Reference has been made (5) to the re-utilization of iron derived from broken down cells in the synthesis of new hemoglobin. It is of interest to know to what extent this blood iron is economized. Twenty-six experiments were completed in which recipient's blood samples were taken at frequent intervals, up to 21 days after transfusion, thus per-

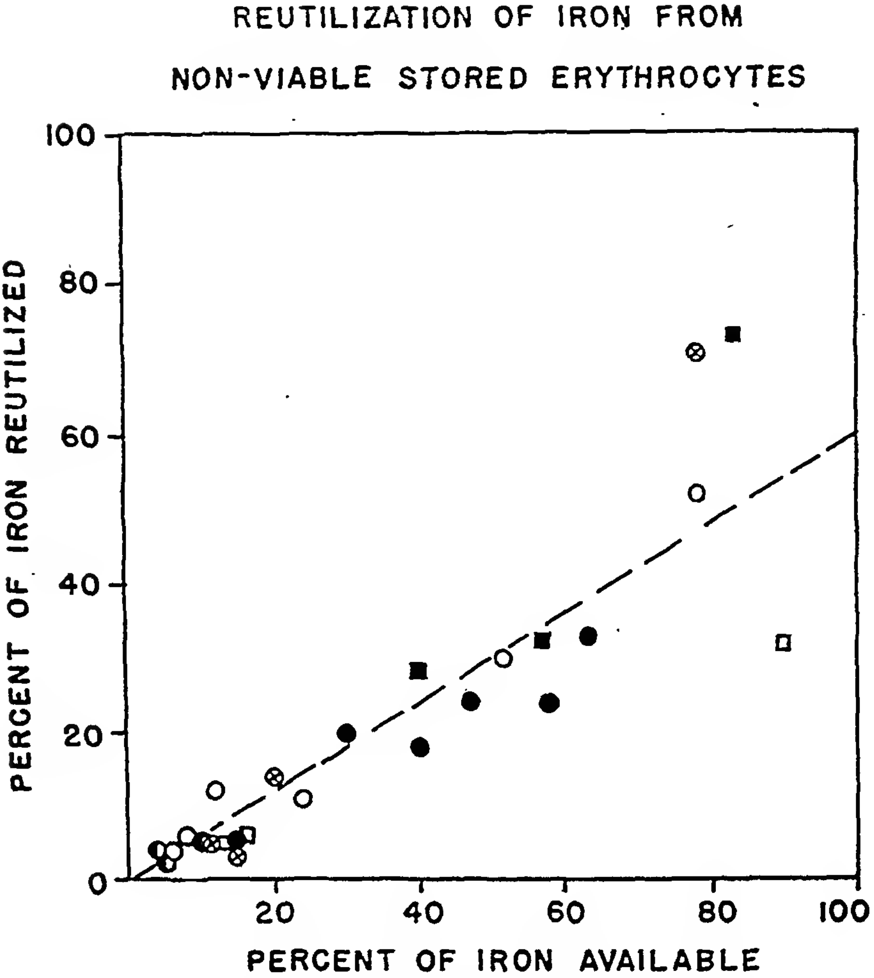

FIG. 5. RE-UTILIZATION OF IRON FROM NON-VIABLE STORED ERYTHROCYTES

The percentage of radio-iron derived from hemoglobin from liberated non-viable tagged transfused erythrocytes found in intact circulating red cells (re-utilized) in relation to the percentage of total transfused cells removed from circulation (available). About 60 per cent of the available iron is economized.

Symbols refer to the following blood preservatives:

● = ACD-1 ⊗ = De Gowin's solution
○ = McGill solution ■ = Cells in 10 per cent corn syrup
◐ = Parpart's solution □ = Cells in 0.85 per cent saline.

mitting measurement of maximum re-utilization. Significant data from these experiments are shown in Table II. In 5 of the series the cells were transfused as whole blood; in 3 as resuspended cells. The quantity of cells given was small, ranging from 19 to 68 ml., averaging 41 ml., the contained hemoglobin, averaging about 15 grams. Individual circulating red cell volumes were from 1,780 ml. to 2,520 ml., averaging 2,214 ml. Survival was from 100 to 17 per cent.

The method of computing the percentage of transfused cells retained, in circulation and regenerated, has been described elsewhere (5). The percentage of iron available for resynthesis is taken as the arithmetic difference between 100 per cent and the percentage retained. These values are listed in Table II. together with the percentage of available iron actually re-utilized.

The percentage of iron re-utilized is plotted against the per cent available, in Figure 5. It is apparent that about ⅔ of the iron does eventually return to the blood stream in the hemoglobin of

new circulating red cells and that this percentage is relatively constant within the range of the dosage given. Forty ml. of cells contain about 50 mgm. of iron. Hence the iron administered as defunct cells ranged from 0 to 40 mgm.

Hahn, *et al* (6) have demonstrated that the absorption of radioactive iron from the normal gastrointestinal tract, as measured by the amounts detectable in circulating red cells, is extremely small. Cruz (7) also found that radio-iron liberated from hemoglobin from destroyed red cells was utilized nearly quantitatively even in the presence of normal iron reserves. It is of considerable interest that iron given intravenously, as hemoglobin in non-viable cells, is utilized approximately 20 times as efficiently as when iron is given orally.

Sufficient data are not available at present to determine the efficiency of utilization when larger amounts of hemoglobin iron are made available. In many experiments, however, in which full transfusions of very much deteriorated cells were given, the recipient's circulating red cell radioactivities have shown utilization of from 10 to 30 per cent of the available iron on the fifth post-transfusion day. Since ½ of the per cent available utilized is usually present on the fourth to seventh post-transfusion day, this would suggest excellent economy of quantities at least 10 times those dealt with in the above experiments.

CONCLUSIONS

(*1*) Non-viable stored human erythrocytes are rapidly removed from the blood stream after transfusion.

(*2*) The rate of removal of non-viable cells varies inversely with the percentage survival of the transfused tagged cells.

(*3*) At or above 80 per cent survival, non-viable cells are completely removed in 24 hours; below this survival level, loss of non-viable cells may continue into the second post-transfusion day.

(*4*) At any survival level, the majority of non-viable cells are removed from the blood stream during the first 2 hours after transfusion.

(*5*) On theoretical and practical grounds 70 per cent retention of all transfused cells may be considered the lowest safe survival level.

(*6*) The bodily economy of iron derived from the hemoglobin of non-viable cells is such that the utilization is about 20 times that of equivalent amounts of iron given orally.

THE EFFECT OF VARYING TEMPERATURES ON THE POST-TRANSFUSION SURVIVAL OF WHOLE BLOOD DURING DEPOT STORAGE AND AFTER TRANSPORTATION BY LAND AND AIR[1]

By JOHN G. GIBSON, 2ND, THEODORE SACK, ROBLEY D. EVANS, AND WENDELL C. PEACOCK

(From the Radioactivity Center, Massachusetts Institute of Technology, Cambridge, Massachusetts; the Medical Clinic of the Peter Bent Brigham Hospital, and the Department of Medicine, Harvard Medical School, Boston, Massachusetts)

(Received for publication August 31, 1946)

The successful establishment of a military whole blood transfusion service is dependent upon reducing damage to the cells from mechanical agitation incident to land, sea, and air transportation to a minimum. Robertson (1) successfully transported whole blood in Rous-Turner solution by ambulance for short distances in World War I. Blood from civilian donor centers was shipped to front lines during the Spanish Civil War (2). Maycock has reported on the use of blood transported in refrigerated trucks during the Battle of Flanders (3). During the invasion of Europe blood banks were in operation in many theatres, blood being obtained from military personnel, a necessarily limited source of supply.

The establishment of the American Red Cross Blood Donor Service, taking blood for processing of plasma, afforded a potentially adequate supply source, provided blood could withstand shipment across the Atlantic and far out into the Pacific oceans. The distances involved were so great that air transport was the only feasible means of transportation that would get blood to medical personnel before it had seriously deteriorated.

It was obvious that only the best known whole blood preservatives would suffice, and 2 solutions, Alsever's (4) and acid-citrate-dextrose (5), were under consideration by the Armed Forces at the time this study was undertaken. The comparative value of these 2 solutions for depot storage under constant refrigeration has been reported (6), ACD being superior to Alsever's. The survival of these cells in these preservatives after long-range shipment, with and without controlled refrigeration, was not, however, known.

De Gowin (7) in 1941, transported whole blood in a modified Rous-Turner solution in vacuum collecting bottles for distances up to 720 miles by automobile, and up to 3,500 miles by airplane. The bottles were refrigerated with cracked ice which was replaced, if melted, every 12 hours. These bloods were transfused without reactions, although no post-transfusion survival studies were made. Marked destruction of cells as evidenced by hemolysis did not occur. Kendrick, *et al* (8) concluded that "blood collected in Alsever's solution, after adequate pre-chilling (24 hours), could be flown unrefrigerated for 24 hours from the United States to the United Kingdom and would be safe to use for 21 days after collection, that is, when the blood is refrigerated continuously following its arrival in the United Kingdom."

These experiments were designed to define the optimal temperature of refrigeration and the effect of uncontrolled refrigeration both during depot storage and during land and aerial transportation. The effects of extreme ranges of temperature, from $-4°$ C. to $+40°$ C., were studied in bloods in both ACD-1 and Alsever's solutions stored in depots. Since the problem of successful transportation involved the determination of adequate refrigeration range, experiments were conducted in which bloods were transported by air both under controlled and uncontrolled refrigeration.

The method of measuring post-transfusion survival by means of 2 isotopes of radioactive iron has been previously described (9, 10).

DEPOT STORAGE EXPERIMENTS

In all these experiments blood from the same donor was taken in equal amounts into both solutions (except

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts Institute of Technology, in collaboration with the Peter Bent Brigham Hospital.

Experiments 51 through 55), and aliquots of each were transfused after storage for equal periods of time under identical temperature conditions.

Experiments 65 (Alsever) and 66 (ACD)

The aliquots of blood were stored at 4° C. for 4 hours and then removed to a constant temperature apparatus and kept at −4° C. for 24 hours. They were then returned to storage at 4° C. until transfused, the blood in ACD at 8 days and that in Alsever's solution at 9 days after drawing. Each transfusion contained about 50 ml. of cells. The blood did not freeze and there was only slight hemolysis in the supernatant fluid. Survival in both experiments was about 75 per cent. Neither recipient experienced any reaction.

Experiments 57, 59, 61 (Alsever) and 56, 58, 60 (ACD)

The aliquots of this blood were kept at 4° C. throughout the whole storage period and were transfused at 11, 15, and 21 days after drawing, described above in the section on whole blood preservatives. Survival in both solutions was satisfactory (70 per cent or better) up to 21 days.

Experiments 63 (Alsever) and 62 (ACD)

Bloods were stored 46 hours at 4° C., then allowed to stand at room temperature (20 to 25° C.) for 24 hours, and returned to storage at 4° C. until transfused 18 days after drawing. Each transfusion contained about 100 ml. of cells. The recipient of the ACD blood had a mild transient febrile reaction, and rabbit pyrogen test on the supernatant was positive. The other recipient had no reaction and the pyrogen test was negative. Survival of blood in ACD was better than that in Alsever's, but both were less good than was obtained for bloods in both solutions stored at 4° C. for 18 days.

Experiments 67 (Alsever) and 64 (ACD)

Bloods were stored at 4° C. for 4 hours, then transferred to an incubator where they remained at +40° C. for 24 hours, and returned to storage at 4° C. until trans-

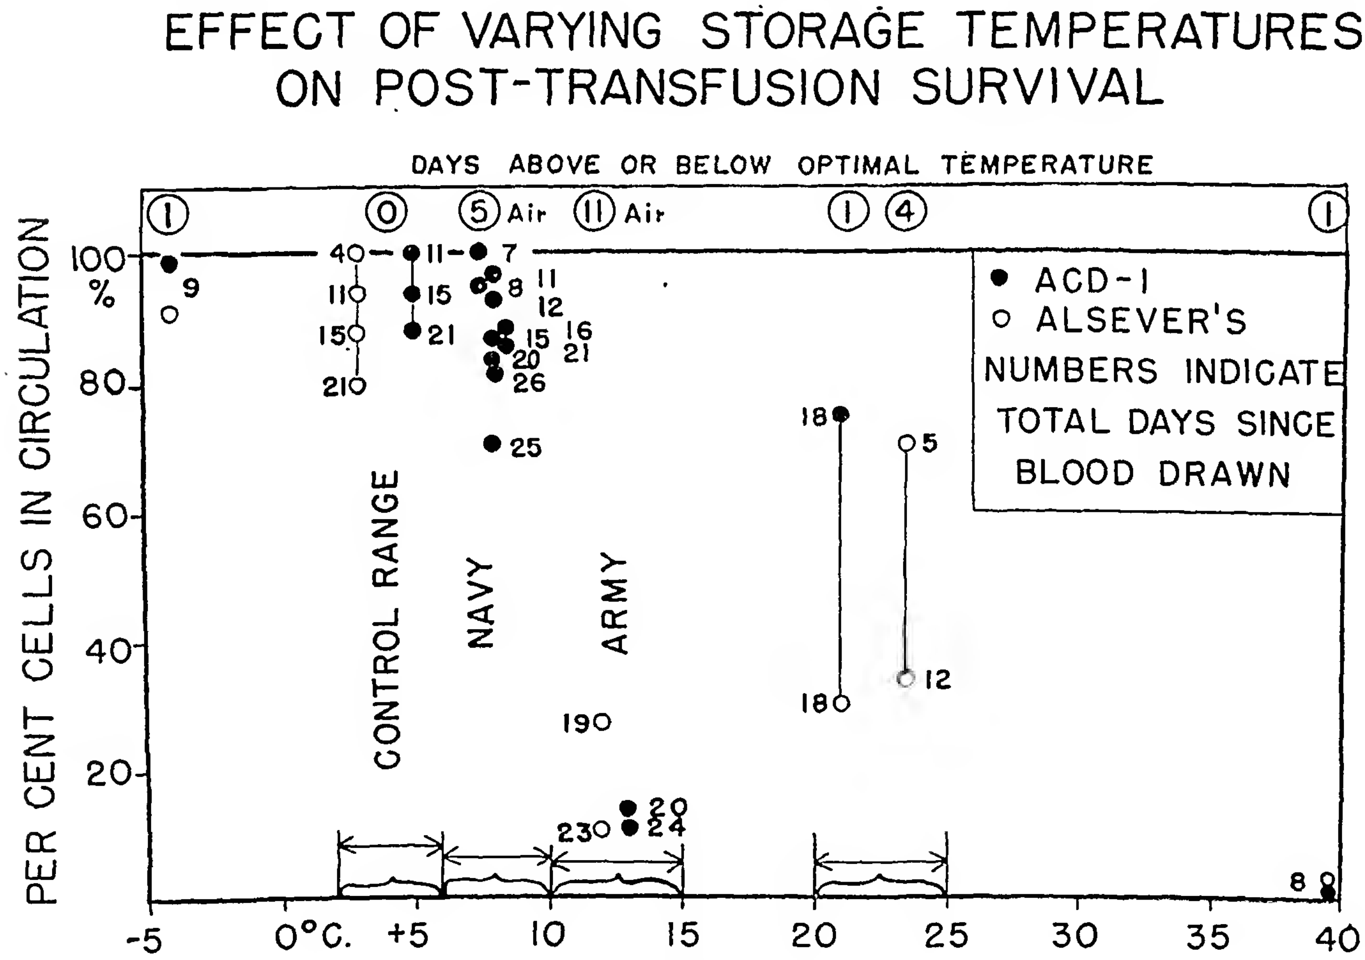

Fig. 1

Figures within circles indicate the days bloods were at, above, or below the optimal (control) range. In all instances the bloods were returned to storage at 4 to 6° C. after exposure to the test temperatures. Aerial transportation, with adequate refrigeration, is not deleterious. Lack of adequate refrigeration is deleterious both during aerial transport and subsequent optimal refrigeration. Exposure to room temperature for even short periods is harmful.

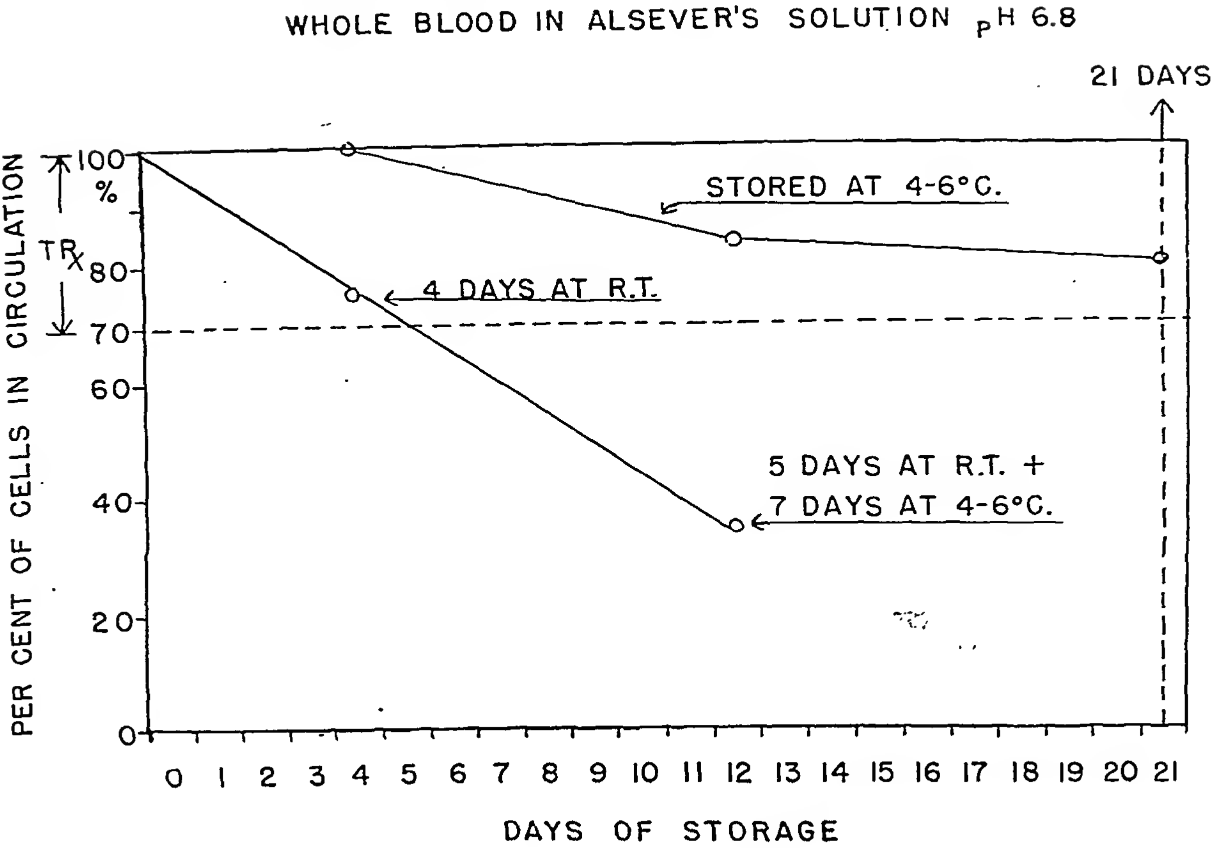

FIG. 2

All aliquots of blood in Alsever's solution were drawn from the same donor. Storage for 4 days at room temperature (20 to 25° C.) initiated deteriorative changes, as evidenced by the superior (25 per cent) survival of the aliquot in depot storage at 4° C. for 4 days, the rate of which was not retarded by subsequent refrigeration at 4° C.

fused 8 days (Alsever's) and 7 days (ACD) after drawing. Each transfusion contained about 80 ml. of cells. The supernatants of both bloods were deeply hemolyzed, but neither recipient had a reaction. Virtually no radioactive cells were found in the blood stream of either recipient 24 hours after transfusion.

The survival data obtained in these depot storage experiments are shown in Figure 1.

Experiments 51 through 55 (Alsever)

These experiments were designed to determine whether deteriorative changes that might occur at room temperature could be arrested by subsequent storage at lower ranges.

Blood from 1 donor was taken into Alsever's solution and divided into 5 equal aliquots. Three of these were transfused after storage at 4° C. for 4, 12, and 21 days after drawing. Another was transfused after storage at room temperature (20 to 25° C.) for 4 days. The other was kept at room temperature for 5 days, then stored at 4° C., and transfused 12 days after drawing. Each transfusion contained about 50 ml. of cells. No reactions occurred.

As shown in Figure 2, survival after 4 days at room temperature was markedly less than after 4 days at 4° C., and even worse after subsequent refrigeration at 4° C. for 7 additional days than was the control stored at depot temperature.

TRANSPORTATION EXPERIMENTS

Two series of experiments were carried out; in one, blood was taken into ACD and transported under controlled refrigeration,[2] while, in the other, bloods in both ACD and Alsever's solution were transported under uncontrolled refrigeration.[3] In both experiments, the bloods were flown about 6,000 miles, in the first overland and in the second overseas.

---

[2] This experiment was undertaken at the request of the U. S. Navy, Medical Corps, in cooperation with Capt. Lloyd Newhouser, U.S.N., M.C.

[3] This experiment was undertaken at the request of the U. S. Army, Medical Corps, in cooperation with Capt. John Elliott, A.U.S., Sn.C., Capt. John Reichel, A.U.S., M.C., and Capt. Ellis Vaubel, A.U.S., M.C.

Controlled refrigeration. Experiments 68 through 77

Full bleedings (480 ml.) were taken on the same day from each of 10 group O, Rh positive radioactive donors into standard 600 ml. vacuum bottles containing 120 ml. of ACD and were immediately refrigerated at 4° C. The

Refrigerator on return from Oakland, California.

refrigerator (Figure 3) in which these bloods were transported was made for this experiment at the Naval Medical Center, Bethesda, Maryland, and consisted of an insulated wooden chest, with 12 compartments for blood bottles and a single large central compartment for water ice and a tightly fitting insulated cover. A Bristol gas-filled recording thermometer was attached to the refrigerator in such a way that the thermal element lay between the 2 rows of bottles. A thermal indicator was attached to the neck of each bottle. These were "L" shaped glass bulbs containing dioxane, the melting point of which is + 10° C. They were frozen with the dioxane all in 1 arm of the tube and so mounted on the bottle that the frozen arm was uppermost. Exposure to temperatures above 10° C. melts the dioxane which then flows into the lower arm, where it remains even though re-frozen.

This shipment of blood went by National Air Transport Service from the East Boston Airport to the National Airport at Washington; from there to Oakland, California, and was returned by National Air Transport Service from Oakland directly to Boston. The package was placed in a cold room at the Naval Medical Center in Bethesda, Maryland, and also at Oakland while awaiting air transportation. The time elapsed between leaving from and returning to Boston was 122 hours. The package was in flight 22 hours, and in mechanical refrigerators for 34 hours. During the remaining 66 hours, the only refrigerant was the ice in the box itself. The box was re-iced once in Oakland during the 5-day trip. The distance covered by air was about 6,000 statute miles.

The recorded temperatures (Figure 4), when corrected for variations in altitude during flight, did not exceed 15° C. at any time during the trip, and 6 of the dioxane indicators were melted and 4 still frozen, with the dioxane in the upper arm of the tube, on arrival. They were promptly returned to depot storage at 4° C.

The condition of these bloods, as determined by *in*

$$\text{per cent cells hemolyzed} = \frac{\text{ml. supernatant} \times \text{Hb. in mgm. per cent}}{\text{Total Hb. in mgm.}}.$$

vitro studies carried out just prior to transfusion, is shown in Table I. Very little hemolysis had occurred, amounts present in the supernatant of a centrifuged sample representing hemolysis of less than 1 per cent of the total cells drawn. The pH of the supernatants ranged from 7.2 to 6.94. Fragility tests showed from 10 to 28 per cent hemolysis in 0.6 per cent NaCl.

These 10 bloods were transfused into group A, Rh positive individual recipients, each of whom had previously been bled 500 ml., at intervals of from 7 to 26 days after drawing. All the blood in the bottle was given except in the cases of the 25- and 26-day-old bloods in which about ½ of the contents was given. Two recipients, with allergic histories, experienced anaphylactoid reactions, and 3 exhibited symptoms which could be attributed to rapid breakdown of red cells. Subsequent analysis of data in one of these receiving a high titre blood, indicated that his own cells had been destroyed (10).

As shown in Table I and Figure 1, the post-transfusion survival of these bloods was not less than 80 per cent up to 21 days after drawing, and not less than 70 per cent in the two oldest bloods.

Uncontrolled refrigeration. Experiments 78, 80 (Alsever); 79, 81 (ACD)

Five hundred ml. of whole blood from each of 5 donors were taken into 500 ml. of pre-chilled Alsever's solution in standard 1,000-ml. vacuum bottles, and 480 ml. of whole blood from each of 5 donors into 120 ml. of pre-chilled ACD in standard 600-ml. vacuum bottles. All donors were group O, Rh positive, and were bled the same day. The bloods were refrigerated immediately after drawing. The bottles were prepared for shipment in a manner simulating that in routine use at the time by the Army Medical Corps for overseas aerial transport. They were replaced in the manufacturer's cartons which were then wrapped in heavy brown paper and sealed with gummed tape. Just prior to this, a dioxane (M.P. 10° C.), caprylic acid (M.P. 15° C.) and a water (F.P. −2° C.) thermal indicator was attached to the neck of each bottle. The 2 cartons, one containing blood in Alsever's and the other blood in ACD, were fastened together and placed in a light wooden box attached to the same recording thermometer used in the previously described experiments, the thermal element being enclosed within the cartons.

This shipment was flown from Boston to La Guardia Field, N. Y., and thence by Air Transport Service to Paris, where it arrived 6 days later. The recorded temperature was 15.6° C. and the package was refrigerated at 3.3° C. in Paris, for 31 hours. It was then flown back to La Guardia Field where it was again refrigerated until returned to Boston. It was en route 11 days. No refrigeration was used during air passage.

Immediately on arrival the bottles were refrigerated at 4° C. All of the dioxane, 5 of the caprylic acid, and all of the water indicators were melted. The exact number of hours the package had been in flight, in refrigerators, or unrefrigerated is not known. The graph of the recording thermometer was blurred so that no readings could be obtained.

The conditions of these bloods, as determined by *in vitro* tests carried out just prior to transfusion, is shown in Table I. Very little spontaneous hemolysis occurred. The pH of the supernatants ranged from 6.65 to 6.80, and hemolysis in 0.6 per cent NaCl from 50 to 83 per cent.

Two bloods in half amounts in Alsever's were transfused at 19 and 23 days, and 2 in ACD at 20 and 24 days after drawing. Each transfusion contained about 125 ml. of cells. The remaining bloods were not transfused. One recipient experienced moderately severe symptoms of rapid breakdown of cells but without lasting sequelae. Post-transfusion survival ranged from 9 to 27 per cent, as shown in Figure 1.

DISCUSSION

It is evident from Figure 1 that the optimal survival of cells in both solutions, in depot storage,

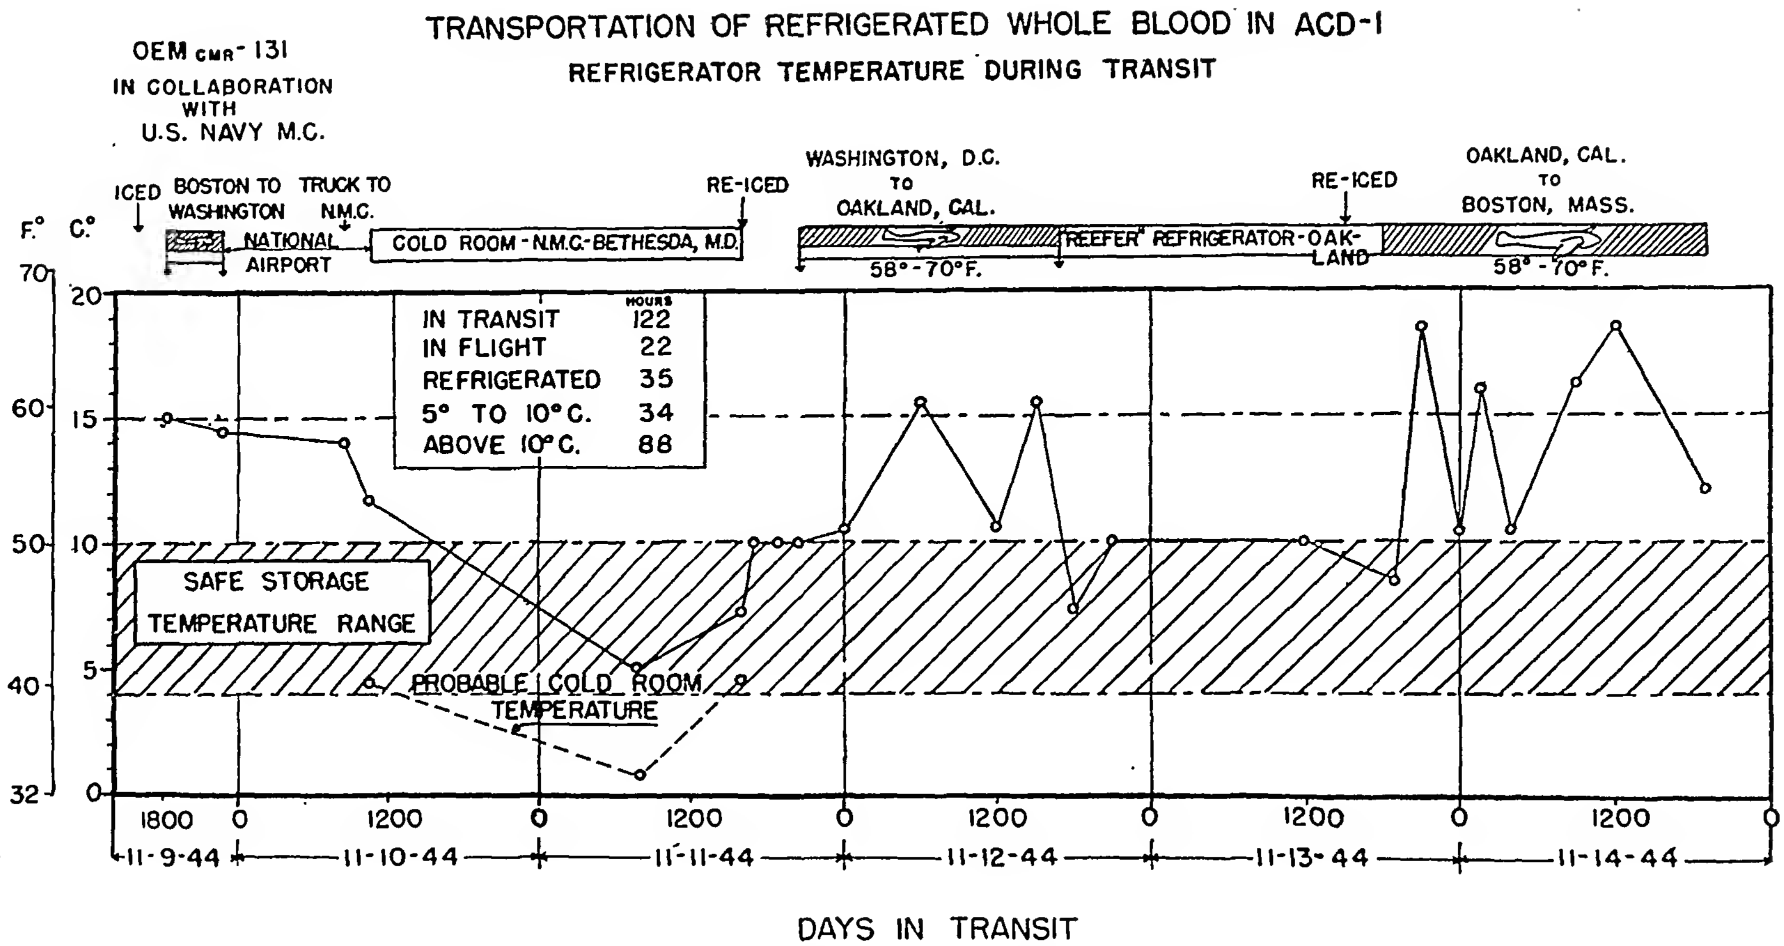

FIG. 4. BLOODS IN BOTH ACD-1 AND ALSEVER'S SOLUTION WERE TRANSPORTED BY AIRPLANE ABOUT 6,000 MILES AS DESCRIBED IN THE TEXT

The cross-hatched bars indicate the time elapsed from leaving and returning to our laboratory; the open bars, the period in depot storage at 4° C. after return. The survival of the bloods transported under controlled refrigeration was equal, at any given observation period, to that of whole blood in ACD-1 in depot storage at 4° C. None of the bloods transported under uncontrolled refrigeration were fit for transfusion, in spite of a period of depot storage at 4° C.

was obtained in the series stored at 4° C. Slight deterioration was evident in the cells stored at − 4° C., much more at room temperature, while complete deterioration occurred at + 40° C. The results obtained in Experiments 51 through 55 indicate that once deterioration is initiated at room temperature, it is not retarded by subsequent storage at lower temperatures, as shown in Figure 2. The data in Figure 2 also indicate a slightly superior ability of cells in ACD to stand up under adverse thermal conditions than in Alsever's solution.

It is apparent that controlled refrigeration at not over 10° C. is an essential for the satisfactory preservation of cells during transportation.[4] No significant deterioration of cells in ACD–1 resulted from the mechanical agitation incident to land and air travel, in the experiment in which temperature was maintained with a fair degree of constancy at about 10° C., since the survival after 5 days of travel and 16 days of subsequent refrigeration was as good as that obtained for blood in the same solution after depot storage for a similar period.

It is also evident that lack of constant refrigeration had extremely injurious effects on red blood cells taken in either ACD or Alsever's solution. The results that would have been obtained had the transportation period been 11 days instead of 5 in the first experiment cannot be known, and unfortunately none of the bloods shipped without controlled refrigeration could be transfused until 19 days after drawing. It was stated above that deterioration is accelerated at temperatures in the region above 15° C. and that this rapid deterioration is not slowed by subsequent cooling. The excellent preservation of the ACD bloods would therefore suggest that little damage was done during transport, since the bloods were in depot storage for from 2 to 21 days after their return, ample time for progressive changes to have continued, had they been initiated during flight.

Evidence was obtained that, in the second experiment, the temperature around the bottles had exceeded 15° C. (melted caprylic acid indicators), and itinerary records obtained make it clear that the package was exposed to temperatures as low as 4° C. at various times. Hence, the bloods were subjected to a fluctuating rather than evenly maintained temperature. It seems probable that marked damage was initiated during transportation and continued during subsequent depot storage.

Because of the extreme degeneration, no comparison between the value of the 2 preservatives during transportation at high temperatures can be made.

In a previous paper (11), we stated that no serious danger to a recipient need result from a full transfusion of stored blood of which at least 70 per cent of the cells remained viable, since the rate of destruction of the non-viable cells was slow, but that hemolysis of cells might occur at a rate and in quantities sufficient to raise the plasma hemoglobin level well above the renal threshold if less than 70 per cent of the transfused cells were

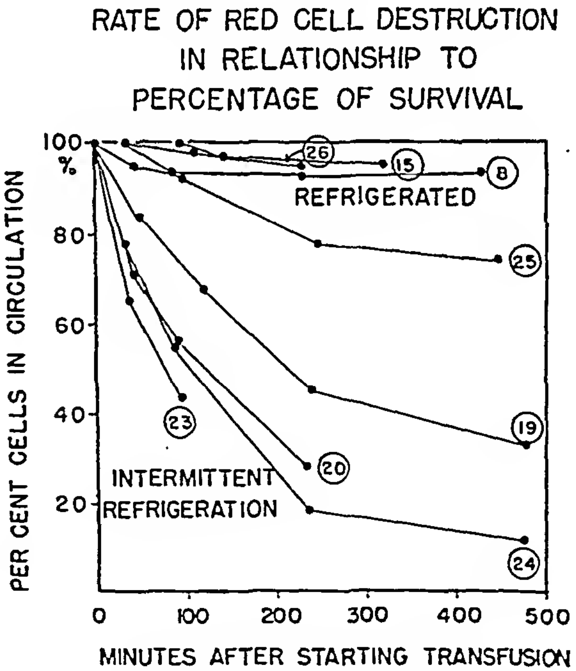

FIG. 5. RATE OF RED CELL DESTRUCTION IN RELATIONSHIP TO PERCENTAGE OF SURVIVAL

The rate of removal of non-viable tagged cells from the blood stream was far less in the refrigerated bloods, the preservation of which was good, than in the intermittently refrigerated bloods, the preservation of which was poor. The figures in the circles refer to the number of days elapsed from drawing to transfusion of blood.

[4] The authors wish to state clearly that no adverse criticism of the performance of the U. S. Army M.C. in flying thousands of bloods in Alsever's solution to E.T.O. is implied. The experiments cited do, however, illustrate the effects of 2 different ranges of temperature control during transportation.

viable. Figure 5 shows the rate of disappearance of cells from the recipient's circulation in both ACD–1 and Alsever's solution, transported under adequate and intermittent (inadequate) refrigeration. It is evident that the greater part of the non-viable cells are eliminated during the first 4 hours after transfusion and that a heavy hemoglobin load may have been placed on those subjects who received the inadequately refrigerated bloods.

The *in vitro* tests were of some value. The relationship of survival as measured by radio-iron and as predicted from changes in osmotic fragility (100 per cent – per cent hemolysis in 0.6 per cent NaCl) was quite good. The supernatant of the refrigerated bloods was slightly alkaline or acid, that of the intermittently refrigerated bloods definitely acid, reflecting a greater production of organic acids in the latter.

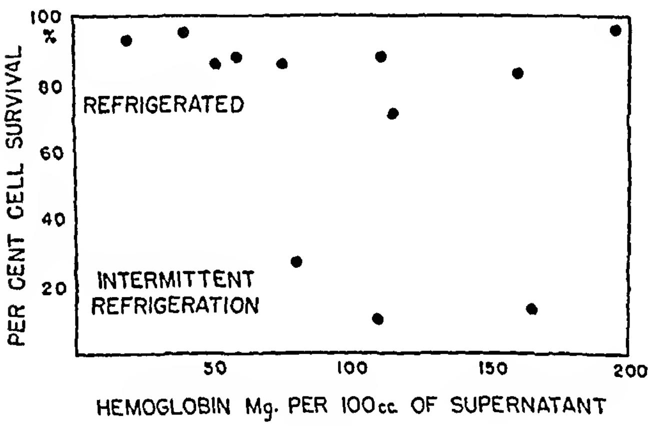

FIG. 6

No correlation between the degree of spontaneous hemolysis, as evidenced by the concentration of hemoglobin in the supernatant plasmas, and the post-transfusion viability of the non-hemolyzed cells was observed in these experiments. The absence of supernatant hemolysis is no criterion of transfusibility. It does not follow that badly hemolyzed bloods can be safely transfused.

A striking fact is the complete lack of correlation between the degree of hemolysis and the measured survival. This is clearly shown in Figure 6. Supernatant hemoglobin ranged from 30 to 196 mgm. per cent in the refrigerated bloods, and from 79 to 166 in the intermittently refrigerated bloods, and yet survival was excellent in the former and extremely poor in the latter series. This does not imply that markedly hemolyzed bloods will have good survival but does demonstrate that absence of spontaneous hemolysis is no indication that stored blood in either ACD–1 Alsever's solution is fit for transfusion.

CONCLUSIONS

(*1*) Refrigeration is an absolute essential f preservation of human erythrocytes drawn a whole blood in either ACD–1 or Alsever's solu tion.

(*2*) The optimal range for depot storage lies between 4° C. and 10° C.

(*3*) Exposure to temperatures below – 4° C. or above 10° C., even for a 24-hour period, increases the rate of *in vitro* deterioration; and this rate is markedly accelerated at temperatures above 15° C.

(*4*) The rate of deterioration resulting from storage at temperatures outside of the optimal range is not retarded by subsequent storage at 4 to 6° C.

(*5*) Whole blood in ACD–1 was transported under refrigeration within the optimal temperature range for 6,000 miles by air; and post-transfusion survival was as good up to 26 days as whole blood in ACD–1 maintained in depot storage at 4° C. for a similar period.

(*6*) Transportation of blood in either ACD–1 or Alsever's under variable temperatures 4 to 15° C. may lead to rapid deterioration of cells in spite of subsequent storage at the point of arrival under optimal refrigeration.

(*7*) The absence of spontaneous hemolysis in bloods transported under controlled or intermittent refrigeration should not be regarded as evidence that such bloods can be safely transfused.

ANTITULARENSE SERUM: CORRELATION BETWEEN PROTECTIVE CAPACITY FOR WHITE RATS AND PRECIPITABLE ANTIBODY CONTENT

By L. FOSHAY, I. RUCHMAN AND P. S. NICHOLES

(From the Department of Bacteriology, College of Medicine, University of Cincinnati, and the Cincinnati General Hospital)

(Received for publication July 21, 1946)

Heretofore all attempts to demonstrate protective antibody in antitularense serums have failed whenever animals were challenged with a strain of high virulence. Previous test animals have been the mouse, guinea pig, hamster, and rabbit. Sources of immune or hyperimmune serums were goats, horses, sheep, rabbits, and man. Our considerable unpublished experience with these animals and serums is in good agreement with the reports of Francis and Felton (1) and Bell and Kahn (2). If injected with serum before challenge these animals will usually exhibit significant prolongations of the survival time beyond that of control animals, but no actual survivals against as little as 1 to 10 M.L.D. of a virulent challenge strain.

The inability to demonstrate serum protection in these highly susceptible animals has contributed to a widespread but unfounded belief that immune and hyperimmune serums are ineffective therapeutic agents in human tularemia. Although reports by Foshay (3, 4) on the results of serum therapy in individual patients, as well as analyses of accumulated data derived from the independent observations of more than 600 clinical observers, have continued to demonstrate significant reductions in mortality and highly significant reductions in morbidity in comparison with comparable data from untreated patients, universal acceptance of the value of serum therapy has been impeded by a lack of suitable means to demonstrate protective antibody and to establish quantitative criteria for potency. The work here reported was undertaken to supply these deficiencies.

The inability of the highly susceptible mouse, guinea pig, hamster, and rabbit to react with any useful degree of resistance before death occurs following infection with a single virulent unit of *Bacterium tularense* makes these animals unsuitable test hosts for serum protection experiments. The reasons for this inability, obviously inoperative for many other infectious agents under similar conditions of testing, are unknown at present. The reactions of these animals to invasion are quite unlike that of man, for whom there is ample evidence that the great majority rapidly develop a high degree of resistance, resulting in a disease that is characterized clinically by a low mortality and, pathologically, by tissue reactions that soon exhibit subacuteness and chronicity.

During the course of the initial investigations on this disease, McCoy (5) noted that rats, both gray and white, were highly resistant to cutaneous infection and considerably resistant to subcutaneous inoculation. Infection was proved by demonstration that the spleens of rapidly recovered rats harbored the virulent organisms. Since the reaction to invasion by the rat more closely approximates that of man than do those of other laboratory animals, the rat was chosen as the test animal for serum protection studies.

MATERIALS AND METHODS

Rats. All rats employed were of the Wistar strain. Special care was taken to secure groups of animals of similar weight in order to insure uniformity of results. The permissible variation in weight was from 70 to 115 grams, and the great majority varied between 85 and 110 grams.

Challenge strain. The strain of *Bacterium tularense* used was the highly virulent strain SCHU, which had been studied extensively and had been maintained frequently in animal passage since its isolation in 1941. Its subcutaneous LD_{50} titers for mice, guinea pigs, and rabbits varied from 9.1 to 9.7/0.5 ml. The LD_{50} titers were determined by the method of Reed and Muench (6). They are expressed as the logarithms of the dilutions, disregarding the minus sign.

Challenge suspensions. Challenge suspensions were prepared from the second of 2 consecutive 16-hour subcultures on glucose glycerol cystine human blood agar. The growth was placed in physiological salt solution and suspended evenly by means of a fine bore pipette. Each

suspension was adjusted to a turbidity of 40 microamperes (M.A. 40) in 18-mm. tubes by means of a reflecting photoelectric comparator. These 10° suspensions were used to make serial decimal dilutions in physiological salt solution.

Challenge dose. The challenge dose for all rats was 1 ml. of M.A. 40×10^{-2} dilution, administered subcutaneously. Many plate counts made by the method of Downs, Coriell, Chapman, and Klauber, as well as numerous virulence titrations in mice, showed that the M.A. 40 suspension contained from 2.5 to 3 billions of viable organisms per ml. Hence, the challenge doses contained at least 25 millions of viable, virulent organisms.

Serums. The serums used had the following histories.

A. Hyperimmune goat serum, pooled from bleedings of 4 bucks that had been inoculated intravenously 3 times a week for 5 months with saline suspensions of living strain SCHU. The initial agglutinin titer was 1:20,480; at the time of rat testing it was 1:5,120. The unconcentrated serum, preserved with merthiolate to 1:30,000, had been stored in 60-ml. quantities at 5° C. This serum was 15 months old at the time of the first protection test.

B. Hyperimmune goat serum, pooled from bleedings of 3 bucks that had been inoculated subcutaneously 3 times a week for 1 month with saline suspensions of living strain SCHU. Each of these animals had been inoculated intravenously during the previous year, for preparation of serum A. The initial agglutinin titer was 1:10,240+; at the time of rat testing it was 1:1,280. Unconcentrated serum was preserved with merthiolate to 1:30,000 and held in 60-ml. quantities at 5° C. This serum was 4 months old at the time of the first test.

C. Hyperimmune horse serum No. 50737, obtained from Sharp & Dohme; pooled from 8 bleedings of 1 horse. This animal had been inoculated intravenously twice a week with formalin-killed suspensions of strain SCHU for 11½ months during 1942. During 1943 it was inoculated intravenously 3 times a week for 2 months with suspensions of living strain SCHU and, similarly, with living suspensions for 4 months during the next year. Thereafter, in order to avoid infection of unprotected personnel, formalin-killed suspensions of this strain were injected intravenously as maintenance doses during the first half of the bleeding period. During the second half of this period maintenance inoculations consisted of intravenous injections of phenol-killed whole cultures of strain SCHU in a semisynthetic soybean hydrolyzate liquid medium. Both unwashed killed suspensions contained about 2.5 billions of bacteria per ml., and included the minute minimal reproductive units of the organism. The weekly dosage was 2 ml. At the time this unconcentrated serum was tested its pooled bleeding aliquots varied in age from 14 to 6 months, and the agglutinin titer was 1:1,280.

D. Aged immune goat serum No. 79409, prepared in 1940–1941 by Sharp & Dohme by intravenous inoculations for 8 months of unwashed heat-killed suspensions of strains of maximal virulence. Pooled serum from 6 goats was preserved with phenol and refrigerated in liquid bulk. At the time of testing it was more than 5 years old, and its agglutinin titer was 1:1,280.

E. Normal horse serum No. 51975, without preservative, obtained from Sharp & Dohme.

F. Normal goat serum prepared from 2 bleedings of an uninoculated kid born of uninoculated parents. One lot contained merthiolate to 1:30,000; the other contained no preservative.

Quantitation of precipitable antibody. The precipitable antibody content of serums was determined by the neutralization method of Culbertson (7). The antigen was a nonimmunogenic polysaccharide prepared from acetone extracted cells of strain SCHU by the phenol extraction method of Palmer and Gerlough (8). Antibody content was usually measured with antigen in steps of 10 micrograms. Serum of low antibody content and dilutions of serums of high antibody content were quantitated with sharp end points with antigen increments in steps of 1 microgram. Antibody content is expressed as mgm. of antigen necessary to exhaust antibody from 1 ml. of serum without resultant antigen excess.

Serum protection tests. Serum protection tests were performed in the following manner. Rats were inoculated in groups of 30 to 32, half of each group receiving one of the potent serums and the other half receiving either the corresponding normal serum or the aged immune goat serum. Each rat was injected intraperitoneally with 2 ml. of undiluted serum and immediately thereafter with the 1-ml. challenge dose, subcutaneously, into the abdominal wall near the groin. The 2-ml. serum dosage was selected with reference to the agglutinin titer curves of pooled serums from normal rats after intraperitoneal injections of an immune goat serum with a titer of 1:5,120. Rats that received 2 ml. of serum had titers of 1:1,280 at 24 hours, and 1:160 at 48 hours. Rats that received 1 ml. of serum had titers of 1:160 at 24 hours, and zero in 1:10 dilution at 48 hours. Deaths were recorded daily for 21 days before release. The infecting strain was recovered from a rat dying on the second or third day from each group, and was used to infect each succeeding group.

Determination of persistence of infection in the spleens of recovered rats. After release all recovered animals were held for sacrifice at weekly intervals from 3 weeks to 3 months after challenge and were tested for residual splenic infection by cultures and by intraperitoneal inoculations into mice of suspensions of ground spleens.

EXPERIMENTAL RESULTS

Preliminary virulence titrations in normal rats. Before undertaking protection experiments the optimal subcutaneous challenge dose was determined by virulence titrations in normal rats weighing 70 to 135 grams. Preliminary subcutaneous titrations in adult rats of 200 to 220 grams showed great irregularity of mortality in respect to challenge doses. Mortality was frequently 100 per

cent from M.A. 40×10^{-1}, 10^{-3}, 10^{-4}, and 10^{-9} dilutions, and only 20 to 60 per cent from the intervening dilutions. An increase in the number of rats used per dilution reduced but did not dispel this irregularity. Although rats are highly susceptible to intraperitoneal challenge, yielding LD_{50} titers/1 ml. equivalent to those obtainable in mice injected either S.C. or I.P./0.5 ml., there is great variation in natural resistance among individual rats that are challenged subcutaneously, and this variable resistance apparently increases with age. Subcutaneous titrations in weight groups of 75 to 95 grams and of 95 to 115 grams revealed less irregularity due to variable individual resistance and gave separate LD_{50} titers of 6.4.

The cumulative mortalities and LD_{50} titers from 6 titrations in rats weighing from 70 to 135 grams are shown in Table I. The LD_{50} titers for the separate titrations were 7.6, 8.4, 5.6, 5.2, 8.0, and 6.0, and the cumulative LD_{50} titer was 6.4. This titer became stabilized between 6.3 and 6.5 only after 90 rats were used. The cumulative intraperitoneal mortalities and LD_{50} titers for rats weighing 70 to 210 grams, with separate titers of 9.3, 8.6, 9.5, 9.7, and 8.4, were obtained from simultaneous titrations with the same dilutions used for the subcutaneous titrations. The cumulative intraperitoneal titer of 9.3 indicates that the rat is about 1,000-fold more resistant to subcutaneous challenge than to intraperitoneal challenge. The relatively minor differences among the intraperitoneal LD_{50} titers indicate that the greater variability observed among subcutaneous LD_{50} titers was caused by differences in individual resistance among rats, and was not owing to lack of uniformity of the separate M.A. 40 suspensions or to errors in decimal dilutions prepared from them. The comparison between subcutaneous and intraperitoneal virulence titrations in mice, many performed simultaneously with the same dilutions, shows that the mouse does not exhibit differences in resistance dependent upon the route of challenge and that the total lack of resistance to experimental infection was shared by all mice.

Since 2 consecutive subcutaneous virulence titrations in the variably resistant rat, 30 and 39 animals being used, with simultaneous intraperitoneal titrations with 9 rats each, gave subcutaneous LD_{50} titers of 8.0 and 5.2, and intraperitoneal titers of 8.4 and 9.7, respectively, it became apparent that virulence titrations, if performed simultaneously with serum protection tests, and with fewer than 90 rats per titration, would not permit calculation of the actual challenge doses received by the protected rats. Calculations made from the separate subcutaneous titrations showed that the challenge dose used in protection experiments might have varied from 1,600 to 250,000 LD_{50} doses. Since it was not feasible to use 90 animals for each titration and protection series, and since the M.A. 40×10^{-2} dilution killed regularly at least 96 per cent of rats of the greater weight range, and at the same time permitted protection of more than 50 per cent of animals in preliminary protection tests, the 10^{-2} dilution was adopted for challenge of all rats of the narrower weight range in the protection experiments. For similar reasons it seemed advisable to express the challenge dose as an average in terms of the cumulative subcutaneous LD_{50} titer. On this basis each rat in the following protection experiments received 25,000 LD_{50} doses.

TABLE I

Virulence titrations with strain SCHU in 70 to 135 grams white rats and in 18 to 25 grams white mice

Comparative mortalities and cumulative LD_{50} titers after subcutaneous and intraperitoneal inoculation. Dosage was 1 ml. for rats, 0.5 ml. for mice.

Animal	Route	Decimal dilutions of strain SCHU from M.A. 40 suspension										Cumulative LD_{50} titers
		10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}	10^{-6}	10^{-7}	10^{-8}	10^{-9}	10^{-10}	
Rat	S.C.	9/9*	30/31	17/20	21/26	15/26	13/24	12/24	10/24	4/21	1/18	6.4
	I.P.							8/8	15/16	11/17	2/14	9.3

	I.P.							25/25	34/34	26/35	9/35	9.4

* 9/9 = 9 of 9 animals injected died of tularemia.

Serum protection of rats in relation to precipitable antibody content. The results of serum protection experiments are given in Table II. Instead of comparing each potent serum with its respective control serum all serums are tabulated in descending order with respect to precipitable antibody content. Each serum was tested on 2 separate occasions, and the number of animals and the mortality ratios are shown for each test in order to indicate the residual effect of variable resistance among rats within a weight range of 85 to 110 grams. These differences are negligible for the most potent serum and for both normal serums. The results showed good correlation between survival percentages and mgm. equivalents of antibody content but little correlation between antibody content and agglutinin titers. The low agglutinin titer and the low precipitable antibody content of the normal horse serum were observed independently and were verified repeatedly, but we have no explanation for their presence.

TABLE II

Correlation between precipitable antibody content of antitularense serums and protective capacity for white rats

No. of rats	Group	Serums	Maximal agglt. titers	Mortality	Survival	Antibody content
					per cent	*mgm. per ml.*
16 16	A	Hyperimmune goat by I.V. inoc.	1:5120	2/16 2/16	87.5	1.10
16 15	B	Hyperimmune goat by S.C. inoc.	1:1280	6/16 2/15	74.2	0.7
16 16	C	Hyperimmune horse by I.V. inoc. no. 50737	1:1280	7/16 3/16	68.7	0.5
15 16	D	Aged immune goat by I.V. inoc. no. 79409	1:1280	9/15 6/16	51.6	0.085
15 15	E	Normal horse no. 51975	1:10	15/15 13/15	6.6	0.001
15 15	F	Normal goat	0	14/15 15/15	3.3	0

Isolation of the infecting strain from recovered rats. Mouse inoculation proved to be more reliable than cultures for the recovery of organisms from suspensions of ground spleens. Infected spleens were demonstrated regularly at 3 weeks after challenge, and with a frequency of 75 per cent at 4 weeks. Thereafter, weekly tests yielded the organisms only twice, from single rats, at the eighth and thirteenth weeks.

DISCUSSION

The decisive results of the serum-protection experiments demonstrated conclusively that protective antibody was present in antitularense serums. The observed differences in mortality between rats that received immune serums and those that received normal serums are significant by inspection. The degrees of significance of the mortality rates from groups A, B, C and D, in comparison with the rate obtained after pretreatment with normal horse serum, are extremely high, all values of p being so small that they are unimaginable figures. Since the virulence titrations in rats having a slightly higher maximal weight limit showed that stability was not reliably secured with fewer than 90 rats, we attach less significance to the observed differences in mortality among groups A, B, C and D. Inspection of the paired mortality ratios for groups B, C and D reveals that variable individual resistance among rats in the narrower weight range was still operative. Hence, it is unlikely that significant differences in potency between these serums could be determined without using a much larger number of rats for each serum. Analysis of the rates for groups A, B and C, in comparison with the rate from group D, showed that no difference was significant, though that between groups D and A barely escaped statistical significance.

The protection test employed is satisfactory to determine the presence or absence of protective antibody. In the above tests it actually gave good agreement between rat survival and antibody content for all serums, and it is perhaps possible that repetition might continue to reveal proportional differences in protective antibody in serums of graded potency in agreement with their respective precipitable antibody contents, but, unless larger numbers of animals were used for each serum, conclusions about the relative potencies are not really justified. It is apparent from the mortality of rats in group D that a very small amount of antibody is sufficient to tip the balance heavily in favor of survival, even against a large challenge dose of a strain of maximal virulence.

The variable resistance of rats to subcutaneous challenge would have necessitated the use of so many animals per serum dilution that determinations of the ED_{50} doses of serums were impractical. The possibility of securing more significant degrees of relative serum protection, with the same or a smaller number of animals, by means of a suitable intraperitoneal challenge dose has not been explored.

Although the protection test described provides a method for the demonstration of protective antibody in antitularense serums it does not in its present form furnish an accurate basis for the establishment of quantitative criteria for potency. Further study of the precipitable antibody content in relation to protective capacity may eventually provide a serologic method to quantitate the potency of serums, thus obviating the use of test animals. Until a satisfactory method is devised temporary safeguards might be adopted. For example, a provisional standard might require a minimum of 1 mgm. equivalent of antibody per ml. of serum or perhaps a survival rate of 75 per cent among rats selected and challenged in accordance with the above specifications.

SUMMARY

Protective antibody was demonstrated in antitularense serums against subcutaneous challenge with an average of 25,000 LD_{50} doses of a strain of *Bacterium tularense* of maximal virulence, using white rats of 85 to 110 grams as the test animals. Good correlation was observed between protective antibody and precipitable antibody content, but not between antibody content and agglutinin titers.

THE ROLE OF PEPSIN, PEPTIC INHIBITORY SUBSTANCES, AND HYDROCHLORIC ACID IN NORMAL SUBJECTS AND IN THE PRODUCTION OF PEPTIC ULCERS[1]

By HARRY H. LE VEEN and LEONARD HALLINGER

(From the Department of Surgery of the University of Chicago)

(Received for publication July 23, 1946)

INTRODUCTION

There is still disagreement as to the respective roles of the pepsin and hydrochloric acid of gastric juice in the production of duodenal ulcer.

In patients with ulcer, free hydrochloric acid has been generally found to be present in increased quantities (1, 2). The work of Dragstedt (3) and of Mann and Bollman (4) have tended to emphasize the importance of hydrochloric acid.

The occurrence of ulcers following the surgical shunting of alkaline secretions (bile and pancreatic juice) away from those portions of intestines where gastric juice was made to enter, served in part as a basis for their deductions. Dragstedt, in addition, pointed out that the rate of digestion of frog's leg in an acid pepsin solution was dependent on acid concentration and independent of pepsin concentration (5). The production of ulcers by feeding hydrochloric acid to experimental animals also served as a basis for their conclusions. Histamine is a potent secretagogue of hydrochloric acid (6), but not of pepsin (7). Ulcers have been produced in practically all species of animals by injection of histamine in beeswax (8). Cases have even been reported in humans following injections of histamine (9). Frequent success over a long period with therapy employing antacids has been another strong argument in support of this premise.

Vanzant, Osterberg, Alvarez, and Rivers (10) have shown that the secretion of pepsin is enhanced in ulcer patients as compared with normal individuals and that a direct correlation existed between the amount of pepsin in gastric juice and the severity of symptoms. Mullins and Flood (11) and others (12) have confirmed these observations. Schiffrin (13) demonstrated that ulcers could be produced by perfusing isolated loops of jejunum or ileum of cats with pepsin and hydrochloric acid solution. Such ulcers were not produced by perfusion with hydrochloric acid alone. Driver's (14) investigations with dogs have yielded comparable results. Matzner (15) was able to produce ulcers in rats by feeding pepsin-hydrochloric acid mixtures.

In any attempt to resolve the controversy over the comparative importance of acid and pepsin, it is necessary to apply more refined quantitative methods of study and to devise mutually exclusive experimental conditions wherein both factors do not vary in the same direction simultaneously.

Accurate determinations of gastric hydrochloric acid are easily made, but most methods for determining pepsin have been either inadequate or cumbersome (16). The reason for inadequacy lies partially in the method and partially in the failure to take cognizance of the kinetics of the enzyme (pepsin) reaction.

THE KINETICS OF THE ENZYME REACTION

Pepsin acts on proteins, splitting them into proteoses, peptones, and polypeptides, but not to the amino acid state (17). In the case of egg albumen, the molecule is either attacked and broken down to a molecular weight of approximately 1,000, or it is not attacked at all (18). Pepsin has a predilection for certain peptide linkages, especially those involving tyrosine and phenylalanine (19). Unlike linkages are split at various rates (19). Pepsin does not act like some simple inorganic catalysts whose mere presence in traces is sufficient to bring about change. This enzyme reaction has been found to obey the Law of Mass Action, so that the rate of reaction and therefore the amount of substance converted are directly proportional both to the amount of active enzyme and to the concentration of active substrate present. However, the rate of conversion is not uniform for more than a brief period. The reaction rate rap-

[1] Done on a grant from the Otho S. A. Sprague Memorial Institute.

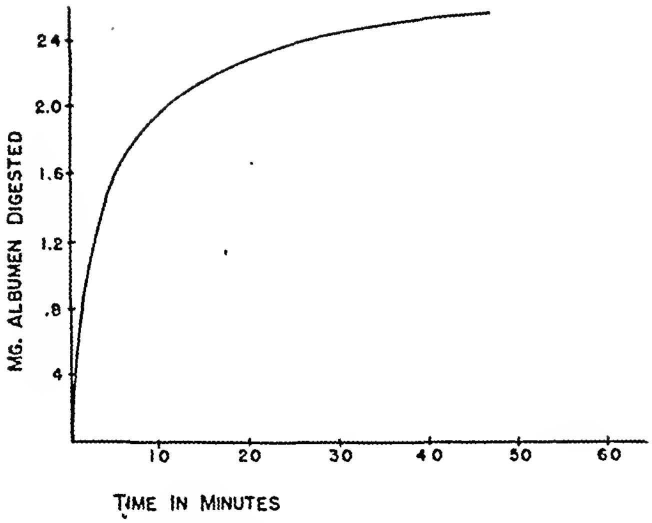

FIG. 1. THE AMOUNT OF PROTEIN DIGESTED IS PLOTTED AGAINST TIME IN MINUTES. THE RATE OF DIGESTION STEADILY DECREASES, REACHING A PLATEAU IN 30 MINUTES

idly diminishes and approaches zero (Figure 1). Peptones,[2] the product of pepsin digestion, combine with the active enzyme to form an inactive pepsin complex. Therefore the quantity of active enzyme present is constantly diminishing as digestion progresses. After the reaction rate has leveled off, the addition of sizeable increment of enzyme fails to produce further digestion, since the small quantity of pepsin initially present has produced large amounts of peptone inhibitor. It is the concentration of these inhibitory substances which determines the amount of pepsin which is active.

This pepsin-peptone complex has also been found by Northrop (20) to obey the Law of Mass Action, so that the following equation applies:

$$\text{Pepsin} + \text{Peptone} \leftrightarrows \text{Pepsin-Peptone}$$

and

$$\frac{\text{Conc. pepsin} \times \text{Conc. peptone}}{\text{Conc. pepsin-peptone}} = K.$$

The equation illustrates the reversibility of the reaction. Thus, if one decreases the concentration of the peptone inhibitors by dilution, active enzyme is liberated from the pepsin-peptone complex and additional digestion occurs. The significance of these concepts will be enlarged upon later in this paper.

The rate of digestion, as heretofore mentioned, is directly proportional to the rate of concentration of the active substrate (21) which is steadily diminishing during digestion. This, together with the fact that the enzyme is being progressively inactivated during digestion, does not allow for the expression of a direct linear relationship between the enzyme concentration and the amount of protein digested under practical test conditions. Northrop (20) has found the kinetics of the reaction to conform to the following equation:

$$\frac{A \operatorname{Log} \dfrac{A}{A - x} - x}{ET} = K$$

A = Substrate concentration
x = Quantity of substrate converted
E = Total enzyme concentration (active and inactive)
T = Time.

Under the experimental conditions of our test, the amount of protein digested is directly proportional to the logarithm of the total pepsin concentration (Figure 2).

Protein is an amphoteric substance and is present in the form of kations in a solution acid to its isoelectric point (22). Pepsin acts only on pepsin kations. (The effect of hydrogen ion concentration on pepsin digestion is purely on the substrate and *not* on the enzyme [23].)

The percentage of protein present in its kationic form increases as the pH of the solvent decreases until 100 per cent is in the kationic form. Thereafter, further decrement in pH will reduce the number of protein kations by the common ion effect. An increase in the active kationic substrate, brought about by pH changes, augments the rate of digestion according to the Law of Mass Action. Since the pH at which all protein is in its kationic form varies from protein to protein, the optimum digestion pH of proteins differs. Peptic digestion of mucosa mimics egg albumen in that both have their optimum digestion pH in the region of 1 (24). The digestion of mucosa may therefore be compared to egg albumen.

[2] Northrop uses the word "peptones" loosely to include all those breakdown products of protein which combine with pepsin. We have retained his definition. We have also included gastric inhibitory substances with peptones, since they certainly react like them and for the purposes of this paper may be considered identical.

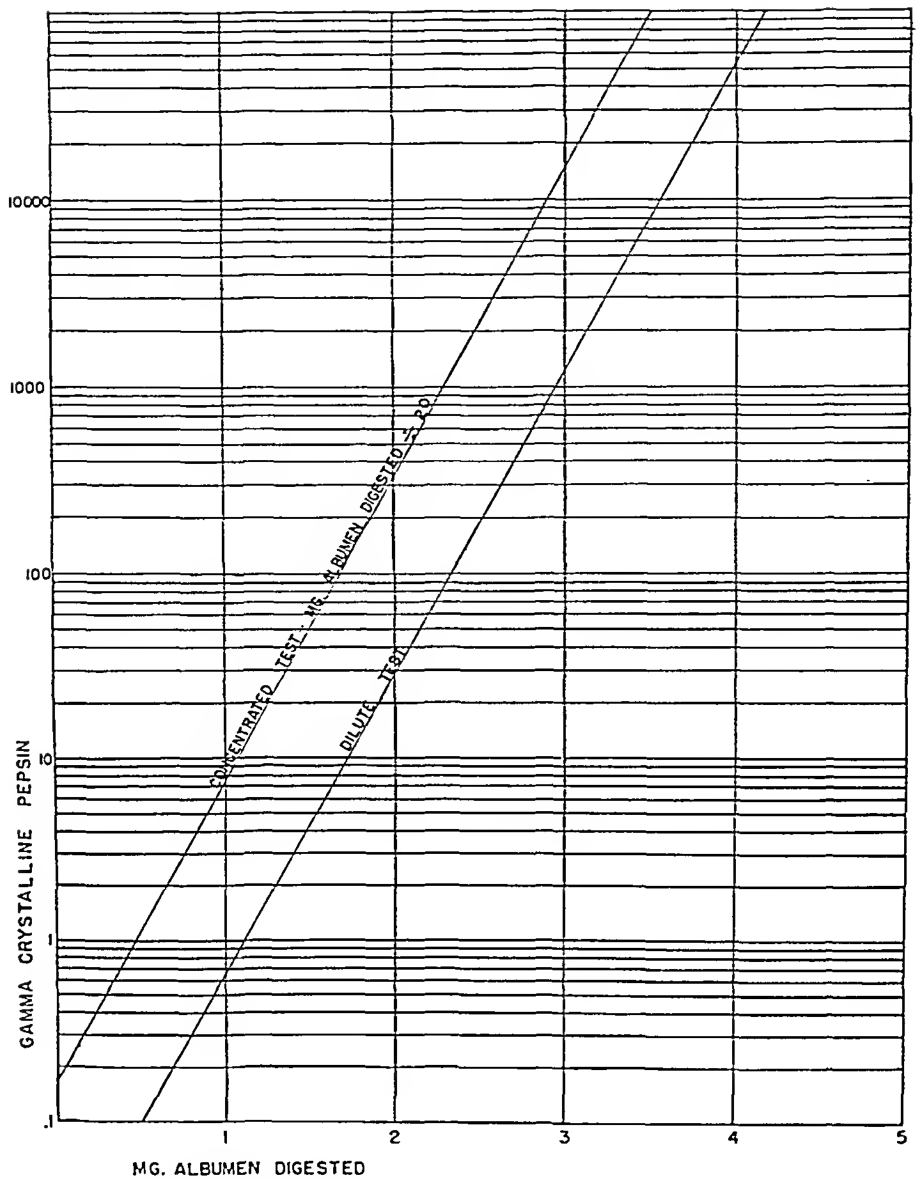

FIG. 2. THE NUMBER OF MILLIGRAMS ALBUMEN DIGESTED IS PLOTTED AGAINST GAMMA OF CRYSTALLINE PEPSIN ON SEMILOGARITHMIC PAPER FOR BOTH THE DILUTE AND THE CONCENTRATED TESTS

In the concentrated test, 2½ × the enzyme concentration produces 20 × the amount of albumen digested.

APPLICATION OF ENZYME KINETICS TO THE STUDY OF GASTRIC JUICE

In gastric juice, the estimation of pepsin activity is complicated by the presence of inhibitory substances analogous to peptones (25). These substances, formerly called anti-enzymes (26), have been thought to play an active role in protecting against autodigestion (26, 27). Langenskiöld (28) indicated that these substances were probably peptones. It may be that the inhibitors of the gastric juice are peptones formed by the action of pepsin on proteins derived from food, mucosal cells, and secreted protein (mucin and plasma protein).

Dilution of gastric juice, under any conditions, by decreasing the concentration of inhibitory sub-

stances (peptones), allows digestion to continue unimpeded. By using highly diluted juice one can assay the total quantity of pepsin present unaffected by the naturally occurring inhibitory substances. Conversely, when one uses low dilutions, one assays only that fraction of pepsin which is uncombined with the naturally occurring inhibitory substances, which we have called the Active Fraction. Bucher, Grossman and Ivy (29) have found that separation is usually complete at 1:100 dilution so that no further augmentation in pepsin activity occurs on continued dilution.

The preceding discussion poses the corollary if tests were performed on undiluted gastric juice, only that fraction of pepsin uncombined with inhibitor would be measured. Even when the gastric juice is mixed with concentrated substrate, however, dilution is unavoidable. In order to correct for this dilution, a curve correlating low dilution of gastric juice with quantity of substrate decomposed has been constructed (Figure 3). (This relationship is observed only in low dilutions.) This establishes that one can interpolate to the undiluted state in order to determine the amount of pepsin in gastric juice that remains unaffected by the inhibitory substances present (30).

We have assayed Total Pepsin Activity at optimum pH utilizing high dilutions of gastric juice (16). At the same pH we have assayed that amount which remains uninhibited (active fraction) by employing low dilutions of gastric juice and interpolating to the undiluted state. The per cent of pepsin inhibition may be thus derived.

Alterations in pepsin activity of this active fraction, produced by variation of pH from the optimum, are depicted graphically (Figure 4). It is evident that the acidity of different gastric juices varies significantly from this optimum. Hence the activity of the pepsin will vary and can be computed by reference to the figure. This pep-

1x is point of no dilution. The represented relationship is 1:1 so that each increase of 1x in dilution increases the square of the peptic power 1.

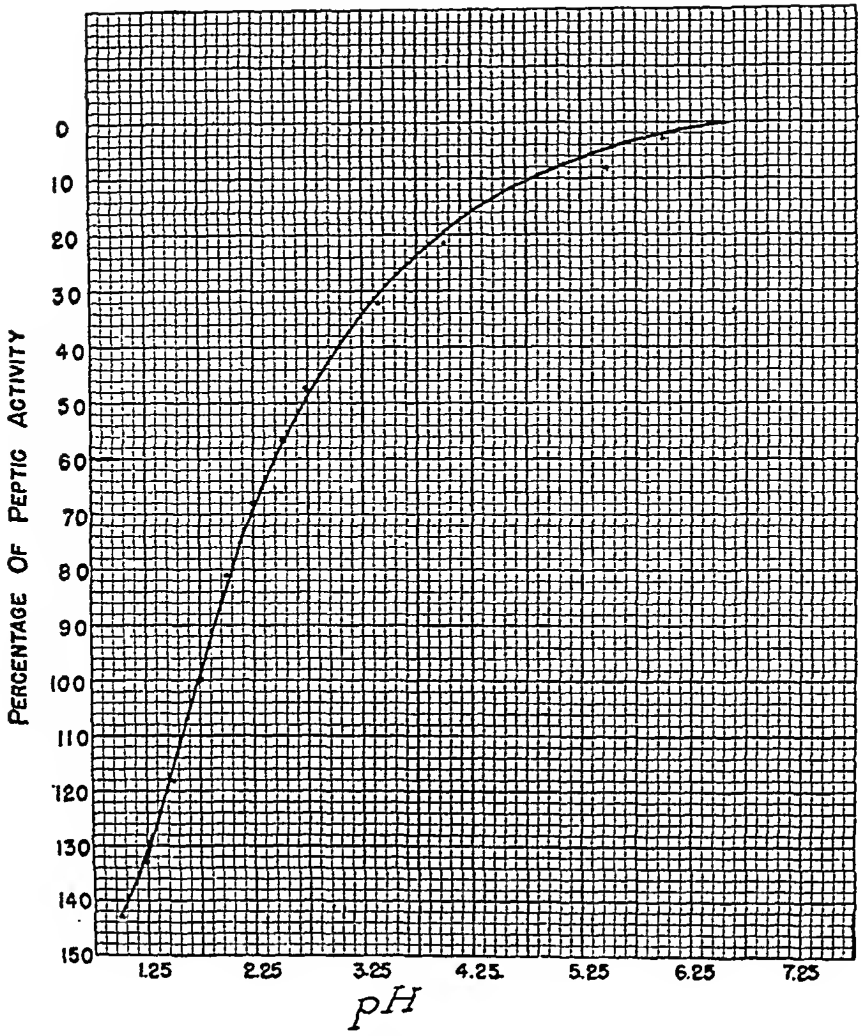

FIG. 4. DIGESTED PROTEIN, REPRESENTED AS THE PERCENTAGE OF PROTEIN DIGESTED AT pH 1.75 (100 PER CENT), IS PLOTTED AGAINST THE HYDROGEN ION CONCENTRATION OF THE DIGESTION MIXTURE EXPRESSED IN pH UNITS

sin activity, corrected for the effect of inhibitor substances and of pH, we have designated Resting Peptic Activity. It is a measure of the pepsin activity which the gastric and duodenal mucosa are resisting in the basal secretory state.

To reiterate, total pepsin activity is merely an index of the secretory activity of the pepsinogenic cells of the gastric mucosa, but does not indicate the true digestive activity of the gastric juice as modified by the inhibitor substances and hydrogen ion concentration.

Since inhibitory substances and pH play such a significant role in the kinetics of the pepsin reaction, it would seem important to know how much pepsin is inhibited via each mechanism in normal and ulcer patients. Up to the present, there has been no information in the literature concerning this.

MATERIALS AND METHODS

All determinations were performed 4 to 8 hours after collection of the gastric juice. pH was determined with a glass electrode.

The methods for pepsin measurements have been described in detail elsewhere (16, 30). A brief outline is given to provide the reader with some conception both of the technic and the derivation of the units.

By precipitating various concentrations of albumen with sulfosalicylic acid under conditions of dilution and hydrogen ion concentration similar to those carried out in

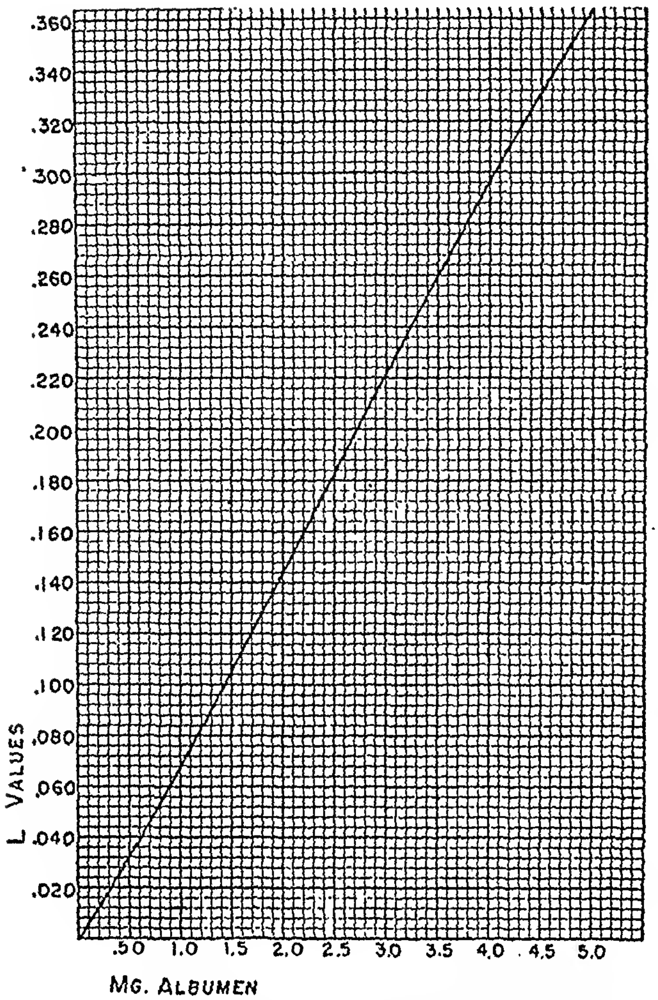

FIG. 5. SHOWS THE RELATIONSHIP OF MGM. ALBUMEN PRECIPITATED BY SULFOSALYCYLIC ACID TO OPTICAL DENSITY EXPRESSED AS L-VALUES

the test, and recording the turbidity in the Evelyn Colorimeter, a nomogram was constructed which related optical density, or L values (Figure 5) to mgm. of albumen present and enabled one to determine by difference the amount of albumen digested.

Although the pepsin determinations in both tests have been standardized against crystalline pepsin,[3] it has been deemed desirable to use relative units, Pepsin Equivalents, instead, because there is no uniformity of activity among the various crystalline preparations of pepsin (31). Our pepsin equivalent unit is equal to 0.076 gamma of crystalline pepsin. (About 50 per cent of this preparation is magnesium sulfate.)

Dilute test—assay of total pepsin

Five mgm. of egg albumen is incubated for 30 minutes at 37° C. with diluted gastric juice so that the final dilution is 1/563. The mgm. albumen digested are determined by precipitating with sulfosalicylic acid after inactivating the pepsin with sodium hydroxide. Units proportional to actual quantities of crystalline pepsin are obtained by expressing the results as the antilogarithm of the mgm. albumen digested. By multiplying the dilution factor, the final result, total pepsin, is designated in pepsin equivalents per ml. of gastric juice.

Concentrated test—assay of active pepsin

Undiluted gastric juice is mixed with concentrated albumen solution and hydrochloric acid solution so that the final dilution of the gastric juice is in the order of ¼. Digestion is carried out at 37° C. for 30 minutes. A duplicate sample is used to determine the pH of the digestion mixture. By use of Figure 4, the amount of albumen which would have been digested at pH 1.75 (the digestion pH of the dilute test) is determined.

Because the lines represented in Figure 3 have the same slope, it is possible to extrapolate the results obtained at ¼ dilution to zero dilution.

After adjusting for the differences in kinetics of the two tests, results are again expressed in pepsin equivalents as before. The units thus derived give values for the active pepsin which are comparable to those for total pepsin. Since the units are comparable the percentage of pepsin inhibited is easily derived from the figures for total pepsin and active pepsin.

Resting peptic activity

Since the active pepsin fraction is expressed as the activity at pH 1.75, it will not represent the activity of the gastric juice at its own pH occurring *in vivo*.

After obtaining the pH of the gastric juice, the active pepsin fraction is corrected to the activity at that pH by reference to Figure 4.

This value shows the summation of the effect of inhibitory substances and pH characteristic of a specimen of gastric juice collected during a basal secretory state. It should be remembered that this is an artificial comparison because the effect of pH is on the substrate and not on the enzyme. It really represents the activity which would result if the enzyme concentration were reduced at a constant pH.

Peptic activity in human subjects

A total of 132 fasting specimens of human gastric juice was obtained from the Gastrointestinal Clinic of the University of Chicago Clinics[4] and the determinations earlier described were made. Out of this number we selected juice from every case of proved duodenal ulcer, totaling 30 cases. All patients had x-ray evidence of ulcer.

Twenty-one fasting specimens of gastric juice were collected from 21 of the students, interns, and resident staff of the Clinics. The criteria for normality were absence of past or present gastrointestinal disease or symptoms.

---

[3] The crystalline pepsin used in this study was obtained from the Plaut Research Laboratories, Bloomfield, N. J.

RESULTS

The results of the pH determinations on the ulcer patients and on the normal human beings are depicted in Table I. One may note that 28 out of 30 ulcer patients, or 92 per cent, had pH values below 2.4, whereas only 11 out of 21 of the normal group, or 52 per cent had high free acid values in the corresponding pH range (Figure 6). This is in fair agreement with what has been described in the literature by other investigators (1, 2).

An examination of the peptic activity of the gastric juices of our human subjects, as illustrated in Table I, reveals the following:

Total pepsin activity. It is notable that there is wide individual variation in the total pepsin activity (or pepsin content) among both the normal and the ulcer groups. Despite this variation, statistical comparison of the two groups as a whole reveals no significant difference.

Active pepsin fraction. Here one may see that the amount of inhibitory substances present is of a huge magnitude for all individuals in both groups, for the actual amount of active pepsin present is very small. Notwithstanding the wide individual variation in total pepsin activity existing among individuals in each group, the active pepsin fraction does not exhibit the same trend, but rather there is close uniformity in the quantity

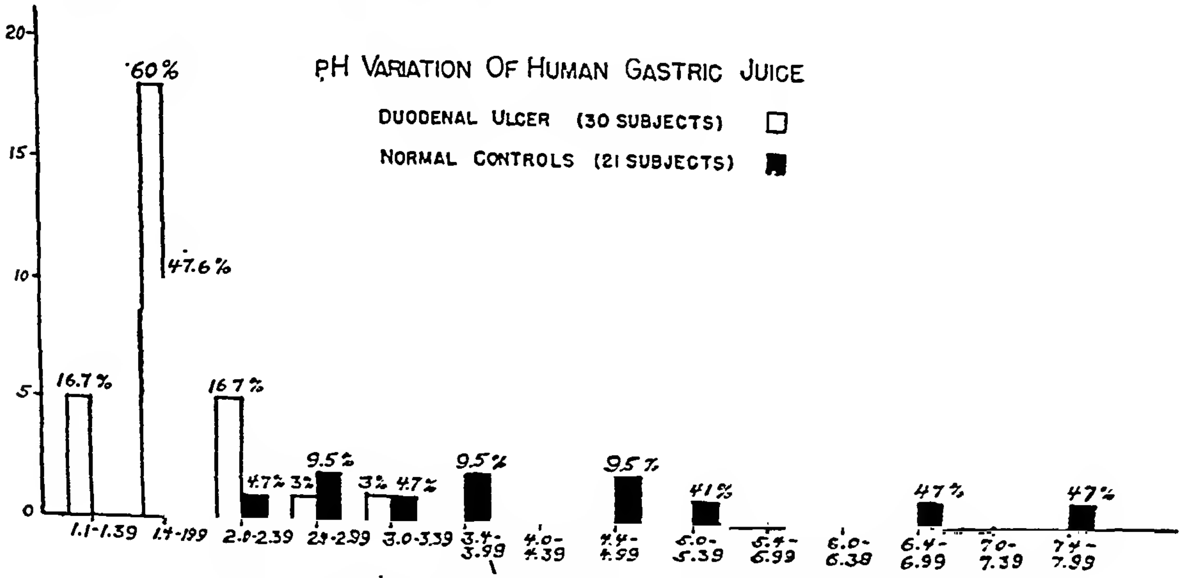

FIG. 6. SHOWS THE DISTRIBUTION OF CASES ACCORDING TO THEIR GASTRIC ACIDITY IN pH UNITS

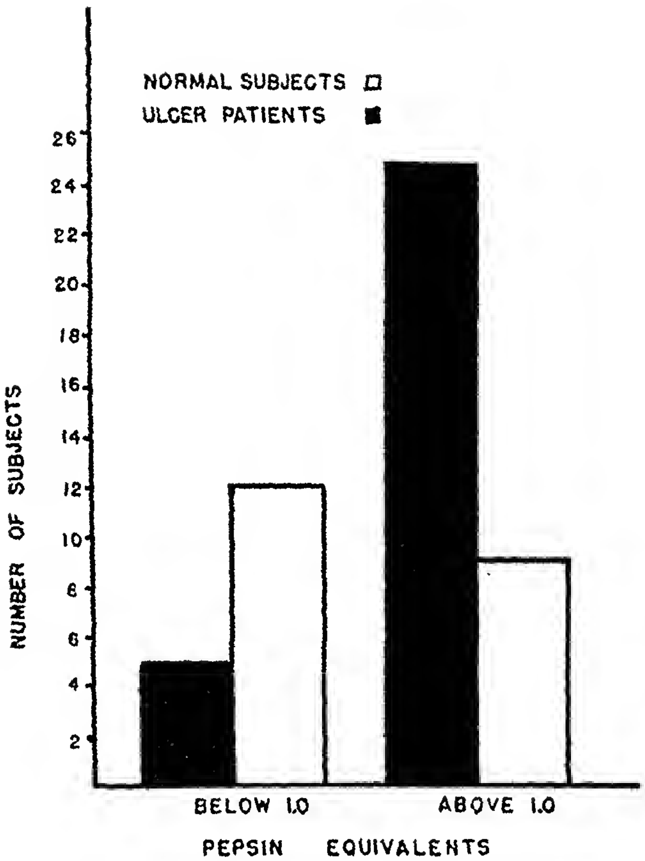

FIG. 7. THE NUMBER OF CASES HAVING RESTING PEPTIC ACTIVITY ABOVE AND BELOW THE VALUE OF 1 IS ILLUSTRATED

of pepsin in both groups. Again, statistical comparison between the two groups shows no significant difference.

Per cent pepsin inhibition. This illustrates again the enormous amount of inhibition present and the uniformity of this phenomenon in all the individuals studied. In all but one case, more than 99 per cent of the total pepsin is inhibited, and in most, there is 99.9 + per cent inhibition.

The percentage of the total pepsin which is active in the presence of the pepsin inhibitory substances of the gastric juice is exceedingly small. With the crystalline pepsin used by us, the quantity of active pepsin present ranges approximately from 0.05 gamma to 0.15 gamma per ml., as compared with an average figure of approximately 270.0 gamma per ml. of total pepsin in both groups.

Resting peptic activity. This estimation of the actual *in situ* digestive activity of the gastric juice, expressed in pepsin equivalents, is also contained in the table.

It is here that one may note the effect of pH of the gastric juice on the active pepsin fraction. Precursory inspection may not reveal a striking change because of 3 abnormally high results in the normal group. However, the majority of ulcer cases, 25 out of 30, have pepsin activities of 1.0 pepsin equivalents or above, whereas less than half, 9 out of 21 normal subjects, have like values. This is pictured in Figure 7. That this result is significant has been proved by the Chi Square Method of Statistical Analysis ($\chi^2 = 9.1$).

DISCUSSION

From the evidence presented, it is manifest that the major differences between the two groups lie in the pH and resting peptic activity. The active pepsin fraction, percentage of inhibition, and total pepsin concentration are almost identical in the two groups.

It is noteworthy that our findings of similar total pepsin concentrations in the normals and in ulcer patients are at variance with the reports of other investigators (10, 11, 12). A criticism that might be made of our findings is the relative smallness of the series. However, the number of cases studied is statistically adequate. We feel that the findings of others quoted (10, 12) may be open to criticism on the basis of error inherent in their method of pepsin determination, as mentioned previously. Vanzant *et al* (10) and Mullins and Flood (11) both used low dilutions of gastric juice, which resulted in the assay, not of total pepsin, but of a variable mixture of pepsin and pepsin-inhibitor complex. Both also obtained their gastric specimens after test meal stimulation. There is some indication that the test employed by Osterberg *et al* was subject to error because of insufficient buffering of their digestion mixture. In our experience, even strong buffers will not maintain a constant digestion pH when mixed with equal volumes of gastric juice. We have occasionally observed unusually high fasting values of total pepsin in ulcer patients, but the group as a whole does not vary significantly from the normals.

The observation that 99 + per cent of the pepsin is inhibited might seem incredible at first. Examination of Figure 1 relating quantity of albumen digested per unit time reveals a rapid initial rate becoming negligible after 30 minutes. Inasmuch as the rate of digestion is directly proportional to the concentration of active enzyme and since the

rate of digestion becomes practically nil, it follows that there must be an extremely small amount of active enzyme present. The pepsin in resting gastric contents is constantly acting on protein substrate (cells, mucin, and protein secreted), and one might expect that it is almost completely inhibited for the same reason. This may well be one of the reasons that the stomach does not digest itself. Formerly, one remarked at the amazing ability of the stomach and duodenum to resist digestion. Now it can be seen that these organs actually have very little to resist and that instead of being resistant, they are probably quite susceptible. The inability of these organs to resist digestion is indicated by those animal experiments in which the feeding or irrigation of bowel with active pepsin-hydrochloric acid mixture quite uniformally and rapidly produced ulceration (13, 14, 15). The rapidity with which apparently normal humans develop perforation and bleeding under certain emotional stresses (32) also, the rapidity with which peptic ulcers sometimes develop after burns (33) would seem to indicate that the mucosa is not resistant to attack by active gastric juice. Herein also may lie the explanation of how ulcers, produced by the ingestion of acid in the experimental animal (4), may result from dilution of inhibitor substances and also further enhancement of the enzyme action by the increased hydrogen ion concentration. Hypersecretion also, by continually diluting the inhibitor substances, might sustain active pepsin at relatively high levels.

The extremely low values of the active pepsin fraction would tend to support the contention that very little pepsin is necessary to produce mucosal ulceration via the digestion mechanisms. Despite the high percentage of observed inhibition, the pepsin is not really destroyed, and is readily made available for digestion by the process of dilution. There is a huge pepsin reserve; the digestive power of gastric juice can be increased 5,000 times by simple dilution. As mentioned in the section on kinetics, even the addition of a sizable increment of pepsin to a pepsin solution with a high concentration of inhibitor will produce little increase in digestive action. For this reason, the actual digestibility of gastric juice does not vary appreciably with excessive increases in pepsin content. Driver (14) found that doubling the pepsin concentration did not alter the extent or frequency of ulceration observed when perfusing isolated loops of small intestine. His perfusion was carried out at the rate of 2 ml. per minute through a loop of bowel that would hold many times that volume. The perfusion was certainly not rapid enough to wash out the inhibitors that formed during the process of peptic digestion, and thus one may conclude that the active pepsin fraction was not significantly elevated. In the discussion on kinetics, it was stated that the amount of albumen digested is not in linear proportion to the pepsin concentration. Therefore, increasing the concentration of pepsin should not change the ulcerating power markedly either in the dog experiments of Driver (14) or the frog experiments of Dragstedt (5). Matthes (34) who was one of the first to irrigate loops of bowel in dogs with pepsin-hydrochloric acid mixtures and gastric juice, concluded that peptones found in gastric juice combined with the free acid and in this way reduced its ulcerating ability. Langenskiöld (28) came to similar conclusions. Their work, however, really lends excellent support to the thesis that ulcers are the product of peptic digestion since the peptones more effectively combine with the pepsin.

Even though large changes in the pepsin concentration do not produce appreciable increase in pepsin activity, small changes in hydrogen ion concentration will produce marked changes in digestive action (Figure 4). Hence this mechanism is by far the most important in controlling the digestive action *in vivo*. It can therefore be established that the pH is of greater importance in controlling resting peptic activity than the total pepsin content of the gastric juice. On comparison of the resting peptic activity of the normals with those of ulcer patients, one sees no clear-cut division between the two groups. Some normals, drawn from medical students and interns, had high gastric acidity and therefore high resting peptic activity. In some cases these individuals said they were hungry because they had missed their accustomed breakfast; others were apprehensive and had difficulty swallowing the tube. The studies of Wolf and Wolff (35) on Tom, a man with a stricture of the esophagus and a large gastric fistula, have shown that emotional stimuli such as resentment and anxiety will increase hydrochloric

acid production tremendously. Also, hunger will produce copious secretion of hydrochloric acid and pepsin. We have not excluded these normals from our series, however, since the ulcer patients have probably experienced the same stimuli. Many of both groups, therefore, were in a secretory state rather than a basal state. True resting contents are well-nigh impossible to obtain under the usual clinical conditions (36). One may always expect some high values in the group. The best method of comparing these two groups is by statistical means. When such a comparison is made the results have been shown to be highly significant.

A better method of investigation than ours for obtaining basal secretory levels would be gastric aspiration during sleep. Winkelstein (37) and others (38, 39) have pointed out that the free hydrochloric acid falls to zero or very low in normal patients during sleep; yet, in sharp contrast, increased values are found in ulcer patients. Such a study, however, necessitates hospitalization.

These present observations on gastric juice while highly suggestive do not prove that ulcer development is a function of the resting peptic activity. One must prove that the ability of pepsin solution to digest a given protein substrate is the same as its ability to produce experimental ulcers.

Experiments (24) have been conducted wherein the mucosal and serosal surfaces of dogs' intestines were irrigated with hydrochloric acid-pepsin solutions adjusted so that the pH of one pepsin mixture was kept at 1.50 and the other at 2.15. This made the peptic activity of the pH 2.15 mixture 60 per cent of that of the pH 1.50 preparation (Figure 4). The activity of the former solution was doubled, however, by increasing its temperature 10° C. (van't Hoff's Law) so that its final activity was 20 per cent greater than that of the more acid solution. (The irrigation temperature was 30° C. for the pH 1.5 solution and 40° C. for the other.) By this means the pepsin activity of the less acid solution was the greater. Ulcers formed more readily and were more extensive both on the mucosal and serosal surfaces of the bowel with the low acid-high peptic activity mixture. Bowel irrigated with hydrochloric acid alone (pH 1.5 and at 40° C.) exhibited no ulceration. When conditions other than temperature variations were sought to reduce peptic activity, it was found that 2 per cent solution of neopeptone ("Difco") reduced the amount of albumen digested by 50 per cent. Bowel was irrigated with two acid pepsin solutions both at pH 1.5 but one containing 2 per cent neopeptone. Neopeptone protected against the development of ulcers. It will be remembered that Matthes (34) had concluded that peptone in gastric juice by reducing the free acid had lessened its ulcerating effect. In the experiment reported, acid was added to the solution containing neopeptone to make the pHs identical, yet the solution containing neopeptone did not readily form ulcers. Such exclusive experiments would tend to indicate that peptic activity plays a major role in the production of ulcers.

CONCLUSIONS

Enzyme kinetics, together with quantitative methods for the determination of total pepsin concentration and inhibitor substances, have been applied in a physiological study of the products of gastric secretion in 31 proved ulcer patients and 21 normal subjects.

The resting peptic activity was found to be significantly greater in the ulcer group. This increase was dependent upon the higher acidity of the gastric juice in the ulcer patients, for there was no increase in total gastric pepsin in this group. The reason that an increase in total pepsin content of gastric juice does not significantly alter peptic activity is that pepsin inhibitor substances are present.

The inhibitor substances present in the gastric juice produce more than 99 per cent inhibition of pepsin in both the normal and the ulcer groups. This, in conjunction with the probable low basal levels of free hydrochloric acid in normal patients, prevents autodigestion.

It would appear that ulcers are really the product of peptic digestion, and that the pH of the gastric juice is by far the most important regulator of the peptic activity, even to the exclusion of pepsin concentration.

It is believed that strict application of the laws of enzyme chemistry has elucidated some discrepancies which have resulted from the inadequate qualitative experiments of the past on gastric digestion.

ACKNOWLEDGMENT

Gratitude is expressed to Dr. Dallas B. Phemister and Dr. William H. Fishman for their aid in the preparation of this manuscript.

THE TOLERANCE FOR POTASSIUM IN SEVERE RENAL INSUFFICIENCY: A STUDY OF TEN CASES

By NORMAN M. KEITH and ARNOLD E. OSTERBERG

(From the Division of Medicine, and Section on Clinical Biochemistry, Mayo Clinic, Rochester, Minnesota)

(Received for publication July 26, 1946)

The concentration of potassium in the serum of a patient who has developed severe renal insufficiency may be normal, increased, or diminished, and no satisfactory explanation for these widely varied concentrations has been advanced. Naturally the finding of an increased content of potassium in the serum of a nephritic patient suggests caution in the administration of potassium salts. On the other hand there are certain undernourished patients who have nephritis and are suffering from lack of potassium and therefore require an increased intake. It is also recognized that many patients who have renal edema can tolerate a considerable daily dose of potassium salts over a period of months without evidences of toxic effects. It is therefore obvious that there are other factors, in addition to renal retention, which play a role in the distribution of the potassium ion in uremic patients.

Observations of potassium tolerance, both in normal subjects and in patients who had adrenal insufficiency, have been made by Zwemer and Truszkowski (1), Wilder and his co-workers (2), and Jaffe and Byron (3). The effects of a small and of a considerable dose of potassium salts were studied by Greene, Levine and Johnston (4), and by Winkler and his associates (5) in renal disease and by Thomson (6) and Sharpey-Schafer (7) in cardiac disease. The doses employed by Winkler and Sharpey-Schafer were frequently large and sometimes proved impractical and even dangerous. We therefore gave normal subjects and patients who had renal disease a uniform and smaller dose of 5.0 grams of potassium bicarbonate by mouth and were gratified to find that this amount could usually be tolerated and also revealed information as to the individual's tolerance. Our procedures and results in normal subjects have already been reported (8). The present communication deals with the results of the same procedures carried out in 10 patients who had definite renal insufficiency. Distinct alterations in potassium tolerance were observed in all of the 10 patients and form the basis of this paper.

SELECTION OF PATIENTS

The chief consideration in the selection of our patients was demonstrable renal insufficiency. Eight of the 10 patients were deliberately chosen because the degree of renal incompetence was marked and we desired particularly to learn the tolerance for potassium of patients who had a minimal amount of functioning renal tissue. The degree of renal insufficiency of these 8 patients was indicated by the increase in the concentrations of urea and creatinine in the blood from 147 to 340 mgm. and from 5.6 to 19.2 mgm. per 100 ml., respectively. The diagnosis in 6 patients was chronic glomerulonephritis; in the 4 remaining, respectively, it was subacute glomerulonephritis, chronic pyelonephritis, bilateral congenital hydronephrosis, and multiple myeloma with chronic diffuse nephritis. Death occurred in 9 of our patients in 2 weeks to 8 months after the test was done. One patient, J. W., with the least degree of renal incompetence, was alive and active when this paper was written, 4½ years after the test (Table I).

PROCEDURES

The procedures carried out in the 10 patients started with the early-morning oral administration of 5.0 grams of potassium bicarbonate, which contains approximately 2.0 grams of potassium; during the next 3 hours, a study was made of its effect on the concentration of potassium and urea in the blood, and on serial electrocardiograms. The actual amount of potassium ingested by the 10 patients varied from 24 to 35 mgm. per kgm. of body weight. Breakfast was omitted and the patients remained in bed during the period of observation. Control samples of blood were withdrawn from a vein of the arm, and control electrocardiographic tracings were taken before the salt, dissolved in 300 ml. of water, was ingested. Subsequently, similar analyses of blood were made and electrocardiograms were taken at approximately 90 and 180 minutes. These were the procedures in 4 cases. In 1 of these, after the patient, H. S., had eaten his lunch, the blood studies and electrocardiograms were subsequently carried out at 8 hours (Tables I to III).

In 6 cases, in addition to the procedure described in the preceding paragraph, studies were made of the clearances of urea and potassium from the blood by the kidneys.

TABLE I

*Clinical data found on initial examination of patients**

Date of admission	Patient	Edema, grade 0–4	Blood pressure, range in 24 hours	Urine albumin, grade 0–4	Diagnosis
			mm. Hg		
10-30-41	M.S.	1	155–230 / 95–140	3–4	Chronic glomerulonephritis
11-28-41	P.K.	1–2	145–195 / 85–130	4	Subacute glomerulonephritis with nephrotic syndrome, necropsy
11-24-41	J.W.	1	110–140 / 60–90	4	Chronic glomerulonephritis with nephrotic syndrome
5-17-43	M.B.	0	150–200 / 110–130	2–3	Chronic glomerulonephritis, D.A.D. group 2
12-22-41	J.B.	2	130–190 / 70–110	3–4	Chronic glomerulonephritis with nephrotic syndrome, polycythemia vera
5-13-42	H.C.	0	110–180 / 70–110	2–3	Chronic glomerulonephritis
7-6-42	J.R.W.	0	80–105 / 40–65	2†	Chronic bilateral pyelonephritis
9-15-42	W.L.‡	0	180–215 / 100–135	3	Chronic glomerulonephritis, D.A.D. group 4
9-29-42	H.S.§	1	155–190 / 100–150	3	Bilateral congenital (?) hydronephrosis, necropsy ‖
4-15-43	L.G.	0	120–135 / 80–85	3–4¶	Multiple myeloma,¶ chronic diffuse nephritis

* Flocculation reactions for syphilis in serum of all 10 patients reported negative.
† Sediment contained pus, grade 3–4.
‡ Vascular retinitis, edema of disks.
§ Acute angiospastic retinitis.
‖ Necropsy elsewhere. Report kindly furnished by Dr. W. L. Ross, Jr., Yakima, Washington.
¶ Bence-Jones protein present in urine. Smear made from circulating blood has greasy quality and shows occasional myeloid immaturity. Serum protein 8.9 grams, serum albumin 4.0 grams, serum globulin 4.9 grams per 100 ml., respectively. Roentgenogram of skull reveals multiple punched-out regions of destruction.

The clearances in 2 periods of approximately 90 minutes' duration were determined in each of the 6 cases and correlated with the blood estimations and electrocardiographic tracings. Urea clearances were determined to give information as to the amount of renal tissue which was still functioning. The entire study in 4 cases was similar to that performed on normal controls and previously reported.

CLINICAL STUDIES

Vomiting occurred in only a single case 148 minutes after the patient, H. S., had ingested the salt. In this instance the vomitus was recovered; it contained only 0.2 gram of potassium. Three patients experienced mild epigastric discomfort or mild nausea soon after drinking the solution.

In previous studies, when large amounts of potassium salts were ingested by normal subjects, we (9), as well as a previous investigator (10), had noted that in certain cases paresthesias developed in the hands and feet while in other cases they did not develop. These paresthesias occurred when the concentration of potassium in the serum approximated 30 mgm. per 100 ml. It is interesting that in the present study, with a relatively small dose of 5.0 grams of potassium bicarbonate, paresthesias of the extremities developed in 4 patients, P. K., M. B., H. C. and H. S., when the content of potassium in the serum ranged from 31.1 to 35.8 mgm. per 100 ml. These findings suggested that the presence of paresthesias in the 4 patients was indicative of a decreased tolerance for potassium. Support for this viewpoint was the fact that paresthesias did not develop, nor did the serum potassium increase above 21.2 mgm. per 100 ml. in normal subjects who were given the same dose. In the remaining 6 cases paresthesias did not develop in the extremities; in 2, the maximal serum potassium varied from 19.9 to 27.1 mgm. per 100 ml. and in 4, it varied from 29.3 to 37.1 mgm. per 100 ml. Therefore, this symptom may not develop even when there is a decided increase of the concentration of serum potassium. Patient H. S. (Table II), the only patient to vomit during one of these experiments, was nervous throughout and was suffering from very severe uremia. The slow rise of the concentration of potassium in the serum and the later appearance of changes in the electrocardiogram lead one to surmise that absorption of potassium was at a considerably slower rate in that patient than in the remaining 9.

STUDIES OF THE BLOOD

We anticipated that the ingestion of 5.0 grams of potassium bicarbonate by our patients would produce changes in the concentration of potassium in the blood serum which would be different from those observed in normal subjects [1] (Figure 1) (8). In 9 of 10 patients the concentration of potassium in the serum, estimated before the salt was given, was abnormally increased to a range from 21.9 to

[1] Nineteen mgm. of potassium per 100 ml., a mean normal figure, = 4.9 m.eq. per 1.

28.4 mgm. per 100 ml. (Figure 2). One and a half hours after the ingestion of the potassium bicarbonate the content of potassium in the serum of the 9 patients increased to a range from 23.1 to 37.1 mgm. per 100 ml. (Figure 2). The greatest increase, from 21.9 to 36.5, or 14.6 mgm., occurred in patient L. G. A similar increase of serum potassium was reported by Greene and his co-workers in a case of chronic nephritis with uremia. With this observation in L. G. and the distinct increase in patient M. S. from 26.7 to 37.1 mgm., we realized that even 5.0 grams of potassium bicarbonate might produce serious toxic effects, especially on the heart. It was rather surprising that the serum potassium in patient J. R. W., who had very serious renal disease, increased only to 27.1 mgm. In 3 hours (Figure 2) there was a decrease in the concentration of the potassium of the serum in 7 patients to values ranging from 24.0 to 35.4 mgm., but in 2 patients, J. B. and H. S., it increased 2.1 and 8.0 mgm., respectively. J. B. had taken a considerable amount of potassium nitrate as a diuretic previous to the tolerance test. The increase in patient H. S. from 23.1 mgm. at 1½ hours to 31.1 mgm. at 3 hours was marked. This late increase in the content of

potassium in the serum of patient H. S. would appear to be due to a slow absorption of potassium from the intestinal tract. In 4 of the 9 patients, the concentration of potassium was estimated after 8 hours and it had decreased to 21.7 to 26.0 mgm., but in 3 of the 4 patients it was at a higher level than that observed in the original control serum. These results in 9 patients indicated a varied and unmistakably abnormal response to the ingestion of a relatively small amount of a potassium salt. The type of response was that of a decreased tolerance for potassium (Figures 1 and 2).

The findings, however, in patient W. L. were distinctly different from those in the 9 other patients. In fact, the alterations in the concentration of potassium in the serum (Figure 2) could not be distinguished from that obtained in a normal subject (Figure 1) after the ingestion of 5.0 grams of potassium bicarbonate. This response in a patient with such a severe degree of renal damage, the latter indicated by a blood urea clearance of 6 ml., surely informs us that the curve of serum potassium after the ingestion of a relatively small dose of a potassium salt may not reveal an altered potassium tolerance. The possibility of decreased absorption of the potassium salt from the intestine of this patient naturally must be considered. However, there is good evidence that intestinal absorption was satisfactory. This point will be discussed later.

STUDIES OF THE URINE AND BLOOD CLEARANCES OF UREA AND POTASSIUM

During the 2 clearance periods of approximately 1½ hours, 3 hours in all, after taking 5.0 grams of potassium bicarbonate by mouth, the mean volume of urine in the 6 patients whose urine was studied (Table II) was definitely less than that observed in normal subjects under the same experimental conditions. In fact the mean volume of urine excreted in 3 hours by 5 normal subjects was 497 ml. as compared with 316 ml. excreted by 6 patients. The concentrations of urea and potassium in the urine had a smaller range and were often lower than in the normal subjects. The mean of the total amounts of urea excreted was diminished. Also, the total amount of potassium eliminated was decreased and in patient W.L. was only 0.23 gram in 3 hours. If this amount of potassium was evenly excreted throughout the day it would total 1.8 grams in 24 hours, which approximates that excreted by a normal starving

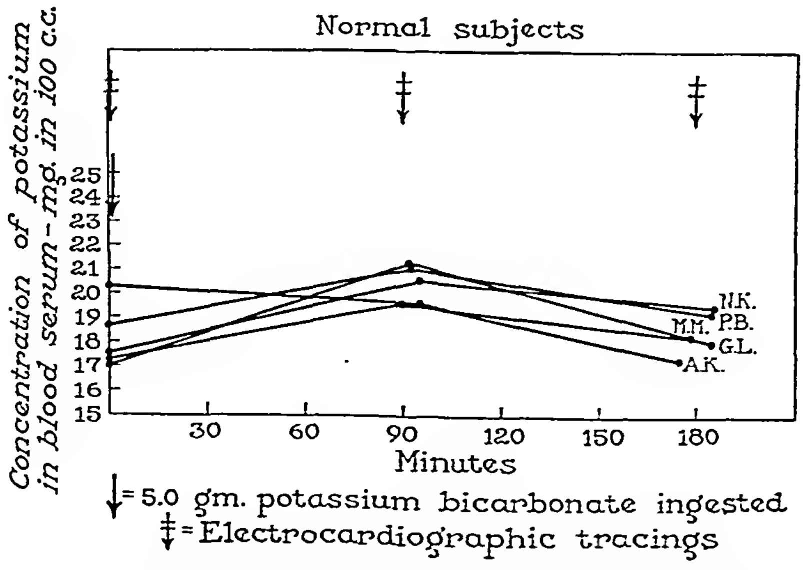

Fig. 1. Five Normal Subjects. The Concentration of Potassium in the Blood Serum Before and at 1½ and 3 Hours After the Ingestion of 5.0 Grams of Potassium Bicarbonate

Details of these studies reported in Proceedings of the Staff Meetings of the Mayo Clinic (8).

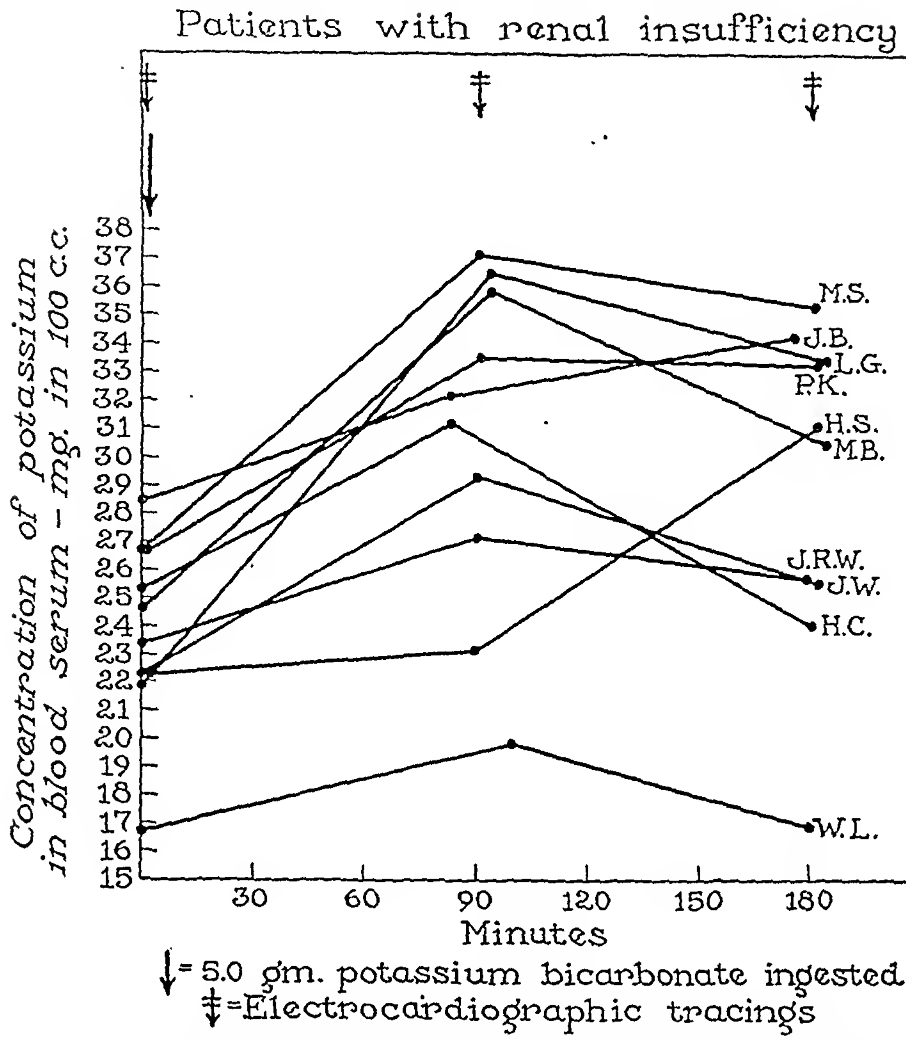

Fig. 2. Ten Patients with Renal Insufficiency. The Concentration of Potassium in the Blood Serum Before and at 1½ and 3 Hours After the Ingestion of 5.0 Grams of Potassium Bicarbonate

In 9 patients the serum potassium is distinctly increased over that observed in normal subjects. Compare with Figure 1. In 3 patients, M. S., M. B., and L. G., the serum potassium at 1½ hours increased to a potential toxic concentration. The curve of patient W. L. is similar to that of normal subjects.

subject.[2] Therefore, patient W. L. was unable in 3 hours to eliminate any of the extra potassium ingested. A similar calculation for 5 other patients revealed an excretion in 3 hours of 4 to 39 per cent of the extra potassium ingested. This is in distinct contrast to a range from 49 to 100 per cent in our studies on normal subjects.

The clearances of urea were greatly decreased to a range from 3 to 15 ml. (Table II). The clearances of potassium, ranging from 5 to 16 ml., however, were similar to those observed in normal subjects and in some patients who had renal insufficiency, when both subjects and patients were fasting and ingesting water only. It is clear, however, that the clearances of potassium, ranging from 5 to 16 ml., for our patients were distinctly less than those obtained, ranging from 29 to 67 ml., for normal subjects who had taken 5.0 grams of potassium bicarbonate. These facts indicate that in our patients there was a diminished and slower response of the kidneys to the stimulus of the potassium salt than in the normal subject. The kidneys of these patients were capable only of eliminating a dilute urine but were enabled by continuous excretion of potassium during the entire 24

[2] In Benedict's study (11), the starving subject on the first day of a prolonged fast excreted 1.63 grams of potassium in the urine.

hours to prevent its excessive retention in the blood.

The variability of the increases in the concentration of potassium in the serum of 6 patients contrasted markedly with the uniformity of the diminution of urinary excretion and clearances of potassium. The serum concentration, 1½ hours after ingesting the salt, varied from 19.9 to 36.5 mgm. or an increase of 5 to 92 per cent from a normal mean concentration of 19.0 mgm. in 100 ml. The mean reduction in the renal excretion of potassium in the 6 patients compared to that in normal subjects amounted to 1.09 grams or 32 per cent.

The decreased excretion and clearance of potassium in patient W. L. is unusually interesting, for, as stated in a previous section, the curve of the concentration of potassium in the blood serum (Figure 2) was identical with that observed in normal subjects (Figure 1) and one would therefore infer that this patient had a normal tolerance for potassium. However, the greatly reduced renal excretion of potassium (Table II) signified a decreased tolerance for potassium on the part of a single organ, the kidney. The results in patient W. L. also emphasized the important fact that there must be several organs that play a role in the internal regulation of potassium.

STUDIES OF THE ELECTROCARDIOGRAM [3]

There were 2 chief reasons for including serial electrocardiographic observations in the study of our 10 patients. The first was to ascertain whether 5.0 grams of potassium bicarbonate, when given to these patients, would cause alterations in the electrocardiogram similar to those observed in normal subjects. The second reason was to determine whether this relatively moderate dose of potassium bicarbonate would lead in patients to an excessive increase in the concentration of potassium in the serum and thus produce toxic effects on the heart. In each of the 10 patients serial electrocardiograms revealed some alterations in the T waves of the electrocardiogram (Table III). The alterations were often, though not invariably similar to those observed in normal subjects. Thus 5 normal subjects and 10 patients on whom this test was performed have revealed changes in the electrocardiogram which we think are due to a rapid increase of potassium in the myocardium. As was to be expected, changes observed in the patients were more varied than in the normal subjects; as a rule they persisted for a longer period and were sometimes observed for 8 hours after the taking of the salt. The changes due to potassium were sometimes more difficult to evaluate in patients than in the normal subject because a number of the control electrocardiograms of the patients were abnormal. For example, several patients had previously had severe hypertension and a tracing characteristic of left ventricular strain (Table III). Figures 3A and B show serial electrocardiograms with characteristic and varied alterations in 2 of our patients (J. R. W. and M. S.).

The electrocardiographic findings for patient H. S. (Table III) confirmed our previous clinical conception that potassium was more slowly absorbed from his intestine than in the 9 other patients. The curve of serum potassium slowly rose from 22.2 to 23.1 mgm. in 1½ hours, and to its peak, 31.1 mgm., in 3 hours and fell to 26.0 mgm. only after 8 hours. The concomitant changes in the electrocardiogram at 1½ hours revealed increased T waves, but at 3 hours these alterations in the T waves were much greater and appeared to be at their peak. Characteristic changes of the T waves, though less than at 3 hours, were present at 8 hours.

The electrocardiographic changes revealed in patient W. L. (Table III) at 1½ and 3 hours, though somewhat atypical, are of interest. It was previously pointed out that in this patient the concentration of potassium in the serum increased only 3.1 mgm. at 1½ hours, an increase similar to that found in normal subjects. Therefore we believe we have evidence in this patient that at least some of the potassium salt was rapidly absorbed from the intestine and produced concurrent effects in the blood serum and in the myocardium that are comparable with the response of the normal subject. The abnormally decreased renal excretion of potassium was the only evidence of a disturbed tolerance for this ion. The entire response in this patient could be explained by a decreased absorption of potassium from the intestinal tract. However, the evidence given earlier in this paragraph

[3] The authors are indebted to Dr. H. B. Burchell for this detailed interpretation of the electrocardiograms.

and the fact that some uremic patients have an abnormally low concentration of potassium in the serum and hence a low concentration in other tissues strongly support the viewpoint that normal absorption occurred and that the extra potassium entered tissues low in potassium content.

We have reliable evidence from the electrocardiographic and blood studies of patient M. S. (Figure 3B) that even the ingestion of 5.0 grams of potassium bicarbonate will produce toxic effects on the heart. In 1½ hours the content of potassium in the blood serum rose from 26.7 to 37.1 mgm. (Figure 2), an increase of 10.4 mgm., and the electrocardiographic tracings revealed early intraventricular block (Table III, Figure 3B). Previously we (12, 13), as well as other investiga-

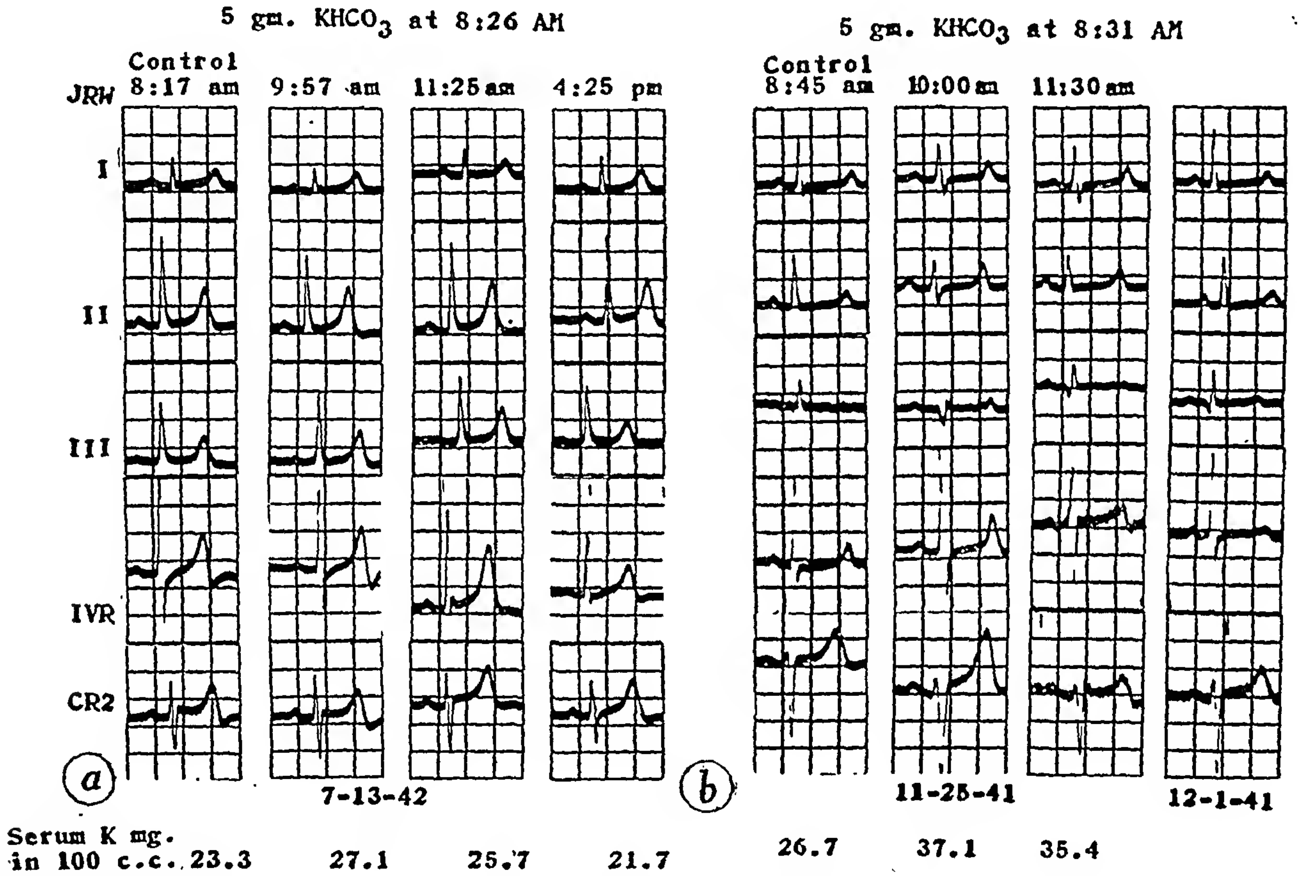

Fig. 3A. Patient J. R. W. Serial Electrocardiograms Showing the Effect of Increased Serum Potassium Levels

The patient did not reveal any abnormal cardiovascular findings. The first column, recorded shortly before administration of potassium, is normal. Following the ingestion of the potassium salt, the records show increases of the voltage of the T wave (2 mm. in lead II, 4 mm. in lead IV–R). It is to be noted that while the potassium level has fallen 1.4 mgm. between 9:57 and 11:25 a.m., the T waves are at their highest at the latter time. In IV–R there are loss of the late negativity and a slight elevation of the R–T interval. The QRS complexes and the various time intervals do not show any significant change.

B. Patient M. S. Serial Electrocardiograms Showing the Effect of Increased Levels of Potassium in the Serum

The control tracing is an essentially normal electrocardiogram. With the increase of serum potassium level there is a concomitant increase in the height of the T wave and in the length of the QRS interval (from 0.07 to 0.09 second). The QRS has become more biphasic and suggests the beginning of the intraventricular conduction defect which is so characteristic of the tracing in patients having potassium concentrations approaching the lethal level. Such a tracing has not been observed previously with such a small dose of a potassium salt. Attention is drawn to the characteristic sharply peaked, narrow-base configuration of the T waves as seen in leads II and IV–R of the second column. The Q–T intervals are respectively 0.48, 0.48, 0.44, and 0.44 second and the corresponding R–R times are 1.05, 0.90, 1.10, and 1.15 seconds respectively. On November 26 the serum calcium was 8.4 mgm. per 100 ml.

tors (14), have reported a similar degree of hyperpotassemia and electrocardiographic findings of intraventricular block among patients suffering from severe uremia and not receiving therapeutic doses of potassium salts. These patients died shortly afterward because of the toxic effect of the potassium on the heart. Fortunately, in this patient at the end of 3 hours the evidence of intraventricular block had almost disappeared although the concentration of potassium in the serum was still high, 35.4 mgm. Several days later, electrocardiograms were taken and proved to be identical with those observed before the potassium salt was ingested. Sharpey-Schafer in 1943 (7) reported the temporary induction of intraventricular block in a patient who had myocardial degeneration and had ingested a much larger dose, 15 grams of potassium salts. Our experience with patient M. S. affords objective evidence that in chronic nephritis there may be a marked decrease of the tolerance for potassium and hence the administration of potassium salts may be a dangerous procedure. On the other hand, it is significant that in the remaining 9 patients, some of whom had very severe renal insufficiency, the electrocardiogram did not reveal definite intraventricular dysfunction.

COMMENT

In 4 cases paresthesias developed in the extremities, a fact which we think is clinical evidence of a lowered potassium tolerance, because these symptoms were observed previously only in subjects to whom much larger doses of potassium had been administered. In all of our 10 patients the excretion of potassium by the kidney was decreased, and in 9 there was an abnormal rise of the curve of serum potassium. Both results indicated a definite decrease of tolerance.

The concentration of potassium in the serum rose to potentially dangerous levels in 3 patients, but only in a single instance did it produce a demonstrable toxic effect on the cardiac muscle. In the 3 patients, the extra potassium ingested was presumably distributed chiefly in the extracellular fluid of the body. Calculation of the distribution of potassium in 1 of these, patient L. G., was as follows: His body weight amounted to 75.7 kgm. If 20 per cent of the body weight may be considered to represent the volume of extracellular fluid, in this subject it would amount to, therefore, 15,000 ml. If then 2.0 grams of potassium, less that excreted in the urine, is dissolved in 15,000 ml. of fluid, the estimated increase in the concentration of potassium would be 12 mgm. per 100 ml.[4] The observed increase in the patient's serum was 14.6 mgm. per 100 ml., which is in close agreement with the calculated value.

In 7 patients the potassium ingested was presumably distributed, in varying proportions, between the extracellular and the intracellular fluid. However, in a single patient a large proportion apparently entered rapidly into the intracellular fluid. This result would lead one to believe that the stores of potassium in the cells of this patient were depleted, despite the presence of severe renal insufficiency. Our results, therefore, indicate a marked variation in the distribution of potassium between the 2 reservoirs of body fluid.

The small increase in the serum curve of patient W. L. also suggests the possibility that in certain patients who have uremia there may be an actual increase of tolerance for potassium. In this connection several observers have recorded concentrations of serum potassium distinctly below the normal range in patients who have renal disease (12). We reported a content of 12.8 mgm. per 100 ml. of serum in 1 such patient (15) and Brown, Currens and Marchand (16) reported a concentration of 7.8 mgm. in the case they reported.

In the present study we have demonstrated the occurrence of a decreased tolerance for potassium. This is in agreement with the findings in the blood serum in 2 cases of renal insufficiency published by Greene and his co-workers. Considerable evidence also has been advanced for the presence of both a normal and an increased tolerance. Further research is necessary to prove the occurrence of these latter conditions. Studies of potassium tolerance are also needed in the states of inanition or semistarvation, which develop rather frequently among patients suffering from chronic uremia.

In a previous paper (17) we recommended caution in administering potassium salts to a nephritic patient who has edema and in whom the concentration of urea in the blood is 100 mgm. or

[4] $\frac{2{,}000 \text{ mgm.} - 266 \text{ mgm.}}{15{,}000} = 12 \text{ mgm. per } 100 \text{ ml.}$

more per 100 ml. In 9 cases, in our present series, in which the tolerance for potassium was reduced, the urea content of the blood varied from 90 to 340 mgm. per 100 ml. We still rely on this chemical observation as a precautionary measure. Therefore, it is suggested that a potassium tolerance test be carried out if a patient has a blood urea of 100 mgm. per 100 ml. and the results should provide evidence as to whether or not a potassium salt could be safely administered. Winkler, Hoff, and Smith (5) have emphasized the point that oral administration of potassium salts to patients who have nephritic edema is a reasonably safe procedure and our results support their contention, especially when there is an adequate renal excretion of the metabolites, urea, sulfate, and creatinine. Fortunately the majority of patients who have nephritic edema will reveal a concentration of urea in the blood which is much less than 100 mgm. per 100 ml.

SUMMARY

A diminished tolerance for potassium has been demonstrated in a series of uremic patients. Other results of this study suggest the presence of a normal tolerance and even an increased tolerance for potassium in certain phases of uremia but further research is necessary to prove or disprove their actual occurrence.

METHODS OF CHEMICAL ANALYSIS EMPLOYED IN THE PRESENT STUDY

Whole blood

Hemoglobin—Sanford, A. H., Sheard, Charles, and Osterberg, A. E., The photelometer and its use in the clinical laboratory. Am. J. Clin. Path., 1933, 3, 405.

Urea—Van Slyke, D. D., and Cullen, G. E., A permanent preparation of urease, and its use in the determination of urea. J. Biol. Chem., 1914, 19, 211.

Creatinine—Folin, Otto, Laboratory manual of biologic chemistry with supplement. Ed. 3, New York, D. Appleton & Company, 1922, pp. 149, 245 and 247.

Serum

Potassium—Kramer, Benjamin, and Tisdall, F. F., A clinical method for the quantitative determination of potassium in small amounts of serum. J. Biol. Chem., 1921, 46, 339. This method in our hands has checked with gravimetric procedures. The precipitation by sodium cobaltinitrite was allowed to proceed for 45 minutes at icebox temperature in order to obtain a good granular precipitate. If this and other steps are rigorously adhered to, the method is satisfactory.

Calcium—Clark, E. P., and Collip, J. B., A study of the Tisdall method for the determination of blood serum calcium with a suggested modification. J. Biol. Chem., 1925, 63, 461.

Total proteins—Macro-Kjeldahl technic of estimation of total nitrogen and total protein, calculated after subtracting nonprotein nitrogen as estimated by the micro-Kjeldahl method.

Albumin and globulin fractions—Howe, P. E., The determination of proteins in blood; a micro method. J. Biol. Chem., 1921, 49, 109. Kingsley, G. R., A rapid method for the separation of serum albumin and globulin. J. Biol. Chem., 1940, 133, 731.

Urine

Urea—Same method as for whole blood.

Potassium—Same method as for estimation in serum except that urine is ashed before precipitation.

THE EFFECTS OF VAGOTOMY ON THE PHYSIOLOGY OF THE STOMACH IN PATIENTS WITH PEPTIC ULCER [1]

By JAMES S. CLARKE, EDWARD H. STORER, AND LESTER R. DRAGSTEDT

(From the Department of Surgery of The University of Chicago)

(Received for publication August 18, 1946)

Since January of 1943 bilateral section of the vagus nerves to the stomach has been performed in this clinic on 160 patients with benign duodenal, jejunal, and gastric ulcers. The technic employed to obtain complete bilateral vagus section and the clinical results have been described elsewhere (1 to 4). During the course of this work there arose the opportunity to study the effect of vagotomy on the continuous night secretion of gastric juice in the empty stomach, on the gastric secretory response to histamine, caffeine, insulin, and sham feeding, and on gastric motility in ulcer patients. A report dealing with a portion of these studies has appeared recently (5). The present paper presents the results of night secretion tests on 37 patients with diseases other than benign ulcers and on 42 patients who underwent vagotomy for benign ulcer. It describes the gastric secretory response to insulin hypoglycemia and sham feeding before and after vagotomy in 23 ulcer patients and the effect of vagotomy on motility in 13 such patients.

In general, the patients who underwent vagotomy and are presented here had ulcer symptoms of many years' duration. With only a few exceptions they had all experienced typical ulcer pain and in most a crater had been demonstrated by gastroduodenal x-ray examination. A majority had suffered pyloric obstruction, hemorrhage, or perforation. They were either refractory to medical management or had been proved unable to follow such a regime. Thus, in every case, the ulcer represented a serious affliction. The patients were led to accept vagus section because of refractory pain, recurrent hemorrhage, pyloric obstruction, or the prospect of cure of their ulcer disease without the necessity for long-term medical management.

Bilateral section of the vagus nerves to the stomach was performed at or just above the level of the diaphragm. In those cases which required gastroenterostomy because of appreciable pyloric obstruction, the vagus section was done through the abdominal incision. In one case in this series (J. A.) a transabdominal subtotal gastrectomy and vagus section were done.

The results of this procedure have so far been extremely gratifying. In many cases x-ray examination has demonstrated progressive healing of large ulcers over a period of 3 to 12 weeks following operation. Prompt relief of ulcer pain following vagotomy is characteristic. All but 4 of the 42 patients reported here experienced immediate relief of all pain without recurrence. Of these 4, 2 (M. H. and J. W.) have had abdominal pain of an atypical character after vagotomy, and it is probable that this pain is not on the basis of ulcer disease. The third patient (H. K.) has had a single brief bout of epigastric distress since operation. A fourth patient continued to have symptoms after operation, and when a total gastrectomy was done elsewhere 8 months later these were determined to be due to obstruction rather than to persistent ulceration (6).

Fifteen of these 42 patients had postoperative diarrhea of varying degree, ranging from 4 to 5 loose stools per day to replacement of preoperative constipation by normal bowel habits. Actual diarrhea has not persisted longer than 3 to 6 weeks following vagotomy. In some patients the relief of preoperative habitual constipation has constituted a pleasant surprise and has persisted for months and to the present time. Postoperative pain in the thoracotomy wound has, with few exceptions, disappeared within 3 weeks following operation.

METHODS

1. *The continuous 12-hour night secretion of gastric juice*

At 9:00 p.m. the stomach was emptied with a Levine tube, or with an Ewald tube if its larger diameter was necessary. The stomach was lavaged with water until the return was clear. A Levine tube was placed in the

[1] This work has been aided by grants from Mr. Andrew E. Wigeland and from the Douglas Smith Foundation for Medical Research of The University of Chicago.

stomach and was left in place under continuous Wangensteen suction for the subsequent 12 hours. Most of these patients were accustomed to intubation and the inlying Levine tube did not upset them nor interfere with their sleep. Approximately 20 per cent, those who could not rest soundly without medication, received 0.12 gram of sodium luminal at 9:00 p.m. subcutaneously. While the tube was in place the patients were not exposed to the sight, smell, or taste of food. The juice aspirated from the stomach during the night was collected at 9:00 a.m. and any specimens which contained particles of food were discarded. The volume of each specimen was measured and the free and total acid were determined in terms of "clinical units" by titration with 0.1 N NaOH to the change of color with Topfer's reagent and phenolphthalein, respectively. The figures on night secretion in patients with diseases other than benign ulcer (Tables I to III) represent the results derived from an aspiration conducted on each patient on the night before operation. All figures on the night secretion in ulcer patients before and after operation (Tables IV to VI) represent in each case the average of 3 or more night secretion tests performed before and again within 2 weeks after operation.

It seemed valuable to express the night secretion of the stomach in terms of "Total acid output in millimoles" and "volume of parietal cell output in ml." Since the total acid concentration of the gastric juice, expressed as "clinical units," is numerically equal to the number of millimoles of HCl per liter in the gastric juice, the following is true.

(Total acid in C.U.) × (Vol. of night secretion in liters) = (Total HCl output in millimoles)

Moreover, it is known that pure parietal cell secretion contains very close to 166 mM. per liter of HCl (7). It may therefore be said that:

$$\frac{(\text{Total HCl output in mM.})}{166} \times 1{,}000 = (\text{Total HCl output in mM.}) \times 6.02 = (\text{Volume of parietal cell output in ml.}).$$

2. *The insulin test*

A Levine tube was inserted in the fasting stomach before breakfast and the stomach emptied. The patient lay quietly in bed in a comfortable semirecumbent position. He was shielded from outside stimuli, especially from food. The gastric juice was collected continuously for

a period of approximately 2 hours. The amount aspirated in each 10-minute period was measured as to volume and free and total acidity. At the end of 30 minutes the patient received 20 or 30 units of crystalline insulin subcutaneously. Blood sugar levels were determined at ½ hour and 2 hours after the beginning of the test. A majority of patients showed a mild insulin reaction about 1 to 1½ hours after receiving the injection. One or 2 insulin tests were done on each patient before and again within 2 weeks after vagotomy.

3. *The sham meal test*

Levine tube was placed in the fasting stomach before breakfast and the stomach emptied. The patients sat up comfortably in bed and his surroundings were made as agreeable as possible. The gastric secretion was collected over three 10-minute periods as a control. Then the patient was presented with an attractively prepared, appetizing "breakfast in bed," consisting of a small glass of orange juice, 2 slices of bacon, 2 pieces of lightly buttered toast, and 1 cup of coffee with cream and sugar. The patient proceeded just as he would with any ordinary breakfast, except that after tasting and chewing it he expectorated the food into a tall container, so chosen as to prevent him from seeing the masticated food it held. The gastric secretion was collected continuously and portioned into 10-minute samples for 1 to 1½ hours after the test breakfast was begun. The volume and free and total acidity of each sample were determined. If the patient swallowed any of the test breakfast, the test was discarded. The patient usually spent 10 to 15 minutes from start to finish of the test meal. One or 2 sham meal tests were done on each patient before and after vagotomy.

4. *Gastric motility*

A Miller-Abbott tube was inserted into the fasting stomach and the balloon was inflated to a pressure of 15 to 25 cm. of water. A record of gastric motility was obtained on a smoked drum by means of a water manometer connected to this balloon. During each test the patient lay supine or on his right or left side. No medication was given to these patients during these tests, but most of them slept at least part of the time. At each test it was determined whether the patient had normal "tonus" waves and normal "hunger contraction." It was also determined whether the patient could feel and identify distention of the balloon beyond the amount used for recording and whether the passage of the contraction waves were accompanied by any sensation. The motility test was performed once before and again once within 2 weeks after vagus section.

RESULTS

1. *The continuous 12-hour night secretion of gastric juice*

It will be seen from perusal of Tables I to IV that there is a marked difference between the ulcer patients and those without benign ulcers in both quantity and acidity of juice aspirated by continuous suction during the 12-hour nocturnal period. The average volume in 12 patients with carcinoma of the stomach was 333 ml. with a free acidity of 7 and a total of 35 clinical units. That of 14 patients with cholelithiasis was 359 ml. with a free and total acidity of 16 and 38 units. Eleven patients with miscellaneous other diseases averaged a night secretion of 477 ml. with a free acidity of 29 and a total of 49 clinical units. These figures contrast with those obtained in 42 patients with benign ulcers. The average night secretion of the 16 patients presented in Table IV, all of whom had little or no element of pyloric obstruction, was 865 ml. with a free acid of 47 and a total of 66 clinical units. In Table V, consisting of patients with moderate to marked pyloric obstruction, the average volume of nocturnal secretion is 1,000 ml. free acidity 36 and total 53 clinical units. Even some of the patients with jejunal ulcers following gastric resection (J. V. and G. P. in Table VI) show an elevated acid output. As determined by this method the difference in acid output between pa-

tients with benign ulcers and without is great. The exceptions to the rule are few.

Analysis of Tables IV to VI also reveals that section of the vagus nerves to the stomach, with few exceptions, causes a marked reduction in the volume and acidity of the nocturnal gastric aspiration. The average total acid output of the stomach in 16 patients (Table IV) was halved by vagotomy. Two of these patients, however (J. D. and E. K.), showed no reduction. It is not surprising that the average acidity of the aspirate was reduced after vagotomy plus gastroenterostomy (Table V), but it should be noted that the volume of aspirate was also reduced, despite regurgitation of duodenal juices through the gastroenterostomy stoma. The night secretion of all but 1 of 7 patients with jejunal ulcers (Table VI) was also reduced after vagotomy.

2. *The insulin test*

The protocols of representative insulin tests are presented in Tables VII to IX. There was no consistent response to insulin hypoglycemia in terms of volume of 10-minute secretions. There was, however, a regular response in terms of acidity of the aspirate following the injection of insulin. Beginning 60 to 90 minutes following injection, there was usually a marked rise in free and total acidity of the aspirated juice. In reviewing this series of tests it appeared that there was a random variation of the acidities of the samples that amounted to approximately 20 clinical units in

some cases. Therefore, it was arbitrarily decided to call the response positive only in those cases in which the total acidity increased following insulin administration by more than 20 clinical units over its control values. Using this criterion, 5 of the 22 ulcer patients tested failed to respond preoperatively by increased acidity of the gastric aspirate to 1 or 2 insulin tests. Following vagotomy, 18 of 21 patients tested failed to respond. No patient who failed to respond before operation gave a positive response after operation.

3. *The sham meal test*

The protocols of representative sham meal tests are presented in Tables X to XII. Here again the volumes of the 10-minute samples were so variable that they were considered to be meaningless. Typically a marked increase in the free and total acidity of the gastric aspirate began within 10 to 20 minutes of the mastication of the sham meal and continued for over an hour. Again it was decided to designate a response as positive if the total acidity increased by 20 clinical units or more over its control value. Fifteen of 20 ulcer patients tested before operation gave a positive response to the sham meal. Following vagotomy only 2 of 22 patients tested gave a positive response. All patients who failed to respond to the sham meal before operation also failed to respond postoperatively.

4. *Gastric motility*

Thirteen of the 23 ulcer patients whose response to insulin and the sham meal are reported in this paper underwent a gastric motility test before and after vagotomy. The results were much the same in every case. Two representative tracings are presented in Figures 1 and 2. All 13 patients

tested showed a basal "tonus" rhythm with a frequency of 2 to 3 per minute (wave duration of 20 to 30 seconds). This was unaltered by vagotomy.

All 13 also showed larger "hunger contraction" waves, as described by Carlson (8), sometimes coming irregularly and sometimes in series, each wave having a duration of roughly 60 seconds. In 12 of these 13 patients these hunger contractions were absent 10 to 14 days following vagus section. In the other patient (J. G.) they were present, but much weaker and more irregular than before operation. The preoperative hunger contraction waves were stronger and more frequent in patients whose ulcers were complicated by a degree of pyloric obstruction than in those without obstruction. There is evidence that these hunger contractions return within several months following vagotomy. They were present and normal in appearance in the case of J. G., when tested 3 months following vagotomy. Another patient (N. W.) had no such waves 10 days following transthoracic vagotomy, but had normal contraction waves 8 days following posterior gastroenterostomy for pyloric obstruction 1½ months later. A third patient (N. K.) had normal rushes of hunger contractions 11 months following transthoracic vagotomy.

In all patients tested, distention of the stomach by the inlying balloon was felt as a vague epigastric pressure or gas pain, and there was no appreciable difference in the quality of the sensation nor its threshold after vagotomy. Five of the 13 patients upon whom motility studies were done were sufficiently introspective accurately to identify preoperatively the hunger contraction waves, describing the sensation as a "pulling in the stomach," a "feeling of suction," and as "hunger pangs." Within the first 2 weeks following vagotomy none of these had sufficiently good contraction

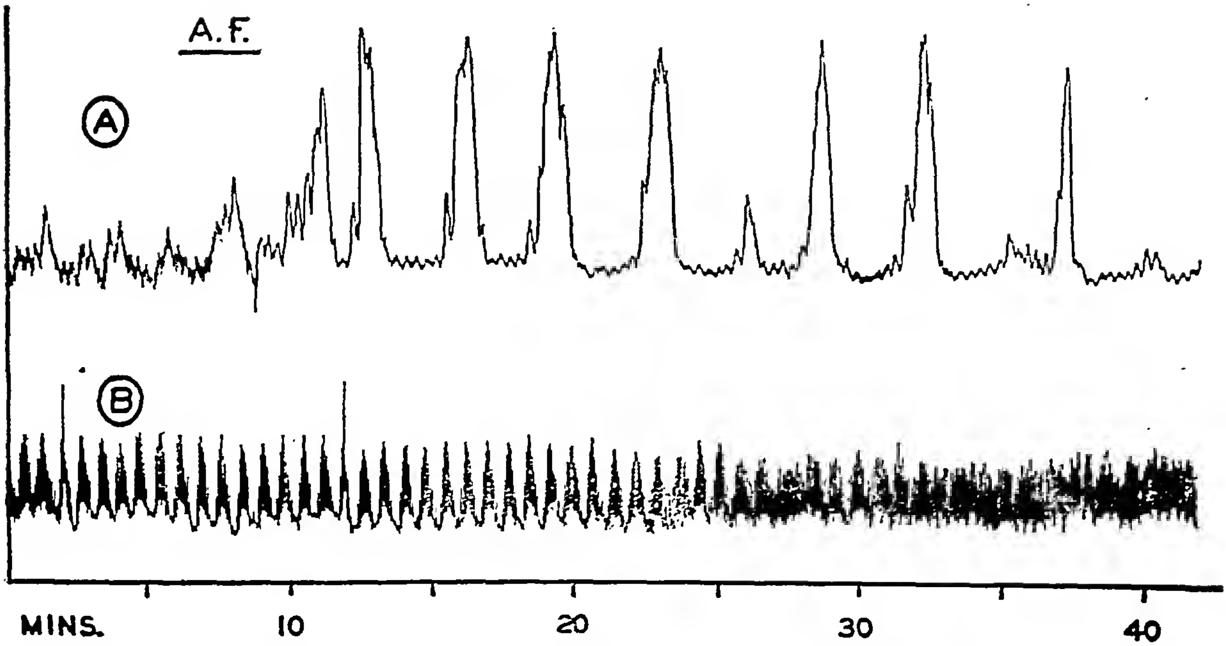

FIG. 1. TRACINGS SHOWING THE MOTILITY OF THE FASTING STOMACH OF A PATIENT (A. F.) WITH A DUODENAL ULCER 2 DAYS BEFORE (A) AND 8 DAYS AFTER (B) SUBDIAPHRAGMATIC VAGOTOMY PLUS POSTERIOR GASTROENTEROSTOMY

waves to give a fair test for postoperative sensation of this sort.

DISCUSSION

During the past 3 years the results of section of the vagus nerves for refractory peptic ulcer have been excellent, both in our hands and those of others (4, 5, 9). Ulcer pain has been absent following vagotomy, but the fact that in a few instances it has occurred briefly makes it unlikely that pain of this sort is mediated via the vagi. Several of our patients (J. G. and N. W.) have suffered rather marked gastric retention following vagotomy, as evidenced by distention, belching of foul gas, and anorexia, and as determined by x-ray examination. This was relieved after gastroenterostomy. In several other patients milder symptoms of this sort, present during the first 2 to 4 weeks following vagotomy, have cleared spontaneously without any additional operative procedure. The initial hypomotility of the stomach after vagotomy will combine with pyloric obstruction, in cases where it is present, to produce decreased gastric emptying. As a result, it is necessary to combine vagus section with gastroenterostomy in cases which show an appreciable amount of pyloric obstruction before operation. It is also imperative to keep an indwelling suction tube in the stomach for the first 2 to 4 days after vagotomy to prevent distention and possible acute dilatation of the atonic viscus.

The postoperative tendency toward loose bowels, which has been an unexpected feature in the postoperative course of 15 of the 42 patients presented here, remains unexplained. On theoretical grounds, parasympathetic denervation of the gastrointestinal tract down to the mid-colon would seem more likely to result in constipation.

The operation of vagus section for peptic ulcers is predicated upon the theory that an abnormally increased interdigestive secretion of gastric acid and possibly pepsin, mediated by impulses proceeding down the vagus nerves, is a major factor in the pathogenesis of such ulcers. Cushing in 1932 (10) reported a group of cases in which lesions in the midbrain resulted in fatal ulceration of the upper gastrointestinal tract. Under experimental conditions typical peptic ulcers can be produced by artificially induced hypersecretion of gastric juice (11) and by permitting the gastric juice to act on the intestinal mucosa without being neutralized by duodenal secretions (12 to 14). It

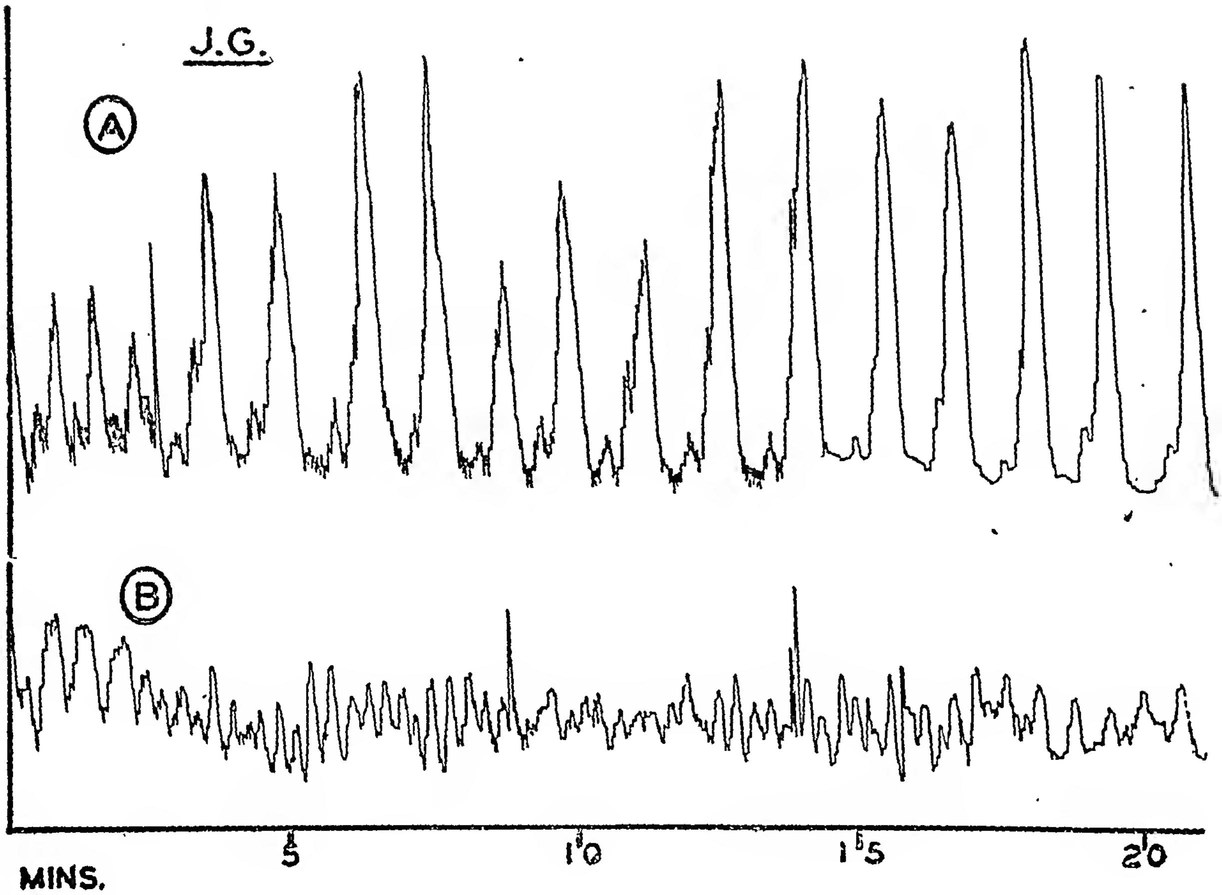

FIG. 2. TRACINGS SHOWING THE MOTILITY OF THE FASTING STOMACH OF A PATIENT (J. G.) WITH A DUODENAL ULCER 1 DAY BEFORE (A) AND 9 DAYS AFTER (B) SUBDIAPHRAGMATIC SECTION OF THE VAGUS NERVES TO THE STOMACH

is therefore important to determine whether or not ulcer patients do have an abnormally increased interdigestive gastric secretion and whether their secretion is reduced following section of the vagus nerves. The continuous nocturnal gastric aspirations reported here represent an effort to answer these questions.

Night secretion tests on patients as performed by the technic described in this paper have their limitations and must be interpreted cautiously. Great care must be taken to ensure that the Levine tube does not become plugged or kinked in the stomach during the night, resulting in a volume of aspirate less than would be obtained under ideal conditions. There is a consistent alteration in character of the aspirate following vagotomy, in that it becomes more mucoid in nature. The increased viscosity may tend to reduce the volume of juice aspirated below its correct value.

There is an inevitable amount of regurgitation of duodenal juice into the stomach in most cases, probably more marked in those patients with gastroenterostomies or gastric resections. This might be expected to alter somewhat the volume of aspirate but should not alter the calculated total HCl output. There is also undoubtedly some loss of gastric juice through the pylorus and this should be decreased in the presence of pyloric obstruction. On comparing Tables IV and V it may be seen that the actual volumes obtained in 18 cases with pyloric obstruction were somewhat elevated above those obtained in 16 cases without appreciable obstruction, but that the free and total acidities were not greatly different in the two groups. Finally, it must be recognized that the non-ulcer patients considered in Tables I to III do not constitute an ideal control group because of the presence of pathology other than ulcer.

Despite these limitations the results summarized in Tables I to VI are sufficiently consistent and the differences sufficiently great to state unequivocally that the continuous night secretion of gastric juice was markedly greater in the ulcer patients than in those without ulcers, both in volume and acidity.

This is particularly emphasized if the calculated total acid output or volume of parietal cell secretion is considered. These conclusions are at variance with those of Sandweiss *et al* (15) whose studies caused them to conclude that the "nocturnal volume of gastric juice in patients with duodenal ulcer (as obtained by continuous suction) is on the average not greater than that of normal subjects of the same age and sex." However, their patients experienced only mild ulcer distress and their ulcer disease was neither so active, so prolonged, so refractory to medical management, nor subject to so many complications as the disease in our series. Even so, they did note hypersecretion of HCl in several of their ulcer patients, and these were, interestingly enough, patients presenting more or less intractable ulcers clinically. In our experience interdigestive gastric secretion studies have constituted a logical and satisfying corroboration to the excellent clinical results of vagus section.

The insulin test was proposed by Ihre (16), Babkin (17), and Hollander (18) as a method of investigating the integrity and function of the vagus nerves to the stomach. Gastric secretion is stimulated as a result of the hypoglycemia induced by insulin (19, 20) and this response is abolished by vagus section (21, 22). In the tests presented in this paper the increase in acidity of the gastric juice occurred at roughly the same time as the maximum fall in blood sugar. In a study of 17 ulcer patients, Thornton, Storer and Dragstedt (5) found that 15 gave a positive response to insulin hypoglycemia before vagotomy and that only 1 of these responded after vagotomy. The results obtained in the present group of 23 additional ulcer patients are roughly the same, a few failing to respond in 1 or 2 insulin tests before operation. Three of our patients gave a definite positive response following operation. A fourth (J. G.), though showing a negative response 2 weeks following vagus section, had a positive response to both the insulin and sham meal test 3 months following vagotomy. It should be noted that all of these 4 patients underwent vagotomy via the abdominal route, a technically more difficult approach to obtain complete bilateral vagus section than through the thorax. Their postoperative response to insulin may be indicative of residual vagus innervation of the stomach. Another patient (N. K.), on the other hand, still showed a negative response to insulin 11 months after vagotomy. We were unable to note any appreciable difference in the response to insulin between our ulcer patients and 6 normal young adults tested in the same manner.

The sham meal test elicits a gastric response which is likewise dependent upon an intact vagal innervation of the stomach. Pavlov showed in dogs (23) that the gastric secretory response to sham feeding and to conditioned reflexes is abolished by vagus section. Necheles and Maskin (24) studied the response of normal and ulcer patients to sham feeding and found little difference between the two groups. A previous attempt on a group of 10 of our patients (5) yielded positive responses before operation in only 3 cases, after operation in none.

Some care must be taken in performing the sham meal test if best results are to be obtained. The inlying Levine tube is naturally distracting to the patient. Positive results were obtained much more consistently in those ulcer patients who had had long experience with gastric intubation than in those unused to the procedure. A positive response was often obtained on a second test, when it had been absent on the first. It is probable that a positive response could finally be obtained in almost every patient if a sufficient numbr of tests were done. Every effort must be made to present the patient with an appetizing sham meal and to shield him from the sight of the expectorated food. If the patient swallows at all during the test, the test is invalidated due to the stimulating effect on secretion of the food itself in the stomach. The response to the sham meal constitutes a conditioned as well as an unconditioned reflex, and psychic inhibition of the normal response occurs easily.

Out of the 20 patients upon whom sham meal tests were done before vagotomy and whose data are summarized in Table XIII, 15, gave a positive response to at least one of 1 or 2 sham meal tests. Following vagotomy, only 2 of 22 gave positive responses. This again may represent residual vagus innervation to the stomach in these cases. The sham meal test and the insulin test appear to be about equally reliable criteria of the integrity of the vagi, and they supplement each other in a useful manner.

Note: Results recorded above are derived from 1 or 2 tests of each sort performed before operation and repeated within 2 weeks after operation.

The gastric secretory response to insulin and the sham meal are thus mediated via the vagus nerves, should be absent after complete vagotomy, and is to be sharply differentiated from the response to histamine and caffeine which has been shown (5) to be little altered by vagotomy.

The results presented here regarding gastric motility and sensation in 13 ulcer patients subjected to vagotomy agree with those obtained previously in this clinic in a study of 8 earlier cases and are in accordance with the findings of Moore *et al* (9). Vagus section does not seem to impair the sensation resulting from gastric distention, nor the sensations of nausea and appetite. Ulcer pain can be felt following vagotomy. We have not yet been able to determine whether typical hunger pang sensations that can be correlated with gastric hunger contractions persist following vagus section.

SUMMARY

1. The continuous night secretion of gastric juice in the empty stomach of patients with benign ulcer is, as a rule, greater in volume and acidity than that of patients without such ulcers. It is usually markedly reduced following section of the vagus nerves to the stomach.

2. The secretory response of the fasting stomach of patients with benign ulcer to the stimulation of insulin hypoglycemia and of a sham meal is abolished by vagus section.

3. The motility of the empty stomach of patients with benign ulcer is, as a rule, markedly reduced for at least 2 weeks following section of the vagus nerves to the stomach. It returns toward normal limits within a period of 1 to 3 months.

4. Following section of the vagus nerves to the stomach, our ulcer patients have shown healing of their ulcers on x-ray examination and, with rare exceptions, they have experienced immediate and persistent relief from ulcer pain and freedom from subsequent development of hemorrhage, perforation, or pyloric stenosis.

METABOLIC ALTERATIONS FOLLOWING THERMAL BURNS. VII. EFFECT OF FORCE-FEEDING, METHIONINE, AND TESTOSTERONE PROPIONATE ON NITROGEN BALANCE IN EXPERIMENTAL BURNS[1]

By FRIEDA L. MEYER, JOHN W. HIRSHFELD, AND WILLIAM E. ABBOTT

(From the Department of Surgery, Wayne University College of Medicine, Detroit)

(Received for publication October 30, 1946)

Previous work (1) demonstrated that following an experimental burn animals were in negative nitrogen balance on a caloric and protein intake that had been sufficient to maintain nitrogen equilibrium during several control periods prior to burning. The total circulating plasma proteins in these animals remained the same, or in some instances increased slightly, while the concentration and total amount of albumin decreased (2). It has been well established (3 to 6) that patients suffering from burns show a nitrogen deficit and a decrease in the plasma protein concentration. Since it has been suggested that the prevention or alleviation of the nitrogen loss would improve the status of the patient it seemed important to attempt to do this by increasing the protein intake or by reducing the protein catabolism through the administration of testosterone propionate, or methionine. It has been proposed that if force-feeding of protein is employed that such feeding should be started at the earliest possible moment (6, 7). By means of increasing the nitrogen intake in a group of patients, the negative nitrogen balance was prevented or diminished, but in most instances when the very high diets were given early, they were poorly tolerated (8). In order to have a better understanding of the importance of securing a positive nitrogen balance at an early stage, and ways of attaining it, dogs were treated shortly after being burned, by force-feeding or by a normal diet plus methionine or intramuscular injections of testosterone propionate.

EXPERIMENTAL

Selection of the animals, diet, and methods of analyses as well as method of burning have been previously described (1). Four animals were used for the force-feeding experiments and 2 each for the testosterone and methionine studies. The first 2 animals in the force-fed groups (Nos. 10 and 11) were given a mixture of Nutramigen and Amigen[2] following the burn, in an amount sufficient to triple the nitrogen and double the caloric intake they had received previous to the burn. The other animals (Nos. 12 and 13) in the force-fed group following the burn were fed a mixture of Amigen and Aminoids[3] which provided a nitrogen intake approximately 3 times the amount they had taken during the control period. The caloric intake in this latter group was not materially altered. The food was mixed in a Waring Blendor with a measured amount of water and fed by stomach tube in 3 divided doses. The first feeding was administered a few hours following the burn. Two animals (Nos. 14 and 15) were maintained on the same diet they had received previous to the burn and were given intramuscular injections of 25 mgm. of testosterone propionate[4] daily for 15 days. Two other animals (Nos. 16 and 17) following the burn were given the regular diet plus methionine[5] in an amount equal to 1.5 per cent of the diet.

RESULTS

The data on 3 of the 4 force-fed animals (Nos. 11, 12 13) are shown in Table I. The nitrogen deficit was reduced over that of the previously reported normally fed dogs (1), but the institution of early force-feeding was poorly tolerated. No collections were obtained on dog No. 10 of the force-fed group because of marked vomiting and diarrhea, and the clinical condition of this animal was such that it was sacrificed on the sixth day following the burn. The food intake was reduced for dog No. 11 and a 3-day urine sample was obtained from the 4th to the 7th day. The results indicate that the animal was close to nitrogen balance dur-

ing this time. However, the animal rapidly grew worse and was sacrificed on the 12th day.

Since the response to the early high food intake in these 2 animals was unsatisfactory, it seemed desirable to study the effect of such a regime on 2 normal animals (Nos. 12 and 13). It was found that this high intake (at least in the form given) was also poorly tolerated by the normal dog, al-

though the symptoms were not so severe as those exhibited by the burned animals. The total nitrogen output (urine, feces, and vomitus) was analyzed for dog No. 13 for the 5-day period and in spite of loss through vomiting, the positive nitrogen balance (period 3) was markedly increased over the control periods. A gain in weight occurred, which was thought to be partly due to water retention. After allowing several weeks for these animals to return to normal, they were burned and then force-fed a diet containing 3 times the nitrogen content of the control diet, but with little change in caloric content. Clinically the animals seemed better than the first 2 dogs (Nos. 10 and 11) but their course was far from satisfactory. The total nitrogen output in these dogs was analyzed during two 5-day periods of force-feeding. Both animals were in marked positive nitrogen balance during the first 5 days following the burn, but in negative balance the second 5 days. Following the 10 days of force-feeding, the animals were given the regular diet *ad libitum*. Dog No. 12 consumed large amounts of food, and nitrogen retention was fairly marked. A gain in weight without evidence of edema also occurred. The other animal ate poorly and did not regain his control weight.

The results on the 2 testosterone-treated dogs (Nos. 14 and 15) are shown in Table II. Dog No. 14 showed a slight skin disorder during the control period which did not seem significant. However, 10 days following the burn, it became worse and there was every indication that the results obtained during the last 5 to 7 days were complicated by this factor. The dog started to refuse food during the sixth period and the experiment was discontinued on the fifteenth day post burn.

The other animal (No. 15) showed only a slight loss of nitrogen after the fifth day and was in positive balance after the tenth day. This was an improvement over the 4 control dogs which were in negative balance for 15 days following the burn.

The nitrogen balance studies on the methionine-treated dogs (Nos. 16 and 17) are shown in Table III. The animals refused the food with the methionine supplement; so it was given by stomach

TABLE III

tube. One of the animals (No. 16) started to vomit on the third day and the course of both animals was poor. Since the supplement in no way seemed to improve the condition over the untreated animals, the methionine was discontinued after the fifth day and the regular diet resumed. Dog No. 16 refused all food and died on the seventh day post burn. The other animal died on the tenth day.

DISCUSSION

No conclusions can be drawn concerning the nitrogen balance studies in the first 2 force-fed dogs (Nos. 10 and 11) which were given the high protein and high caloric diet, but from the 1 collection period for dog No. 11, it would appear that the nitrogen loss was reduced. The nitrogen balance of the other force-fed dogs (Nos. 12 and 13), which were given triple the nitrogen intake but almost the same caloric intake, was negative during the second 5-day period in spite of the high nitrogen intake. The course of the animals was certainly in no way improved by the positive balance during the first 5 days. Cuthbertson (9) noted in his work on fracture patients that high caloric and protein diets (as much as 231 grams protein and 4,100 calories) failed to eliminate the negative nitrogen balance during the height of the catabolic phase. He first observed a period of retention, then a period of loss which was followed later by a period of retention. This pattern is similar to that noted in our animals. Howard, Winternitz, Parson, Bigham and Eisenberg (10) found that fracture patients on a low protein, low caloric diet lost no more nitrogen than those on a higher nitrogen and caloric intake. However, their high diets contained only 15 grams of nitrogen and 24 calories per 1.73 sq. m. area and therefore cannot be considered similar to those of Cuthbertson (9).

No attempt was made to force-feed animals with large amounts of their regular diet. It seemed of particular interest to use amino acid preparations since their use has been advocated for increasing the protein intake. It is quite possible that large amounts of native protein may be somewhat better tolerated than the hydrolysates or that the amino acid mixtures if started after the shock phase had subsided and gradually increased might have been beneficial. Free and Leonards (11) found that when large equivalent amounts of nitrogen were taken in the form of meat, blood, and amino acids, the latter form caused gastrointestinal upsets in both subjects. While the form of nitrogen and the fact that it was given in such large amounts may have aggravated the diarrhea and vomiting noted in our animals, the gastrointestinal upset was not the only undesirable effect noted in these experiments.

Plasma protein, albumin, and plasma volume alterations were followed in these animals and will be discussed in another report. However, it can be stated here that the volume changes were more marked and no doubt contributed to the undesirable effects of force-feeding. Since it has been shown (12) that increased intakes of nitrogen are accompanied by an increased intake of water, the imbalance following a burn was, no doubt, accentuated by feeding large amounts of protein. That the force-feeding in itself has an effect on water metabolism is indicated by the studies on the 2 normal animals. During the 5-day period of force-feeding (period 3) previous to the burn, dog No. 13 consumed more than 4 times the amount of water than that drunk on the regular diet and the apparent water retention (intake minus urine output) was doubled over the control periods. Following the burn, all the force-fed animals showed a marked edema and several had generalized muscular twitchings which had been noted by other workers (13, 14) in cases of "water intoxication."

Once the anabolic phase begins (from 15 to 20 days post burn in our animals) large amounts of food can be taken to advantage. During period 14, dog No. 12 voluntarily consumed 21 grams of nitrogen and retained 5 grams per day with a gain in weight of 1.5 kgm. Another animal (not shown in the table) was also given food *ad libitum* from the nineteenth to twenty-fifth day post burn and consumed an average of 33 grams of nitrogen per day with a urinary nitrogen output of 26 grams, and during this time gained 2.3 kgm. Neither of these dogs showed edema or the other undesirable effects seen in the early force-fed dogs.

Since testosterone propionate has been shown to increase nitrogen retention (15), there has been an interest in the use of this hormone to decrease the loss of nitrogen following injury. Its use has

been reported by Howard (16) in a fracture patient in whom it seemed to have some effect in reducing the nitrogen loss. Testosterone propionate was therefore administered to 2 female dogs following a standardized burn. It is difficult to draw conclusions from this work, since only 2 animals were studied, and the results on the one animal were complicated by the skin disorder previously described. Because of comparable results obtained with testosterone propionate in patients (17), it seems that the improvement in the nitrogen balance noted in dog No. 15 might be of some significance. The use and cautions to be exercised in employing testosterone propionate have been brought out in another report (17).

Croft and Peters (18) reported that the addition of methionine reduced the nitrogen loss following burns in rats. They presented the hypothesis that there is a need for methionine following injury and that to cover this requirement, tissue is broken down resulting in a large loss of nitrogen. The methionine supplement administered to the 2 dogs in the present experiment was without effect on the nitrogen balance. While no conclusions can be drawn from this small group, the results are in keeping with the negative findings in a patient treated with this amino acid and with the report of Schenker (19) and Chanutin and Ludewig (20) who noted no improvement in the nitrogen balance with the administration of methionine.

Howard and his associates (10) have pointed out that the nitrogen loss following injury does not occur in malnourished patients and apparently feel that the nitrogen catabolism in healthy injured subjects may be a desirable reaction. There seems to be some question, therefore, whether it is advantageous to attempt to prevent or alleviate the nitrogen loss during the catabolic phase. Cuthbertson, Shaw and Young (21) reported that a crude anterior pituitary extract prevented weight loss and reduced the nitrogen loss in injured rats, but did not increase the rate of restoration of the muscles which atrophied as the result of injury.

These observations force one to question the advisability of attempting to prevent the loss of nitrogen by force-feeding during the first week or 2 following a burn or other severe trauma. It is obvious, however, that if a negative nitrogen balance persists for more than 2 or 3 weeks the patient will suffer from a serious protein depletion. It is important, therefore, to institute adequate feedings as soon as the patient can tolerate them. It is our impression (17) and that of others (22) that during the first 2 days the caloric and protein intake should not be forced. In several very severely burned adult patients we have recently given between 800 and 1,200 calories (mostly carbohydrate) during the first 2 days following the burn. The caloric and protein intake was then increased to 1.6 times the patients' basal caloric requirement and subsequently gradually increased to an intake of 200 grams protein and about 3,000 calories. These patients exhibited a minimum nitrogen loss and seemingly have been in as good a condition as can be expected.

SUMMARY

Four groups of 2 female dogs were fed a standardized diet and, after a burn, given the following treatment:

1. Force-fed a diet containing triple the protein (in the form of amino acids) and twice the caloric intake received during the control periods.
2. Force-fed a diet containing triple the protein, but little change in caloric intake.
3. The regular diet and injections of 25 mgm. testosterone propionate daily.
4. The regular diet plus 1.5 per cent methionine.

The results indicate that force-feeding improved the nitrogen balance, but the treatment was poorly tolerated.

There is some indication that testosterone propionate reduces the nitrogen loss following a burn. Methionine seemed to have no beneficial effect on the nitrogen deficit which occurs after a burn.

THE BILIARY EXCRETION OF VARIOUS BILE ACIDS BY PATIENTS WITH CHOLEDOCHOSTOMY DRAINAGE, AND THE EFFECT OF ORAL ADMINISTRATION OF DESICCATED BILE OF THE OX AND THE HOG [1]

By CHARLES G. JOHNSTON and J. LOGAN IRVIN

(*From the Laboratory of Surgical Research, Wayne University College of Medicine, Detroit*)

(Received for publication November 8, 1946)

Choledochostomy drainage of bile by means of a T-tube frequently is established following surgery of the biliary tract, and often such drainage is maintained for periods ranging from several weeks to several months. During this time only small amounts of bile, usually quite deficient in bile salts (1, 2), enter the intestine. Replacement by oral administration of bile is indicated. A method for large-scale preparation of desiccated bile has been reported, and average analyses of desiccated gallbladder bile of the hog have been presented (3). Such preparations of desiccated bile are being used with success in replacement therapy (4) and for symptomatic treatment of patients with gastrointestinal disorders associated with biliary insufficiency (5).

Bile acids of man, the ox, and the hog consist of a steroid nucleus possessing a carboxyl group which usually is conjugated through amide linkage with glycine or taurine. In bile of man and the ox approximately 50 to 75 per cent of the total quantity of the bile acids [2] is conjugated with glycine and the major portion of the remainder with taurine (6). However, this proportion is somewhat variable, and often a considerable fraction of the bile acids is in the "free" or unconjugated form (7). By contrast, the bile acids of hog bile are conjugated solely with glycine (6, 8). The bile acids of these 3 animals differ also in the nature of the steroid nuclei and in the relative proportions of these bile acids present in the bile. The principal bile acid (steroid nucleus) of hog bile is α-hyodesoxycholic acid (3,6-dihydroxycholanic acid) (8). The principal bile acid in bile of man and the ox is cholic acid (3,7,12-trihydroxycholanic acid), but important amounts of desoxycholic acid (3,12-dihydroxycholanic acid) and chenodesoxycholic acid (3,7-dihydroxycholanic acid) also are present (9, 10). Hyodesoxycholic acid has not been found in bile of man and the ox, and cholic acid is absent from the bile of the hog.

In view of the qualitative and quantitative differences in the bile acid composition of bile of various animals, it is important to have information concerning the utilization of various bile acids as a guide to adequate replacement therapy in human patients with biliary insufficiency. In previous communications (11, 12) we have reported experiments which have demonstrated very efficient enterohepatic circulation of foreign bile acids in animals with experimental biliary fistulae. The present paper is a description of studies on the administration of desiccated bile of the hog and the ox to human patients with choledochostomy drainage.

EXPERIMENTAL

Cholic acid and total dihydroxycholanic acids [3] were determined by methods which we have described previously (12, 13). The method for determining "cholic acid" yields the sum of free cholic acid, glycocholic, and taurocholic acids. Desoxycholic acid was determined by an adaptation of the procedure of Kaziro and Shimada (14). The reaction with benzaldehyde was conducted in 23 N sulfuric acid instead of the more concentrated acid specified by Kaziro and Shimada, thus minimizing interference by chenodesoxycholic acid. In order to attain greater specificity and eliminate interfering substances, the reaction was applied to the dihydroxycholanic acid fraction which was separated from cholic acid and from the monohydroxycholanic acid fraction by the pro-

[1] Aided by a grant from Parke, Davis and Company.

[2] It is customary to refer to the bile "acids" in bile although it is understood that at the pH of bile these acids are almost completely ionized as anions which are matched by sodium, potassium, and calcium cations.

[3] The dihydroxycholanic acids which have been isolated (9, 21) from bile of man are desoxycholic acid and chenodesoxycholic acid. Hyodesoxycholic acid of hog bile also is a dihydroxycholanic acid (8, 15). Our method for the determination of "total dihydroxycholanic acids" (12) yields the *sum* of these 3 acids.

cedure which we have described previously (12). Optical density measurements were made with a filter photometer at a mean wavelength of 620 mμ.

For the determination of hyodesoxycholic acid a sample of bile estimated to contain 25 to 75 mgm. of this acid was extracted and hydrolysed, and the dihydroxycholanic acid fraction was separated by the method previously described (12). The dihydroxycholanic acids, including hyodesoxycholic acids, were oxidized by chromic acid to diketocholanic acids as described previously (12), a proportionately larger amount of chromic acid being required because of the larger sample. The diketocholanic acid fraction was dissolved in glacial acetic acid, and the optical rotation (D line of sodium) was determined in a polarimeter equipped with a micro tube of 1 decimeter length requiring 1 ml. of solution. Then hydrochloric acid was added to the solution to a concentration of 0.5 per cent by volume, and the solution was boiled for 1 hour under reflux. During this process, the 3,6-diketocholanic acid (resulting from the oxidation of hyodesoxycholic acid) underwent rearrangement to 3,6-diketoallocholanic acid. The solution was evaporated to dryness in vacuo; then the residue was dissolved again in glacial acetic acid and brought to a volume equal to that used in the initial polarimetric measurement. The optical rotation of this solution was determined, and the initial quantity of hyodesoxycholic acid in the sample was calculated from the *change* in optical rotation which accompanied the rearrangement of 3,6-diketocholanic acid to 3,6-diketo-allocholanic acid. This method is specific for hyodesoxycholic acid inasmuch as the other diketocholanic acids (resulting from the oxidation of the other dihydroxycholanic acids) do not undergo such rearrangement. Calculations were based upon determinations with standard amounts of hyodesoxycholic acid which were carried through the same procedure, the "unknown" being referred to polarimetric values which were obtained with standards of nearly the same concentration. This method utilizes principles which were described in the studies of Windaus *et al* upon the constitution of hyodesoxycholic acid (8, 15). Following the polarimetric measurements, a portion of the diketocholanic acid fraction was used for determination of the total diketocholanic acids from which the total dihydroxycholanic acids originally present in the sample could be calculated.

Total bile acids were calculated as the sum of cholic acid and the total dihydroxycholanic acids. This calculation of the "total bile acids" left unaccounted the traces of monohydroxycholanic acids and keto bile acids which have been found in bile.

Total conjugated bile acids and tauro-conjugated acids were determined essentially by the method of Schmidt and Dart (16). Glyco-conjugated acids were calculated by difference between the total conjugated and the tauro-conjugated acids.

The patients studied in this report were all treated for obstruction of the common duct.[4] Patients C. D., A. M., and C. M. had institution of drainage of their common duct by means of a T-tube. Patient F. W. was in exceedingly poor shape when operated upon; the gall-bladder was removed and drainage instituted by a large tube placed in the dilated cystic duct. Bile was allowed to flow unimpeded into a sterile bottle with a vent as described by Richey (17), the bottle being placed a few inches below the level of the patient. The few inches which the bile flowed by gravity through a large tube was not considered sufficient to obstruct the flow by causing collapse of the tube.

The collection of bile in these cases could not be considered as complete. However, since there was no impediment offered to the outflow of bile, it is to be presumed that very little bile found its way into the duodenum and that most of it was collected. That this assumption is valid has been corroborated by the fact that hyodesoxycholic acid, a bile acid not found in significant quantities in man, was recovered almost quantitatively through the drainage tube after administration to the patient by mouth. It was not possible to control each study, and the possibility of partial recoveries introduces the probability of error. Those errors which are due to incomplete recoveries would tend to give lower values than actually found. Accordingly, in considering the data presented on recoveries of bile acid, it must be recognized that there is a possibility that they may be somewhat low rather than high.

DISCUSSION OF RESULTS

The excretion of various bile acids in the choledochostomy drainage bile of these cases can be discussed more clearly by dividing the presentation into a section on the excretion in the absence of orally administered animal bile and a section on the excretion during administration of bile. Eleven cases were studied, but this report is confined to a discussion of 5 cases which were investigated in greatest detail and which illustrate the principal observations and conclusions which were derived from the entire series.

(1) *Excretion of bile acids in the absence of orally administered animal bile:* Following cholecystectomy and establishment of choledochostomy drainage of bile, a post-operative period of 10 to 20 days usually elapses before resumption of synthesis of bile acids by patients whose biliary tracts have been obstructed for a long period of time. Such delay in the resumption of the synthesis of cholic acid was noted previously by Ravdin *et al* (1), and a similar delay in synthesis of "bile acids" was observed in some of the more severely obstructed cases of Greene *et al* (18, 19) by application of an analytical method of somewhat questionable specificity. In the cases studied in the present in-

[4] See Case Histories.

vestigation all of the various bile acids were entirely or nearly lacking from the bile excreted during the first few days following the operation. However, the excretion of desoxycholic acid and the total dihydroxycholanic acid fraction (which includes desoxycholic acid) was resumed somewhat earlier than the excretion of cholic acid. By means of other analytical methods, Breusch and Johnston (20) obtained evidence for a similar effect. The more rapid appearance of the dihydroxycholanic acids was particularly striking in the case of A. M. (Table IV), but was less marked in the cases of C. D. and C. M. (Tables I and VI). In all cases in which both the total dihydroxycholanic acid fraction and desoxycholic acid, a specific member of that fraction, were determined, the quantity of total dihydroxycholanic acids exceeded the amount of desoxycholic acid. This is evidence for the presence of one or more additional members of the dihydroxycholanic acid series. Inasmuch as Wieland *et al* (9, 21) have isolated chenodesoxycholic acid,[5] a dihydroxycholanic acid, from gallbladder bile collected from cadavers, it is likely that the differences between our figures for total dihydroxycholanic acids and the corresponding figures for desoxycholic acid are a measure of the amounts of chenodesoxycholic acid present. However, as mentioned below, in order to obtain values for chenodesoxycholic acid in those cases in which hog bile was administered to the patients it would be necessary also to subtract the figure for hyodesoxycholic acid since this bile acid is included in the dihydroxycholanic acid fraction. The traces of "hyodesoxycholic acid" recorded in Table IV for periods in which hog bile was not administered to this patient correspond to "blank" values obtained with the polarimetric method for the determination of this bile acid and probably do not represent the presence of true hyodesoxycholic acid in these samples. Average figures for these "blanks" were used in correcting all values obtained for hyodesoxycholic acid by this method.

The biliary excretion after approximately the twentieth day following the operation probably represents an *approach* to normal hepatic bile, at least in a few of the cases in which there appeared to be minimal liver damage from obstruction and cholangitis. The extent of such damage is difficult to assess, but, of the cases studied in greatest detail, it would appear that C. D. (Tables I and II) most nearly attained a normal state of biliary

excretion. Even in this case it is doubtful whether the maximum *concentration* of the bile acids had been attained at the termination of the period of drainage inasmuch as the concentrations were continuing to increase at that time. However, the *relative proportions* of the various bile acids were rather constant after the twentieth day. The average proportion of cholic acid to desoxycholic acid to chenodesoxycholic acid for days 20, 21, 24, and 25 was 3:0.98:0.74. Days 22 and 23 were omitted from the calculation because hog bile was ad-

[5] Wieland isolated this bile acid from the bile of man in 1924, and he gave it the name, anthropodesoxycholic acid. Windaus in the same year announced the isolation of the identical compound from the bile of the goose and named it chenodesoxycholic acid. No general agreement regarding the name appears to have been reached, but the name proposed by Windaus seems to be favored since the prefix, *cheno*, was used first by Heintz and Wislicenus in connection with an imperfectly characterized acid which they isolated from bile of the goose in 1859.

ministered on those days. The *proportions* of these 3 bile acids in hepatic bile of this case are in good agreement with those obtained by Wieland *et al* (9, 21) by calculation from the isolation of bile acids from pooled samples of gallbladder bile obtained from human cadavers. However, the absolute concentrations of these bile acids obviously were smaller in hepatic bile than in gallbladder bile. On the other hand, these data for the relative proportions of the bile acids do not agree with data reported by Colp and Doubilet (22) for the ratios of cholic acid to "desoxycholic acid" in gallbladder bile of a series of cases. However, these authors stated that the method which they used for determination of "desoxycholic acid" was not specific for that acid and probably included chenodesoxycholic acid, lithocholic acid, and possibly other bile acids of unknown nature.

A considerable fraction of the bile acids excreted by C. D. (Table II) was unconjugated during the first 10 days following the operation, but the percentage of the total bile acids in the conjugated form rose to 85 during the latter part of the period of drainage. The average ratio of glyco-conjugated bile acids to tauro-conjugated acids was 1.3: 1 in the bile of C. D. during periods when hog bile was not administered.

In the case of C. M. (Table VI) with apparently greater liver damage than C. D., recovery of the synthesis of bile acids was delayed longer, and the bile acid concentrations attained after 40 days were approximately ½ those which occurred in the bile of C. D. after 20 days. During the first 3 weeks following the operation, the bile excreted by patient C. M. contained much sediment, and it was pale brown in color and possessed an offensive odor. Thereafter, there was progressive improvement in the appearance of the bile, and after approximately the thirty-fourth day, the bile was fairly clear and of normal appearance. This improvement in the appearance of the bile was accompanied by a rapid increase in the excretion of bile acids. Excretion of desoxycholic acid and other dihydroxycholanic acids (presumably chenodesoxycholic acid) by C. M. was resumed before the excretion of cholic acid. However, on days 39 and 40 the *proportion* of cholic acid to desoxycholic acid to chenodesoxycholic acid was 3:1:0.7 which is in good agreement with the proportion found in the case of C. D. As late as the fourteenth and eighteenth days following the operation, 56 and 49 per cent of the total bile acids were unconjugated, but the percentage of unconjugated acids had decreased to an average of approximately 11 at the end of the period of drainage (calculated from the data for days 39 and 40, during which ox bile was not administered). At this time the average glyco/tauro ratio was 1.91: 1 (Table VII).

Patient A. M. (Tables IV and V) was in rather

poor condition. Nevertheless, the excretion of cholic acid was resumed almost as soon after operation as occurred in the case of C. D., and the recovery of the excretion of dihydroxycholanic acids actually was more rapid than in the case of C. D. In fact, it was more rapid than occurred in any of the other cases which we investigated. Unfortunately, analyses for desoxycholic acid were not conducted on samples of bile from A. M., therefore the nature of the dihydroxycholanic acids was not determined. Again a large fraction of the total bile acids was unconjugated during the first six days after the operation, but thereafter recovery of the ability to conjugate the bile acids was rapid.

(2) *Excretion of bile acids in drainage bile following oral administration of desiccated bile:* Following oral administration of dried gallbladder bile of the hog,[6] excretion of hyodesoxycholic acid, the predominant bile acid of hog bile, in the choledochostomy drainage bile, commenced after 1 to 2 hours. Thereafter, the excretion rose to a peak at about 7 to 10 hours, then gradually declined, the total period of excretion comprising 18 to 20 hours.[7] In Table I (case C. D.) the concentration of hyodesoxycholic acid in the bile collected during a 24-hour period following administration of hog bile is recorded, together with the total volume of bile. From these data the total *amounts* of hyodesoxycholic acid excreted were calculated. The average excretion of hyodesoxycholic acid by this patient was 87.5 per cent of the amount admin-

[6] Preparations of desiccated gallbladder bile of the hog (trade name, *Desicol*) and the ox were supplied by Parke, Davis and Company.

[7] This period of circulation or total "clearance-time" is considerably longer than that reported for man by Josephson (23), but it is comparable with the data for hogs (12) and for dogs (24, 25). Josephson calculated the clearance-time by observing the time required for biliary excretion of the natural cholates to return to the normal secretory level from the high level induced by recirculation of bile or by administration of cholates. Inasmuch as the normal rate of excretion of cholates is subject to some variation, it would be difficult to determine the total clearance-time precisely by that method. On the other hand, the time required for attainment of the *peak* of clearance of hyodesoxycholate in our experiments was comparable with the total clearance-time reported by Josephson. It is probable that enterohepatic circulation may have been somewhat delayed in the patients of our series as compared with the relatively normal subjects studied by Josephson. In addition, the circulation of hyodesoxycholate may require a longer time than the circulation of the natural cholates.

istered. In the case of A. M. (Table IV), hog bile was administered daily, as recorded in column 2, from the twentieth to the twenty-eighth day. The drainage bile was pooled for the intervals shown in column 1, and the *average* daily volume and *average* daily excretion were calculated. The average excretion of hyodesoxycholic acid by this patient was 78.5 per cent of the amount administered. In Tables II and V it can be seen that in the 24-hour period following administration of hog bile there was an increase in the ratio of glyco-conjugated acids to tauro-conjugated. Inasmuch as hyodesoxycholic acid of hog bile is conjugated solely with glycine, this increase in the glyco/tauro ratio of the drainage bile, together with the excretion of hyodesoxycholic acid, suggests strongly that glycohyodesoxycholic acid was absorbed from the intestine and excreted unchanged in the drainage bile. The efficiency of utilization of this foreign bile acid by these patients appears to be somewhat less than the efficiency with which glycocholic acid was handled by hogs with biliary fistulae (12). However, it is doubtful whether the bile collected by drainage through a T-tube represents the *entire* biliary secretion even under carefully supervised conditions.

It was of considerable interest to study the enterohepatic circulation of bile acids in these patients. The hyodesoxycholic acid of hog bile provided a "tracer" for study of such circulation since this bile acid is foreign to the normal biliary secretion of man. These studies were conducted as described in our paper on enterohepatic circulation in hogs (12). Following oral administration of hog bile containing the quantity of glycohyodesoxycholic acid recorded in column 1 of Table III, the external choledochostomy drainage tube was clamped shut in order to direct the flow of bile into the intestine. Following the period of circulation recorded in column 2, the clamp was removed and the bile was collected for a 20-hour period for determination of the amount of hyodesoxycholic acid remaining at that time (column 3). The percentage loss of glycohyodesoxycholic acid is recorded in column 4. Even after 4 days, some of the hyodesoxycholic acid remained in the circuit. Again the efficiency of circulation was somewhat less than that of the hog, but, nevertheless, such circulation provides an important mechanism for the conservation of bile acids.

Inasmuch as the bile acid composition of ox bile is very similar to that of man, it was more difficult to assess quantitatively the effect of administration of ox bile to these patients. However, it is appar-

12	1.42	1,140	1.66

ent from Tables VI and VIII that administration of desiccated ox bile to these patients, in the early post-operative period before recovery of the excretion of bile acids, was followed by an immediate increase in the excretion of bile acids, particularly cholic acid. Inasmuch as the average ratio of cholic acid to desoxycholic acid is 5.5:1 in ox bile (10) as compared to 3:1 in the bile of man, it is to be expected that the administration of ox bile to human patients would cause a proportionately greater increase in cholic acid. Administration of ox bile did not produce a significant change in the glyco/tauro ratio in the bile of C. M. (Table VII) if the period from days 30 to 38, during which ox bile was administered, is compared with days 39 and 40, during which administration of ox bile was discontinued. This is to be expected in view of the similarity in the conjugation of bile acids of man and the ox.

Administration of either hog bile or ox bile to these patients produced an increase in the *volume* of bile excreted during the ensuing 24 hours. The question of the effect of the administration of animal bile upon the *synthesis* of bile acids by the patient is important but is difficult to decide from our data inasmuch as the synthesis of bile acids was increasing progressively in most of the cases *before* animal bile was administered. The *quantity* of bile acids excreted per day can be calculated from the corresponding data for the *volume* of bile and the *concentrations* of the bile acids. Such data for the quantity of bile acids excreted in the bile per day are recorded for three of the cases in Figures 1 to 3. Also, in these figures data for bile

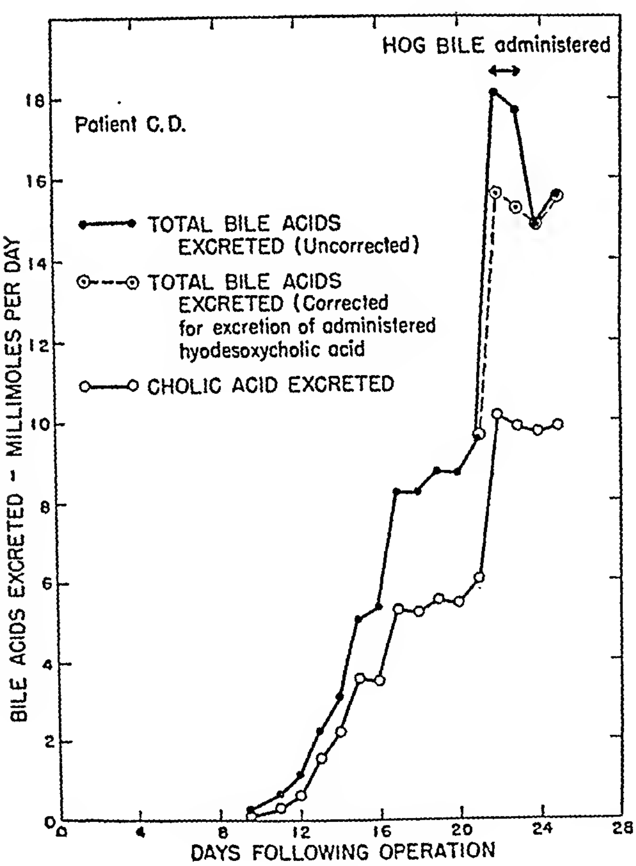

FIG. 1

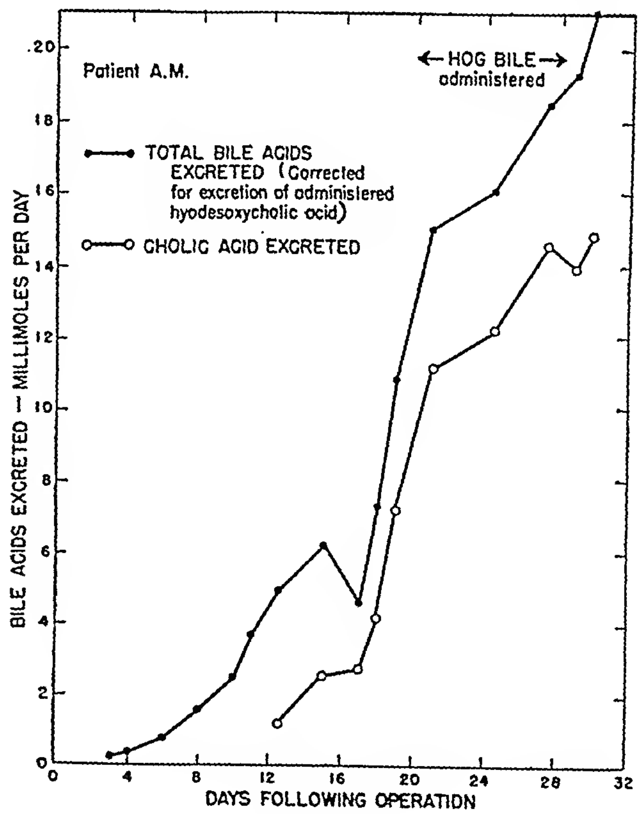

FIG. 2

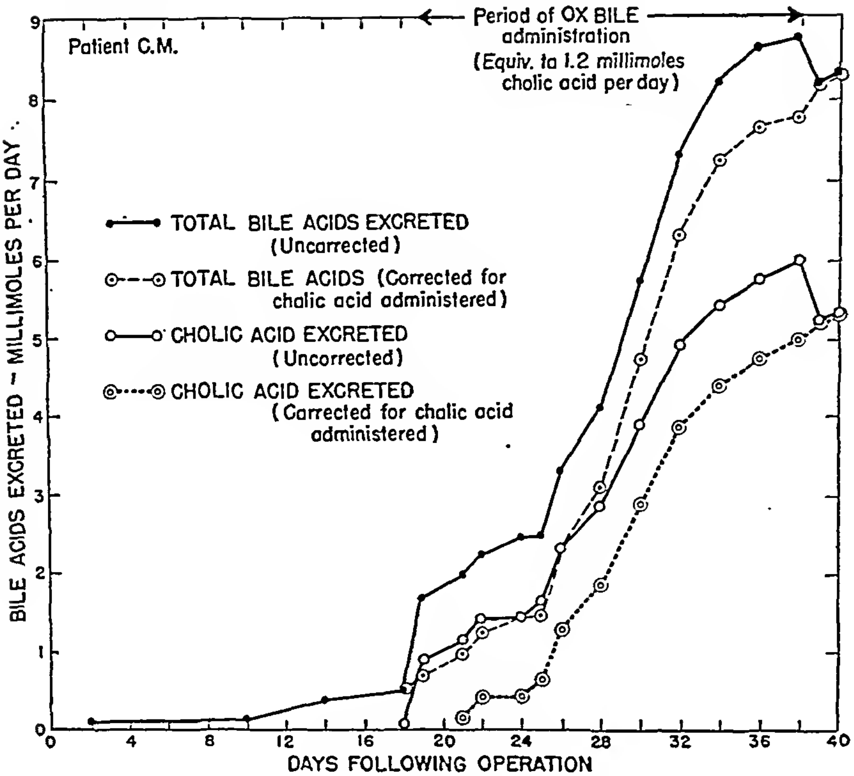

FIG. 3

acid excretion are presented which have been "corrected" for the excretion of the bile acids contained in the administered animal bile, thus yielding data for the production of bile acids by the patient. It can be observed from these corrected curves that administration of bile of the ox or the hog did not depress the production of bile acids by the patients although there was a slight leveling of the slope of the curves in the case of A. M. (Figure 2) who received the largest doses of hog bile. On the other hand, there *appears* to have been some stimulation of bile acid production in the cases of C. D. (Figure 1) and C. M. (Figure 3). However, such a conclusion would seem to be unwarranted from the limited data available in view of the difficulties mentioned above. In the case of C. D. (Figure 1), the sharp increase in excretion of bile acids upon administration of hog bile might have been due to release of a slight obstruction to the flow of bile as a result of the pressure of the increased bile flow caused by the administered hog bile. However, the increase in *concentration* of the bile acids, in addition to the increase in *volume* of bile excreted, following administration of hog bile (Table I), is somewhat suggestive of a stimulatory effect. Nevertheless, if such an effect occurred, it must be assumed that it persisted *after cessation* of hog bile administration in view of the continued increase in the *concentration* of the bile acids (Table I) and of the maintenance of the *quantity* of bile acids excreted (Figure 1). In the case of C. M. (Tables VI and VII and Figure 3) there was progressive increase in the excretion of bile acids throughout the period of ox bile administration, and the production of bile acids by the patient was maintained during the 2 days of observation following cessation of ox bile administration (corrected curves of Figures 3). Again, stimulation of bile acid production cannot be claimed since similar progressive increases in bile acid production have been observed in other patients during periods in which ox bile was not administered. During the period of observation this patient did not attain so high a level of bile acid excretion as did patients C. D. and A. M., but, as mentioned previously, the bile of this patient was quite abnormal during the first 3 weeks (improving slowly thereafter) suggesting

a pathological state of the liver or bile ducts, or both.

While the possible stimulation of bile acid production by administration of animal bile to these patients cannot be decided conclusively from these data, it seems desirable to emphasize again those effects which are demonstrated unequivocally, *i.e.*, the increase in *volume* of bile-flow and the absorption and reexcretion of the bile acids supplied in the animal bile. The intestinal absorption of these "foreign" bile acids by the patients suggests that these animal biles can be used successfully in replacement therapy. Additional evidence of their successful function in replacing the bile of the patient has been provided by observations of increases in the values for prothrombin assays during periods when animal bile was administered.

In previous papers (12, 13) we have demonstrated that normally the concentration of cholates in blood of the peripheral circulation is less than 1 mgm. per 100 ml., but appreciably greater concentrations of cholates appear in peripheral blood of men and dogs with biliary obstruction (13, 23) except in those cases in which the obstruction is of such duration that the damaged liver has lost the ability to synthesize cholates. However, even in the latter condition, the oral administration of cholates to animals with biliary obstruction is followed by the appearance of cholates in the circulation (12, 13). In Table IX there are recorded the results of analyses for cholates in blood samples obtained from a patient with biliary obstruction.

TABLE IX

Concentrations of cholates in blood of the peripheral circulation of patient C. S. before and after operation for the removal of obstruction of the bile duct, and the effect of oral administration of hog and ox biles

Pre-operative period	Desiccated bile administered orally	Cholate concentration in whole blood, "cholic acid"

40	0.0	0

This patient (C. S.), a 45-yr.-old black male, had had a cholecystectomy performed 6 months previous to admission, and an attempted drainage of his common duct one month after the cholecystectomy because of increasing jaundice. Following his operation a small amount of bile drained from his wound but his jaundice did not disappear. At the time of admission his skin had been markedly icteric for 6 months, he had had frequent intermittent attacks of upper abdominal pain associated with chills and fever, and suffered intense itching. His stools had been persistently acholic. Shortly after admission the Van den Bergh was direct, immediate with 9.3 mgm. bilirubin per 100 ml. of blood.

He was operated upon 37 days after admission and no evidence of the common duct was found. There was a small scarred area in the hilus of the liver from which thin, pale green bile was aspirated. The duodenum was sufficiently mobilized to permit direct anastomosis, over a pezzar catheter, with the hepatic duct, the catheter being brought out to the anterior abdominal wall through the stomach. Drainage of bile through the catheter was continued for 6 weeks. The catheter was then removed, and within 24 hours drainage from the wound had stopped.

Samples were obtained during pre- and post-operative periods and during the administration of desiccated bile of the hog and the ox. During the thirty-sixth to the eighteenth day before the operation there was a decline in the concentration of cholates in the peripheral blood which probably was indicative of a decline in the ability of the liver to synthesize cholates. This decline in the concentration of cholates occurred during a period when desiccated hog bile was being administered orally. However, hog bile does not contain cholates (8, 12), and our method (13) was specific for the determination of that bile salt, either unconjugated or conjugated with glycine or taurine. At the time of these studies, we did not have available a method for the determination of hyodesoxycholates in blood; therefore, we were un-

able to study the interesting question of the possible appearance of that bile salt of the hog in the peripheral circulation of obstructed patients receiving hog bile by mouth. On the eighteenth day (pre-operative), administration of hog bile was discontinued. During the period from the thirteenth to the sixth pre-operative day, a daily oral dose of 1 gram of desiccated ox bile (which contains cholates) was administered. The concentration of cholate in the peripheral blood had risen to 7.69 mgm. per 100 ml. by the eighth pre-operative day. Administration of ox bile was discontinued on the sixth day before operation, and at the time of operation the concentration of cholate had declined again to 1.91 mgm. per 100 ml. of blood. After removal of the obstruction by operation, the concentration of cholate in the peripheral circulation remained low even when large doses of dried ox bile were administered orally.

SUMMARY

Bile samples collected post-operatively by choledochostomy drainage from a series of 11 cases were analyzed for cholic, desoxycholic, and total dihydroxycholanic acids and for glyco, tauro, and total conjugated bile acids. A period of 10 to 20 days after operation usually elapsed before resumption of synthesis of these bile acids by patients whose biliary tracts had been severely obstructed. In some of the cases, the excretion of desoxycholic acid and the total dihydroxycholanic acid fraction was resumed somewhat earlier than the excretion of cholic acid. In most cases, a considerable fraction of the bile acids was unconjugated during the first week or two following the operation, but usually recovery of the ability to conjugate the bile acids (with glycine or taurine) did not lag far behind recovery of the synthesis of the steroid nucleus of the bile acids.

After a recovery period of 20 to 25 days, the average proportion of cholic acid to desoxycholic acid to chenodesoxycholic acid was 3:1:0.75 in the bile of a patient with apparently minimal liver damage. Similar proportions between these bile acids were obtained for most of the other cases during the late post-operative period, but the absolute *concentrations* of the bile acids were smaller in the bile of those patients with the greatest liver damage.

Oral administration of desiccated gallbladder bile of the hog to these patients was followed by the biliary excretion of hyodesoxycholic acid, a bile acid which normally is foreign to the bile of man but which is a principal component of hog bile in which it is found conjugated with glycine. There also was an increase in the glyco/tauro coefficient which suggests that glycohyodesoxycholic acid was absorbed and reexcreted unchanged in the drainage bile. This foreign bile acid was handled fairly efficiently in the enterohepatic circulation, a portion remaining in the circuit even after 4 days.

Following oral administration of desiccated gallbladder bile of the ox to these patients, there were increases in the excretion of cholic and desoxycholic acids which were proportional to the amounts of these bile acids in the administered ox bile.

Preparations of desiccated bile of the hog and the ox provide a convenient and effective means for replacement of bile during choledochostomy drainage. Both preparations are well tolerated, both stimulate an increase in the volume of bile-flow, and both provide bile acids which are effective in supplementing the output of bile acids by the patient, apparently without inhibiting the synthesis of bile acids.

Cholates normally are present in blood of the peripheral circulation in concentrations less than 1 mgm. per 100 ml., but the concentrations increase appreciably when the biliary tract is obstructed unless the synthesis of cholates is decreased by liver damage. Even in the latter case, the oral administration of cholates, or ox bile containing cholates, produces an increase in the concentration of cholates in the peripheral circulation in contrast to the absence of this effect when the biliary tract is not obstructed.

CASE HISTORIES

Case 1.—F. W., a 53-year-old white male, entered the hospital 5-11-40 because of fever, chills of 5 days' duration, and epigastric pain for 3 days. He had noticed a yellow tinge to his skin for several days. More than a year previous to this time he had stopped eating pork; over this same period he had suffered heart burn regularly. He had lost 25 pounds in the past year.

Temperature 100.8°, pulse 100, respiration 20, blood pressure 106/60. Icterus was obvious. There was rigidity in the right upper quadrant with tenderness in this area. The liver was 2 cm. below the costal margin.

There was a right inguinal hernia present. There was stasis dermatitis on both legs.

Van den Bergh 1.3 mgm., direct; blood urea nitrogen 143; serum albumin 4.6 per cent, globulin 4.0 per cent. Urine showed only faint trace of albumin consistently. Hb 11.5 grams, RBC 2,240,000, WBC 6,400, polys 85 per cent. Opaque shadows in flat film suggested gallstones. The patient was treated symptomatically, given blood transfusions and fluid by vein. Despite the high, maintained blood urea the patient appeared moderately improved, and it was believed that the high urea was associated with liver disease.

Operation was performed on 5-21-40, at which time a lobulated scarred liver was found. Marked adhesions were present about the gallbladder and common duct. The gallbladder was exposed with some difficulty. It contained numerous small stones. Despite the need for common duct exploration, on account of the difficulties encountered, it was decided to drain the common duct through the dilated cystic duct. The proximal portion of the gallbladder and the cystic duct were sutured about the tube for future use if needed. Bile readily drained from the tube. The patient was given several transfusions of whole blood post-operatively. His blood pressure quickly becoming stabilized at 110/60. Within five days the temperature returned to normal, the highest post-operative temperature being 102°. Despite the generally improved appearance of the patient, he complained of feeling weak and ate very little. Within 2 weeks post-operatively it became more difficult to get him to take nourishment by mouth. The tube was removed 21 days after operation. The patient expired on 6-13-40. Postmortem examination was not performed.

Case 2. C. M., a 50-year-old colored housewife entered the hospital 10-26-40, because of acute epigastric pain of 10 hours' duration. The pain radiated to the interscapular area and was associated with nausea and vomiting. For 15 years she had had intolerance to fatty foods. On admission she was restless, moving about with recurrent attacks of acute pain. There was rigidity of the right upper quadrant. Temperature 102°, pulse 100, respiration 24, blood pressure 90/60.

Shortly after admission following administration of morphine sulphate, nitroglycerine and intravenous fluids, the blood pressure was 150/104 and the patient became more comfortable. Hb 11.5 grams, WBC 7,300, urinalysis showed faint trace of albumin. Van den Bergh direct, immediate, 1.9 mgm per 100 ml. All evidence of icterus gone, icteric index being 7.5.; operation was performed on 11-9-40 at which time a chronically inflamed gallbladder was removed and the dilated thickened common duct was explored. A T-tube was placed in the common duct for drainage. The capsule of the liver was thickened and there was increased trabeculation of the liver. No obstruction was found. Following operation, the patient's blood pressure dropped to 90/50, but following plasma infusion, rose to 140/100. After a few stormy days, her temperature, pulse, respiration, and blood pressure became stabilized at normal levels. Drainage was carried on for 40 days. The patient was discharged to the outpatient department.

Case 3. C. D., a 58-year-old white woman, was admitted to the medical service because of severe epigastric pain of 1 day's duration. This was but one of many repeated similar attacks which she had had for the preceeding 7 years. These attacks usually began as pain in the epigastrium or in the right upper quadrant. There had been no jaundice noted, but there had been chills and fever on occasion, and she had noted dark urine. Temperature 98.4°, pulse 98, respiration 20, blood pressure 130/70, weight 88½ pounds.

On physical examination there were definite tenderness and slight rigidity of the right upper quadrant. The right kidney was palpable and there was tenderness in the right costovertebral angle. The liver was palpable 2 centimeters below the costal margin. Other positive findings were a right inguinal hernia and external hemorrhoids. Icterus was not obvious clinically. The Kline test was negative, hemoglobin 11 grams RBC 4,340,000, WBC 11,800, polys 86 per cent. Serum albumin 3.5 per cent, globulin 1.6 per cent, van den Bergh 0.6 mgm. per 100 cc. Flat film of the abdomen revealed 2 large radiopaque shadows which were interpreted as gallstones. Barium study revealed diverticula of the duodenum. Intravenous pyelogram revealed nothing unusual.

Immediately following admission, pain and tenderness subsided, but 11 days later she had pain in the epigastrium, vomiting, and return of tenderness associated with chills and a fever of 103°. This promptly subsided to recur 2 days later. Similar but milder attacks occurred every 2 to 4 days thereafter until she was operated upon 1-8-40. At operation a contracted thickened gallbladder was found with a 1½ cm. stone imbedded in the fundus. The common duct measured more than 2 cm. in diameter and was filled with a large, putty-like mass, greenish brown in color, which formed a cast of the common duct. This material was removed, the duct washed clear, and a large T-tube placed in the common duct. The gallbladder was removed. The liver was found to be large and extended 4 cm. below the costal rim. The surface was finely granular and green tinted.

Following operation the patient's condition was satisfactory. Drainage was continued for 25 days, following which, after determining patency of the duct, the tube was removed. The patient returned a year later for repair of her inguinal hernia at which time she had had no recurrence of her symptoms and was able to eat without restriction.

Case 4. A. M., a 61-year-old Turkish male, was admitted to the medical service on 10-23-38 because of right upper quadrant pain, jaundice, and vomiting. For 2 years previously he had had intermittent attacks of right upper quadrant pain with nausea and vomiting. He had lost seventy pounds in the 2 years, but stated he ate very little for fear of precipitating an attack. Two days previously he had had an attack which was more severe than usual which was accompanied with chills and fever, and he noted for the first time that he was jaundiced. Upon

examination he was found to be markedly icteric and the skin and mucus membranes were quite dry. Temperature 99°, pulse 100, respiration 22, blood pressure 100/70. Moist rales were present over the right base posteriorly. The liver edge could be felt 3 cm. below the costal margin in the midclavicular line and there were marked tenderness and moderate rigidity of the right upper quadrant. The spleen was palpable on deep inspiration. There was pitting edema of dependent parts. On admission, the urine contained bile, albumin 4 and an occasional white cell. Hb 12.5 grams, RBC 4,300,000, WBC 31,300, polys 96 per cent. Kline test negative, van den Bergh immediate, direct, 4.5 mgm. There was a trace of urobilinogen in the urine, blood cholesterol 228 mgm. On 11-14-38, three weeks after admission, his white count was 8,800 and his hemoglobin 8.0 grams, serum albumin 3.3, globulin 2.8, clotting time 3½ minutes, bleeding time 4 minutes, 10 seconds, prothrombin 52 per cent.

The patient was treated symptomatically. He was given 0.4 gram pig bile t.i.d. with several experimental preparations of vitamin K given orally.

Just preceding operation, which was performed on 1-17-39, the prothrombin was 58 per cent, hemoglobin 12.6 grams, WBC 7,800, van den Bergh 0.75 mgm. At operation the liver appeared but slightly enlarged, was paler than normal, and the capsule was moderately thickened. The gallbladder contained numerous stones and was removed. The common duct was thickened and admitted the index finger easily. Three stones were removed from the duct, following which the probe passed easily into the duodenum and into the liver. A T-tube was sutured into the common duct and brought out through the abdominal wall. Following operation he had no unusual difficulties and was discharged in good condition.

THE EFFECT OF GLYCINE ON THE PRODUCTION AND EXCRETION OF URIC ACID[1]

By MEYER FRIEDMAN

(From the Harold Brunn Institute for Cardiovascular Research, Mt. Zion Hospital, San Francisco, California)

(Received for publication November 28, 1946)

INTRODUCTION

Although most investigators (1 to 4) have agreed that the ingestion of protein increases the output of uric acid in man, there has been no clear elucidation of the mechanism whereby this is accomplished. Mâres (5) believed that the increased uric acid in urine following high protein feeding resulted from the deterioration of nuclei of digestive cells concerned in the assimilation of the ingested protein. He offered in support of this theory the observation that atropine decreased and pilocarpine increased the output of uric acid. Taylor and Rose (1) found that, although urinary uric acid increased after an intake of high protein, the excretion of urinary creatinine did not change. Lewis, Dunn and Doisy (4) administered various amino acids to men in order to obviate as much as possible the probability of digestive gland activity necessarily involved in converting protein into its constituent amino acids. They found that all amino acids tested except sarcosine increased the output of uric acid. Since this latter amino acid was not catabolized in the body, the authors concluded that the uric acid metabolism of the body was increased by the specific dynamic action of catabolizing amino acids. Rose (6) concluded that the increase in uric acid output after high protein ingestion was due to generalized cellular stimulation occasioned by a higher caloric intake, thus implying that the increase in urinary uric acid was due to some intrinsic protein or amino acid effect. Christman and Mosier (7) gave glycine to subjects and observed an increased urinary uric acid but no change in the renal excretion of creatinine. They apparently concurred with Rose's theory concerning the general stimulating effect of protein or amino acids on cellular metabolism with consequently increased production and secondarily increased excretion of uric acid. Quick (8) also observed that glycine feeding increased uric acid excretion, particularly when combined with salicylate ingestion.

However, various observations have been made which cannot be fitted in with the theory of increased production of uric acid after ingestion of protein or amino acids. Thus, although Lewis, Dunn, and Doisy (4) implied that the specific dynamic action of ingested amino acids effected an increased production of uric acid, they also found that glutamic acid (an amino acid without significant dynamic action) increased uric acid output as markedly as any amino acid tested. Furthermore these investigators in this particular study never determined the concentration of uric acid in blood after ingestion of amino acids—it was assumed apparently that such a rise occurred because of the increased urinary output observed. Later however, Gibson and Doisy (9) were unable to detect a rise in blood uric acid in man after the ingestion of amino acids. Finally, Pitts (10) showed that an excess of an amino acid (glycine) might influence the renal excretion of a blood constituent not by increasing the production of the latter but by competing with it in the renal tubular reabsorptive process. These latter observations suggested the possibility that excess amino acid ingestion might increase urinary uric acid not by initially increasing the concentration of the latter in the blood but by interfering with its renal tubular reabsorption after its glomerular filtration (11).

In order to explore the validity of this last possibility as well as to determine other possible mechanisms involved in the increased excretion of uric acid after ingestion of amino acids, rats were given glycine. Studies then were made of the creatinine, hippurate and uric acid clearances together with the blood uric acid concentrations. Similar studies with the exception of the hippurate clearance were made on 2 human subjects.

[1] Aided by a grant from the Dazian Foundation for Medical Research.

Finally studies were made of the blood concentration of uric acid in nephrectomized rats given glycine. The results of these studies suggested that glycine increased the output of uric acid by effecting initially a decrease in the amount of uric acid reabsorbed by the renal tubules.

METHODS

A. *Animal experiments*

(1) *Clearance and blood uric acid studies*

Nineteen male albino rats, approximately 6 months of age, fed Purina Dog Chow, were used in this study. Control creatinine and hippurate clearances were determined for 2 hours exactly as described in a previous study (12). However, uric acid studies were also made on the rats at the same time by allowing the total period of urine collection to continue past the 2 hours necessary for the above mentioned clearances until a period of 5 hours had been attained. The blood uric acid was determined on the initial and final blood samples taken for the creatinine and hippurate clearances as well as on a third blood sample taken at the end of the 5-hour collection period. The urine collected for 5 hours was analyzed also for uric acid. The blood uric acid clearance was calculated by determining the average uric acid output per hour and dividing this figure by the average blood uric acid concentration per ml. over the 5-hour period (determined by averaging the blood uric acid concentrations of the 3 blood samples taken). In this manner, the creatinine, hippurate, and uric acid clearance as well as the blood uric acid level were determined concomitantly although the uric acid clearance was calculated on a 5-hour collection period. After these control clearances had been made, they were repeated 1 week later on the same rats except that the latter were given 50 mgm. of glycine per 100 grams of body weight at the beginning of the collection period and 5 mgm. every hour for 5 hours. The creatinine and hippurate clearances have been expressed in ml. of plasma per hour per 100 grams of body weight. The uric acid clearance was not found to vary with body weight, hence has been expressed in ml. of blood per hour per rat.

Uric acid in blood was determined according to the method of Folin (13) except that proportionately smaller quantities of reagents were employed in order to determine the uric acid content of no more than 0.5 ml. samples of whole blood. Uric acid in urine was determined according to the method of Benedict and Franke (14).

(2) *Blood uric acid levels in nephrectomized rats*

Seventeen healthy rats were nephrectomized after control blood uric acid determinations had been made. Nine of these rats then received 100 mgm. of glycine by stomach tube immediately after operation and 50 mgm. 3 times a day as long as they lived. The remaining 8 rats received no glycine and served as controls. Blood samples were obtained daily from each rat and analyzed for uric acid. Water but not food was given to the rats.

B. *Human experiments*

Two healthy adult men (W. C., age 34 and M. F., age 36) previously on a purine-free diet for over 48 hours were studied. At 9:30 a.m., each subject was given 2.5 grams of creatinine in 500 ml. of H_2O. At 10:15 a.m., the first blood sample was taken and urine collection begun. Five hundred ml. of H_2O were taken every half hour for 4 hours. At 12:15 p.m. a second blood sample was taken and a final blood sample at 2:15 p.m., at which time urine collection ended. The first two blood samples were analyzed for both creatinine and uric acid but the third sample was analyzed for uric acid alone. One-half ml. of urine was obtained from the collecting jar at 12:15 p.m. and analyzed for creatinine and the urine collected for the entire period of 4 hours was analyzed for uric acid. Thus, a 2-hour creatinine and a 4-hour uric acid clearance were able to be obtained. The 0.5 ml. removed from the collection jar at the end of 2 hours, as in the rat experiments, was included in estimating the total volume (collected over the 4 hours) for the determination of uric acid clearances. Two weeks after these control studies had been made, the entire procedure was repeated on the same 2 subjects except that at the beginning of the collection period, each ingested 25 grams of glycine. Creatinine and uric acid clearances have been expressed in ml. per minute.

RESULTS

A. *Effect of glycine on uric acid output and clearance of the rat*

The administration of glycine to rats over the 5-hour clearance study was found (see Table I) to have increased the uric acid output of 17 of the 19 rats studied. The average uric acid output before glycine ingestion was 0.136 mgm. per hour and 0.170 mgm. per hour afterwards, an increase of approximately 25 per cent. Likewise the average uric acid clearance increased from 10.70 ml. to 14.50 ml. per hour, an increase of 35 per cent.

The average urine volume was observed to decrease (see Table I) from 3.90 ml. to 2.90 ml. per hour after glycine ingestion. The average creatinine clearance however showed no significant change being 34.3 ml. before and 35.4 ml. per hour after glycine had been given. The hippurate clearance also showed no significant change as it was 138 ml. before and 139 ml. per hour after glycine administration. It was clear from these studies then that the increase in uric acid output observed after glycine ingestion was due neither to in-

[5] U. A. C. equals uric acid clearance in ml. per hour.

creased glomerular filtration nor to increased renal blood flow.

B. *Effect of glycine on blood uric acid of the rat*

Uric acid content of rat's blood was found to increase from 10:00 a.m. to 3:00 p.m. (the hours employed for the clearance studies) in the control rats. Thus (see Table II) the control average blood uric acid was 0.97 mgm. at the beginning of the clearance study, 1.16 mgm. at the end of 2 hours and 1.51 mgm. per 100 ml. at the end of 5 hours. Similarly the blood uric acid was found to increase in those rats given glycine (see Table II), but the increase was not greater than in the control animals. There was little evidence, then, from these results to support the assumption that glycine *per se* increased the *production* of uric acid in the animal body.

The evidence obtained from the nephrectomized rats fed glycine also failed to support the assumption that more uric acid was produced or mobilized in the blood stream following increased intake of amino acid. Thus the average blood uric acid level of 8 control rats before nephrectomy was 1.85 mgm. per 100 ml. of blood. Twenty-four hours after nephrectomy the blood concentration was 1.88 mgm. and 1.96 mgm. per 100 ml. after 48 hours. This represented an increase of 6 per cent in the blood uric acid 48 hours after nephrectomy. The average blood uric acid content of 9 rats given glycine following nephrectomy was 1.71 mgm. per 100 ml. before and 1.80 mgm. and 1.84 mgm. per 100 ml., 24 and 48 hours, respectively, after nephrectomy, representing an increase of but 8 per cent. In short, glycine feeding did not significantly increase the blood uric acid of nephrectomized rats. It must be remembered, however, that the rat converts uric acid into allantoin. It is therefore possible that any excess uric acid produced in these nephrectomized rats may have been converted so quickly to allantoin that no rise in blood uric acid occurred. Accordingly, the experimental data obtained on these nephrectomized rats are not necessarily applicable to human subjects.

C. *The effect of glycine on uric acid output and clearance of man*

The ingestion of 25 grams of glycine by 2 subjects was found to increase the uric acid output of both. The average uric acid output (see Table

* Each rat given 50 mgm. of glycine per 100 grams body weight at start and then 5 mgm. every hour of the 5-hour study period.

III) was 23.40 mgm. before and 39.95 mgm. per minute after the administration of glycine (an increase of 71 per cent). Similarly, the average uric acid clearance increased from 11.90 ml. to 17.50 ml. per minute (an increase of 47 per cent).

As was observed in the rats, the average urine volume also decreased (see Table III) from 3.26 ml. before to 2.49 ml. per minute after glycine. The average creatinine clearance also decreased from 116.0 ml. before to 100.0 ml. per minute after glycine had been given. Similar again to the rat study, no significant change was observed in the blood uric acid level after glycine had been given.

DISCUSSION

The above results suggest quite strongly that glycine does not increase the production of uric acid in the body of either rat or man. On the other hand it was certain from the observations made that glycine ingestion does increase the renal excretion of uric acid, despite the fact that both creatinine and hippurate studies demonstrate the fact that there is neither increase in the rate of glomerular filtration nor in the renal blood flow after glycine. As a matter of fact, the creatinine clearance slightly decreased after glycine in the 2 human subjects tested. These facts lead to the inescapable conclusion that glycine in some manner probably impedes tubular reabsorption of the uric acid contained in tubular fluid. In other words, uric acid output is increased after glycine, not because the blood contains more uric acid nor because the kidney filters or secretes more of it, but because the renal tubule does not reabsorb the usual quantity of uric acid in the presence of excess glycine. The latter may compete with uric acid for reabsorption at the identical tubular site. This mechanism may be quite similar to that postulated by Pitts (10) to explain the preferential tubular reabsorption of glycine with impedance of creatine reabsorption when both are in the glomerular filtrate. Such a mechanism would explain also the fact that, in the present study, there was not the expected change in the rat's creatinine clearance commensurate with the decrease in urine volume (12)—a phenomenon which suggests increased water reabsorption by the tubule.

[1] U. V. equals urine volume in ml. per minute.
[2] C. C. equals creatinine clearance in ml. per minute.
[3] U. A. E. equals milligrams of uric acid excreted in urine per minute.
[4] U. A. C. equals uric acid clearance in ml. per minute.
[5] Glycine given after the 10:00 a.m. blood sample had been obtained.

The failure of the blood uric acid to decrease in the presence of this increased renal output of uric acid may well be due to the ability of the extravascular tissues to maintain the blood uric acid concentration despite its increased renal excretion.

SUMMARY

The administration of glycine to the rat and to man was found to increase the renal excretion of uric acid without a concomitant change in either the renal hemodynamics or in the concentration of uric acid in the blood. Furthermore, glycine feeding was not found to increase the uric acid content of nephrectomized rats' blood.

These findings suggested the probability that glycine increased the excretion of uric acid by impeding its renal tubular reabsorption.

ELECTROPHORETIC ANALYSIS OF ANTE- AND POSTMORTEM SERUM IN DIFFERENT DISEASES [1]

By PHILIP P. COHEN, FRANCES L. THOMPSON, and GEORGE A. NITSHE, JR.

(From the Departments of Physiological Chemistry and Medicine, University of Wisconsin, Madison)

(Received for publication December 16, 1946)

Our present knowledge of the protein components of normal human plasma has been markedly advanced in recent years as a result of the blood fractionation program carried out by Cohn and his group (1). To a considerable extent the success of this program was due to the availability of large quantities of pooled plasma from normal humans. In attempting to extend the available information on normal human plasma to pathological human plasma, one is faced with the serious technical difficulty of being restricted to relatively small samples from a patient with a given disease. It therefore seemed desirable to investigate the possibility of using postmortem blood obtained at autopsy. The chief question to be answered in such a study is that of the influence of postmortem conditions on the plasma protein composition. Scudder (2) in a study of various factors influencing blood preservation stated that a serum and plasma sample obtained at autopsy were both "abnormal" on electrophoretic analysis. No reference was made as to the antemortem clinical status, nor were any antemortem analyses carried out. In view of this report it seemed important to determine what changes, if any, were to be found in samples of postmortem blood in different diseased states. Essentially the problem was that of obtaining a sample of blood antemortem and a second sample postmortem and comparing the electrophoretic patterns. A study of 9 cases is reported in the present paper, the results of which indicate that postmortem blood, which may be obtained in considerable quantity, shows no striking electrophoretic variation from that observed antemortem during the course of the disease.

METHODS

Collection of blood samples

At times varying from 8 to 240 hours before death, 25- to 30-ml. samples of blood were collected and allowed to clot at room temperature in a 50-ml. centrifuge tube. After retraction of the clot had begun, the tube and contents were centrifuged at 3,000 r.p.m. for 10 minutes. The clear serum was transferred to a 50-ml. Erlenmeyer flask which was then placed on its side in a quick-freeze unit. Blood was again collected at times varying from ½ to 13 hours after death and treated in the same manner as the antemortem samples. A number of different methods were used to obtain the postmortem blood. If the antecubital veins were in good condition it was found that by placing a tourniquet below the antecubital fossa and allowing the arm to drop off the side of the table with the opposite shoulder elevated so that the back was perpendicular to the table, 25 to 30 ml. could be procured from the distended veins. Frequently the veins in this region were not suitable and thus it was necessary to resort to either cardiac puncture or puncture of the femoral vessels. In cases of necropsy within 3 hours postmortem, the following procedure was found effective for obtaining large quantities of blood (1,500 to 2,500 ml.). The vena cava was incised and a length of tubing 10 mm. in diameter inserted and directed toward the heart. This was secured by tying a ligature about the vessel. The superior portion of the vena cava was either tied or clamped. The distal end of the tube was placed in a suitable container, and the body then elevated so that the feet were at the top of an incline of approximately 40°. It was found convenient to include a glass T-tube near the distal end of the tube to permit application of suction in instances where clots interfered with free drainage.

Electrophoretic analysis

The frozen samples were thawed out at room temperature. The resulting solutions were centrifuged and diluted with 2 parts of 0.10μ sodium diethylbarbiturate buffer, pH 8.6. The diluted samples were then dialyzed against 2 liters of buffer at 1 to 2° C. for 48 hours. The dialyzed samples were examined in the electrophoresis apparatus using the Schlieren scanning technique of Longsworth (3). Electrophoresis was carried out in 11-ml. cells for 150 minutes at a potential gradient of about 6 volts per cm. at 1.5° C. Relative composition of the serum samples was estimated by measuring the areas under the projected patterns after the areas were resolved into a series of symmetrical curves. In all instances, the percentage composition represents the average of the ascending and descending boundaries.

Mobilities were determined by measuring the migration distances of the different components from the starting

[1] Aided in part by a grant from the Wisconsin Alumni Research Foundation.

boundaries. Conductivity measurements were made on the protein-free buffer used as the dialyzing solution.

Total protein was determined by the micro-Kjeldahl technique.

RESULTS

Examination of Table I reveals that in only 1 instance (case 5) was there any significant change in the composition of the postmortem samples as compared with the antemortem samples. It appears from the analyses in case 5 that there is a postmortem decrease in beta globulin and an increase in gamma globulin. Whether this is actually due to a quantitative change in these components or to some unknown qualitative change causing a portion of the beta globulin fraction to migrate as gamma globulin is not apparent. The fact that the postmortem sample in this instance was taken only 1 hour after death suggests that the change is not due to postmortem conditions as such. It should be noted that the average values of the ratios of ante and postmortem analyses are remarkably close to unity.

With the exception of case 9 the total protein determination ante- and postmortem agreed quite closely. The high postmortem value found in this instance is in all probability an artefact due to dehydration of the sample in the freezer.

The serum protein patterns in several of the conditions studied showed marked variations from normal. The range of normal values obtained with sera from young normal adults and determined with the same technique is given in Table II.

S.E. of mean	0.9	0.6	0.5	0.5	0.6

In cases 1, 3, 4, and 8 the serum albumin levels are extremely low. Of interest, however, is the fact that the globulin components are not uniformly increased. Thus, in case 1, marked increases are seen only in the alpha-1 and alpha-2 fractions; in case 3, in all the globulin fractions; in case 4, in the alpha-1, alpha-2, and gamma globulin fractions; and in case 8, in the alpha-1, beta, and gamma fractions. The one fraction showing the most consistent and striking variation from normal in all the conditions studied here is the alpha-1 globulin. This finding is in keeping with the observations made previously by Shedlovsky and Scudder (4).

Tracings of the electrophoretic patterns ante- and postmortem of the different cases and that of a typical normal serum are shown in Figure 1. The greatest apparent variation in the patterns of the ante- and postmortem specimens is seen to occur in the beta-anomaly of the descending patterns. However, variations of the same degree and type have been observed in determinations on a series of normals and even in a series of 3 determinations on the same individual at varying intervals of time.

The mobility values of the different fractions of the normal, antemortem, and postmortem series are shown in Table III. It is apparent that the protein components in serum from cases of disease, ante- and postmortem, have the same mobility values as those found with normal serum.

TABLE III

Mobilities ($cm.^2/volt\ sec. \times 10^{-5}$)

		Albumin	Alpha-1	Alpha-2	Beta	Gamma
Normal	Mean	6.8	5.8	4.6	3.3	1.5
	S.D.	0.23	0.25	0.19	0.22	0.21
Antemortem	Mean	6.8	5.7	4.5	3.2	1.4
	S.D.	0.30	0.30	0.32	0.29	0.26
Postmortem	Mean	6.7	5.7	4.5	3.4	1.5
	S.D.	0.30	0.32	0.31	0.32	0.28

SUMMARY

Serum samples taken ante- and postmortem from 9 cases of different diseases were examined electrophoretically. While all the cases showed some variation from a series of normals, no striking electrophoretic differences were noted in the postmortem as compared with the antemortem samples. On this basis it would appear that up to 13 hours postmortem, serum proteins undergo no significant changes. Thus, the possibility presents itself of preparing purified protein fractions from postmortem blood of diseased patients and comparing their physical, chemical, and biological properties with those obtained from normal pooled plasma.

THE PLASMA NON-PROTEIN NITROGEN DISTRIBUTION AND ITS CORRELATION WITH THE EFFICACY OF FLUID REPLACEMENT THERAPY FOLLOWING THERMAL INJURY[1]

By OTTO ROSENTHAL, and M. D. McCARTHY

(*From the Harrison Department of Surgical Research, Schools of Medicine, University of Pennsylvania, Philadelphia*)

(Received for publication September 6, 1946)

It has been previously pointed out by us (1) that the rise of the undetermined and the amino nitrogen in the plasma of scalded rats is directly related to the severity of the burn. In the present paper it will be shown that the extent to which the increases in these two nitrogen fractions are reduced by therapeutic measures provides an index of efficacy of the fluid and salt treatment. The therapeutic agencies under comparison were physiological saline, gelatin, albumin, and plasma, which were administered intravenously to the scalded rats at varying intervals of time and in varying quantities. In addition to the effect of these substances upon the azotemia, their influence upon the urinary excretion of water and nitrogen was investigated.

EXPERIMENTAL METHODS

The standardized back-burn procedure, the collection of blood, and the determination of non-protein nitrogen, urea nitrogen, and amino nitrogen in tungstic acid filtrates of the plasma have been previously described (1, 2). The difference (non-protein nitrogen − [urea nitrogen + amino nitrogen]) will be referred to as the undetermined plasma nitrogen.

Plasma protein levels were calculated by multiplying the difference (total plasma nitrogen − non-protein nitrogen) by the factor 6.25. The estimation of the gelatin content of plasma following the infusion of this plasma substitute was based upon the fact that 3 per cent trichloracetic acid precipitates only the plasma proteins while tungstic acid removes both plasma protein and gelatin. The gelatin solution used for infusion contained 1.0 gram of precipitable nitrogen per 5.5 grams of gelatin. Hence the term (non-protein nitrogen of the trichloracetic acid filtrate − non-protein nitrogen of the tungstic acid filtrate) × 5.5 provides an estimate of the gelatin level of plasma.

Urine was collected under "Klarol"[2] in separatory funnels[3] which were placed under metabolism cages. The funnels were drained for measurement and analysis of the urine at intervals of 12, 21, or 24 hours as required. Analyses of total nitrogen, non-protein nitrogen,[4] urea nitrogen, and ammonia nitrogen were carried out with the method of Sobel, Mayer, and Gottlieb (3). The difference (non-protein nitrogen − [urea + ammonia nitrogen]) will be referred to as the undetermined urinary nitrogen.

During the first 24 hours following scalding the rats received no food. Thereafter they were fed in separate cages for periods of 2 hours in the morning and 1 hour in the afternoon, a procedure recommended by Croft and Peters (4). Urine voided during the periods of feeding was absorbed in filter paper. The paper was then extracted with N/50 sulfuric acid and an aliquot of the extract analyzed for urea + ammonia nitrogen. The nitrogen content and the volume of the 3-hour specimens were computed on the assumption that the nitrogen partition and the nitrogen concentration were identical with those of the corresponding 21-hour specimens of known volume and composition.

The urine of rats contains normally a small amount of protein (5). Only during the first day or 2 following the burn, however, were the total nitrogen values of the samples distinctly above the non-protein nitrogen values. Hence, for collection periods other than the first 48 hours following burn, non-protein nitrogen analyses were often omitted and only the total nitrogen determined in addition to urea and ammonia nitrogen.

The following agents were used in the transfusion experiments: (*1*) 0.85 per cent sodium chloride solution referred to thereafter as saline; (*2*) 4 per cent gelatin solution (Knox P-20). In addition to 726 mgm. of nitrogen precipitable with tungstic acid, 100 ml. of the gelatin solution contained 12.5 mgm. of undetermined nitrogen, 2.5 mgm. of amino nitrogen, 1.25 mgm. of ammonia nitrogen and 0.63 mgm. of urea nitrogen, the latter prob-

[1] Part of the results have been presented at a Meeting of the Physiological Society of Philadelphia on October 15, 1946 (Am. J. Med. Sci., 1946, 212, 755).

[2] A very light mineral oil manufactured by Sonneborn and Son, N. J.

[3] In glass funnels filled with a non-polar medium, such as mineral oil, water droplets stick rather tightly to the glass walls and are only incompletely removable mechanically. Perfect drainage was obtained when, on the suggestion of Dr. K. C. Blodgett of the General Electric Research Laboratory, the funnels were coated with a water repelling surface film. We are grateful to the Chemical Department of the General Electric Company, Schenectady, N. Y., for a gift of DRI-FILM No. 9987.

ably derived from arginin; (3) 5 per cent human albumin solution containing 1.06 per cent of sodium chloride. This infusion fluid was prepared by adding 4 parts of saline to 1 part of a 25 per cent solution of normal human serum albumin (Lederle) containing 1.8 per cent of sodium chloride; (4) plasma from citrated or heparinized rat blood. The curative effectiveness of both types of rat plasma was identical. Infusion intervals and volumes are given in the figures and tables.

The standard for computing mortality rates was 10 days' survival. The rates referred to in the following sections were obtained in separate experimental series which will be discussed elsewhere (6).

EXPERIMENTAL RESULTS

Effect of fluid replacement on azotemia

Figure 1 illustrates the effect of the intravenous infusion of saline on the non-protein nitrogen levels in the plasma of scalded rats. It is seen that a single infusion, when administered 2 hours after the burn in an amount corresponding to 2 per cent of the body weight, failed to retard the increase of the plasma nitrogen. Repetition of the infusion at 5 hours after the burn prevented a further rise of the undetermined and the amino nitrogen fractions and reduced the mortality rate of the group to 50 per cent. In the survivors examined 24 hours after the burn, these 2 nitrogen fractions had returned to approximately normal level. When the saline infusion was increased to 10 per cent of the body weight of the animal, approximately normal levels were found as early as 12 hours after the burn and all animals survived. It should be noted that the urea nitrogen levels fell much more slowly. Normal urea levels were not obtained until 48 hours after the scalding. This slow reduction in the presence of effective therapy is in keeping with our previous conclusion (1) that there is no definite correlation between the accumulation of urea in the plasma and the severity of the scald or the prognosis.

For comparing the therapeutic action of plasma and colloidal plasma substitutes with that of saline, an arrangement was needed where saline therapy was only of limited value. For this purpose the 30 per cent surface-35-second scald was chosen, which renders the animals less responsive to saline therapy than does the 45 per cent surface-15-second scald. The volumes of the different agents administered corresponded to 4 per cent of the body weights of the animals, the maximum amount that could be given in the case of colloidal solution without leading to undesirable large increases of the circulating blood volume. Under these circumstances the survival rate following saline therapy was 29 per cent.

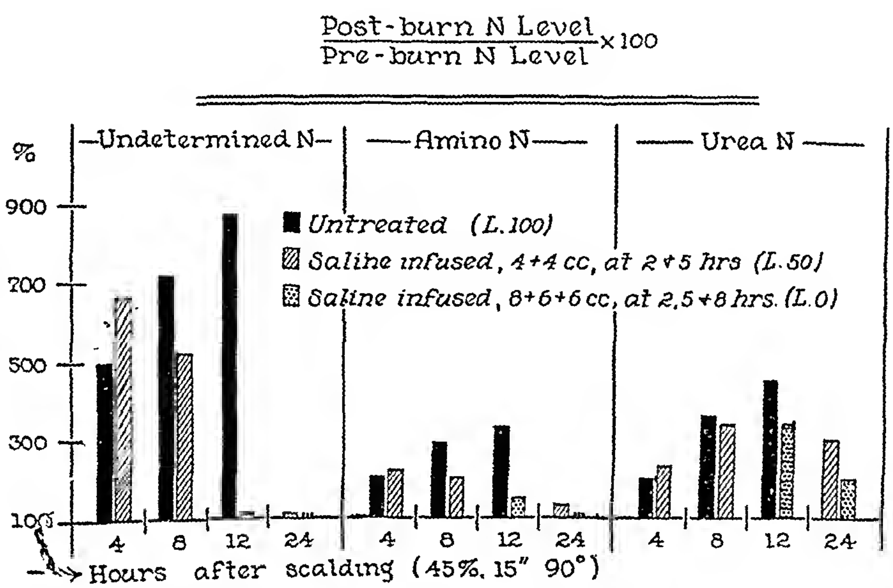

FIG. 1. EFFECT OF THE INFUSION OF VARYING VOLUMES OF SALINE ON THE NON-PROTEIN NITROGEN LEVELS OF SCALDED RATS

Forty-five per cent body surface, 90° C., 15 seconds' scald. Pooled blood from 2 to 4 rats was used for the individual determinations. The nitrogen levels are represented as percentages of the average levels in normal rats. The letter L denotes the average percentile lethality in the animal series.

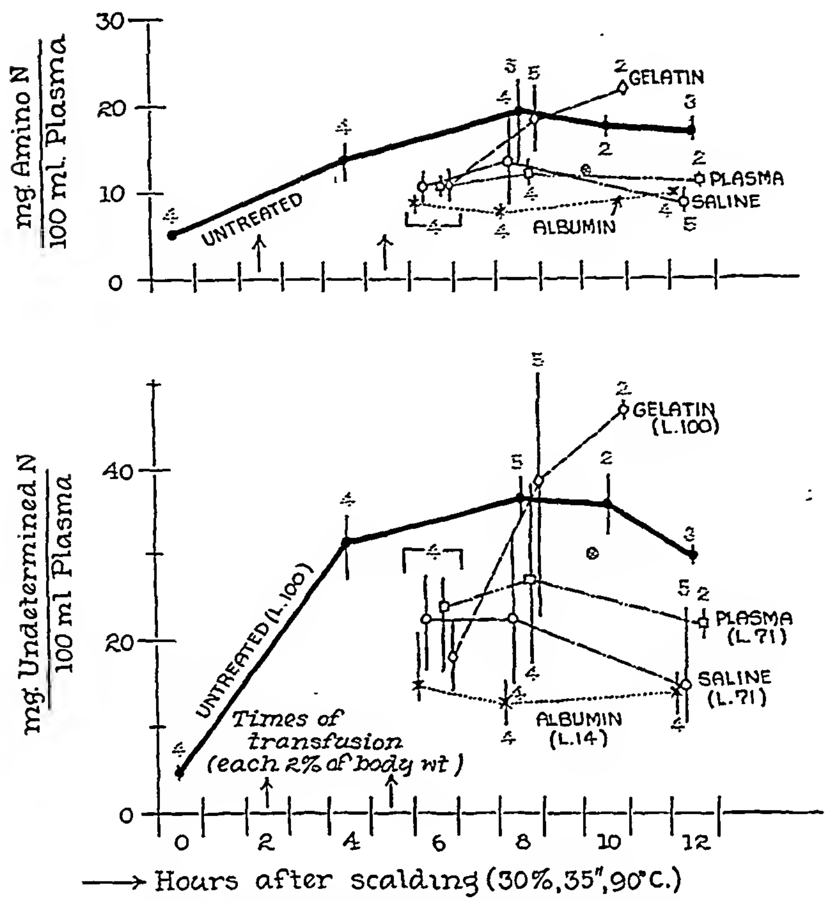

FIG. 2. AMINO NITROGEN AND UNDETERMINED NITROGEN LEVELS IN THE PLASMA OF SCALDED RATS FOLLOWING DIFFERENT TYPES OF FLUID REPLACEMENT THERAPY

Scald: 30 per cent body surface, 90° C., 35 seconds. The analyses were done upon plasma from individual rats.

Note that in the diagram the units of time as marked on the abscissa are represented by the distances between the pairs of vertical lines instead of by points. Within the vertical columns thus formed the values for each of the 5 experimental groups are plotted at arbitrary, but constant, positions with reference to the abscissa. This arrangement prevents the overlapping of the 5 plots. The points of the curves show the group means for each interval of time. The light vertical lines through these points indicate the difference between the highest and the lowest individual analysis while the numerals refer to the number of rats examined. The encircled daggers designate the analyses in an individual moribund rat following albumin treatment. This value has been omitted from the general plot of the albumin group.

A comparison of the plasma nitrogen values with the mortality rates (L) presented in Figures 2 and 3 shows that the response of the undetermined nitrogen levels brought out most strikingly the differences in efficacy of the various types of fluid replacement therapy. It is seen from Figure 2 that albumin infusion, which yielded the lowest mortality rate, was most effective in permanently reducing the undetermined nitrogen levels. This is contrasted to the transient effect of gelatin infusion which did not produce a single cure. Normal rat plasma and physiological saline solution

had an intermediary position with reference to the reduction of the undetermined nitrogen levels and to the lowering of the mortality rates.

The amino nitrogen levels, which are also given in Figure 2, showed trends similar to those of the undetermined nitrogen levels. The differences between the treated and untreated groups were, however, less pronounced. Only following albumin treatment were the group means significantly below those of the controls during the entire experimental period. Plasma infusion resulted in statistically significant reductions at the 8- and 12-hour post-burn interval while the reduction following saline treatment became significant not before 12 hours following the scalding. Gelatin infusion failed to produce significant reductions at any interval of time. The urea nitrogen levels (Figure 3) were not significantly different in the 5 experimental groups under comparison.

Inspection of the data presented in Table I reveals the following details regarding the undetermined nitrogen levels. Six hours after the burn, *i.e.*, 1 hour after the final infusion, the levels in all treated groups were significantly lower than they had been 4 hours after the burn in the untreated controls. Albumin and gelatin appeared to be slightly more effective than physiological saline

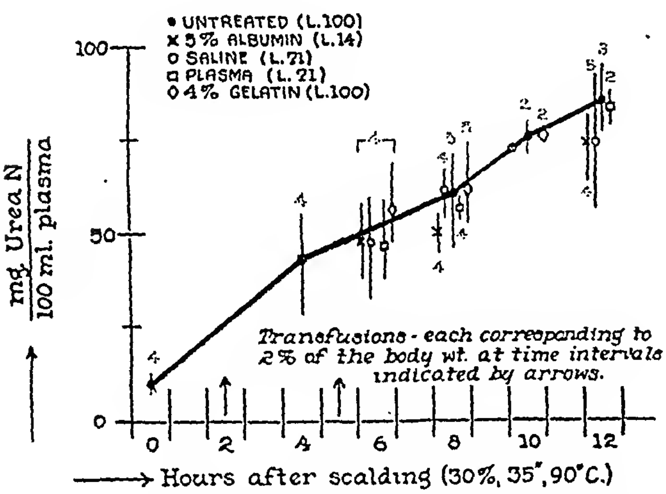

FIG. 3. UREA NITROGEN LEVELS IN THE PLASMA OF SCALDED RATS FOLLOWING DIFFERENT TYPES OF FLUID REPLACEMENT THERAPY

Experimental and diagrammatic arrangements and abbreviations are explained in the legend to Figure 2. Only in the untreated control series have the group means for each interval of time been connected by a curve. None of the group means in the treated series differed significantly from the corresponding control mean.

TABLE I

* $S\bar{x} = \sqrt{\dfrac{\Sigma(\Delta x)^2}{n(n-1)}}$.

† $S\Delta\bar{x} = \sqrt{(S\bar{x}_u)^2 + (S\bar{x}_t)^2}$ where $S\bar{x}_u$ and $S\bar{x}_t$ designate the standard errors of the means of the untreated and treated groups, respectively.

‡ P = probability of $\Delta\bar{x}$ to have arisen by chance. The P values are taken from Fisher's (7) table of t.

solution and plasma. During the following 2 hours, however, marked differences developed among the 4 groups of infused animals. While the group means for the albumin and saline series remained significantly below that of the untreated controls, the difference between gelatin-treated and untreated animals disappeared and the difference between the plasma group and the controls became statistically insignificant. While the mean for the albumin group was significantly below that of any other treated group, the differences among the 3 other groups were not statistically significant due to the large range of variation of the individual values. The large scatter range in the saline, plasma and gelatin groups can be most readily seen from Figure 2. Since burned rats *in extremis* always exhibited greatly increased undetermined nitrogen levels, heterogeneity of the group can be considered as an indication that in several individuals the beneficial effect of the transfusion had already disappeared and that death was near, although the apparent conditions of most of the treated animals was fair to good at the 8-hour interval of time. During the following 4 hours, however, 70 per cent of the gelatin group, 36 per cent of the plasma group, 20 per

cent of the saline group, and 10 per cent of the albumin group died.

It should be noted that, from the standpoint of alterations from the normal, none of the therapeutic measures can be designated as adequate for the treatment of this particularly severe burn; for, contrary to the 100 per cent successful saline therapy illustrated in Figure 1, all types of fluid therapy failed to reduce to normal the increased undetermined nitrogen levels within a period of 12 hours.

Azotemia and hemoconcentration

Figure 4 serves to demonstrate that gelatin, plasma ,and albumin were about equally effective in relieving the hemoconcentration of burn shock and in maintaining the restored plasma volume. Saline therapy resulted in a temporary hemodilution and hypoproteinemia which disappeared within 3 hours of the last infusion. This was followed spontaneously by a second period of hemodilution with constant plasma protein levels. It is obvious that the effects of these agents upon hemoconcentration do not throw light upon the reasons for their different therapeutic efficacy. Nor can hemodilution *per se* be considered as the essential mechanism in the reduction of the increased undetermined and amino nitrogen levels.

The effect of fluid replacement therapy on water and nitrogen excretion

Table II provides information on urinary nitrogen and water excretion and fluid intake of normal rats during 5 days of feeding and 1 day of

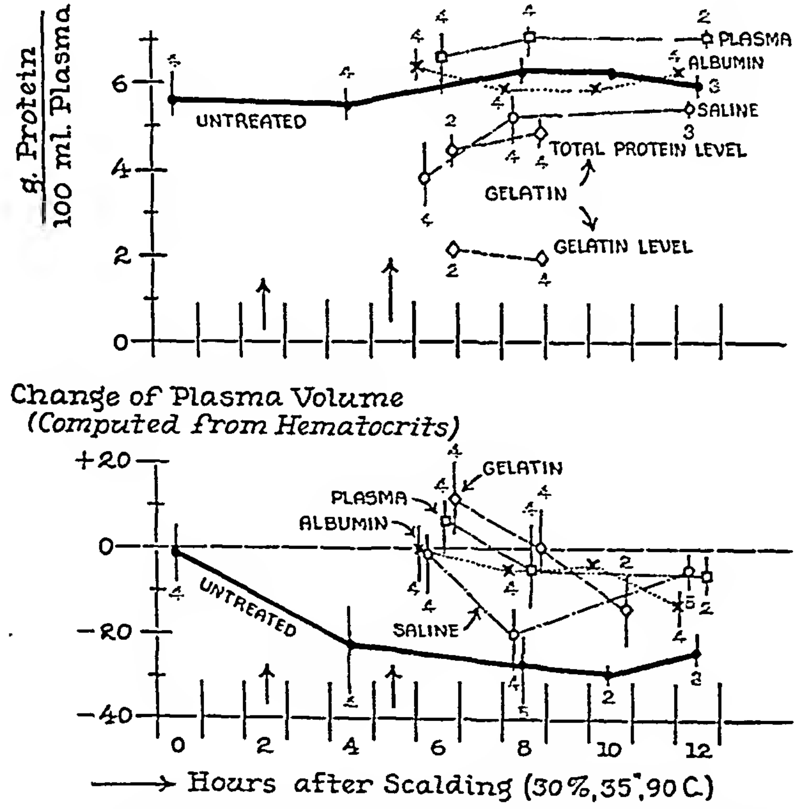

FIG. 4. CHANGES OF PLASMA VOLUME AND PLASMA PROTEIN LEVELS IN SCALDED RATS FOLLOWING DIFFERENT TYPES OF FLUID REPLACEMENT THERAPY

Diagrammatic arrangement as in Figure 2. Hematocrit readings were done upon tail blood. If I is the hematocrit value (expressed as percentage) before the scalding and F the hematocrit reading at the time the animal was sacrificed, then the percentile change (ΔV) of the plasma volume is

$$\Delta V = \frac{[(100 - F) - (100 - I)]\,100}{100 - I} = \left(\frac{I - F}{100 - I}\right) 100.$$

* The data are averages for 5 experimental days, 2 before and 3 after the day of fast. The rats were scalded on the fourth day after the fast. Post-burn data are presented in Figure 5.

** Water was withheld for 12 hours in the daytime in order to simulate the post-burn conditions.

† This term should be considered as only a minimal estimate of the exogenous nitrogen because part of the nitrogen excreted during a single day of fast will still be of exogenous origin. Exposure of the rats to longer periods of starvation was not attempted as it would probably have altered their resistance to the scald.

‡ In general, approximately ⅔ of the urine was excreted during the night hours.

fast. Fasting reduced the output of urea + ammonia by approximately 50 per cent while the excretion of undetermined nitrogen and of water was not affected by the nutritional state of the animal. The urea + ammonia excretion during the period of feeding showed the smallest individual variations and the water intake and output the largest.

The experiments upon scalded rats listed in Table III concern the response of urinary excretion to saline therapy corresponding to 10 per cent of the animal's body weight. Data are presented on 2 successive 12-hour periods following the scalding and on 2 types of fatal burn in which the treatment leads to 100 per cent recovery of the animals. It is seen from Table III that in untreated rats, water excretion and, especially urea elimination, virtually ceased. Following the infusion of physiological saline solution the urinary volumes during the first 12 post-burn hours were of a similar order of magnitude as in normal rats during a 12-hour period in the daytime. Abnormal chemical findings in the urines consisted of hemoglobin and low ratios of urea nitrogen to total non-protein nitrogen. The ratio of ammonia nitrogen to non-protein nitrogen, which is not recorded in the table, remained essentially normal (about 6 per cent). During the second 12 hours after the burn, when the animals had access to water, large volumes of urine with a normal nitrogen distribution were excreted. As in fasting normal animals, considerable individual variations were encountered with reference to the quantities of water and nitrogen excreted during the 2 12-hour periods. On the average, the amount of urea + ammonia nitrogen (142 ± 8.2 mgm.) excreted during the first 24 post-burn hours by the group of 6 rats reported in Table II was slightly above the corresponding mean (117 ± 6.5 mgm.) for fasted normal rats. The mean value for the undetermined nitrogen (30.1 ± 3.1 mgm.) was also higher than that (23 ± 1.08 mgm.) for the unburned controls, but this difference was not statistically significant.

Table IV shows the effects of 2 inadequate types of fluid therapy upon the urinary excretion of rats subjected to a 30 per cent surface-35-second scald. As mentioned before, in this type of 100 per cent lethal burn saline infusion corresponding to 4 per cent of the animal's body weight yielded only 29 per cent survival while the infusion of gelatin had no curative value. The saline-treated animals of the experimental series presented in Table IV were in good clinical condition when sacrificed 12 hours after the burn, whereas the gelatin-treated rats were moribund at the time of blood collec-

* At the end of the period given in column 3.
** Undetermined nitrogen in urine = non-protein nitrogen—(urea nitrogen + ammonia nitrogen). Undetermined nitrogen in plasma = non-protein nitrogen—(urea nitrogen + amino nitrogen).
† Rats kept in single metabolic cage.
‡ Volume of intravenous saline infusion corresponding to 10 per cent of the animal's body weight. Forty per cent of the total volume were given 2 hours post-burn, the remaining 60 per cent in equal doses 5 and 8 hours post-burn.
§ Three rats died 8 to 9 hours after the scald. The survivor was used for plasma analysis.
¶ Nineteen per cent urea nitrogen and 11 per cent ammonia nitrogen. The non-protein nitrogen concentration was 1.2 grams per 100 ml. of urine.

tion, between 7.5 and 10.5 hours after the burn. Yet the urine volumes of the gelatin-treated rats were within the range previously obtained with corresponding periods of time in scalded rats which received an adequate saline therapy. There was only one statistically significant difference in the urinary excretion following gelatin treatment. The concentration of urea + ammonia nitrogen averaged 0.41 ± 0.05 gram per 100 ml. of urine as contrasted to an average concentration of 0.96 ± 0.10 gram in the urine of 11 saline-treated rats during the first 12 hours following the scalding. This suggests the possibility that the concentration ability of the kidney was impaired in the gelatin-treated rats.

Figure 5 serves to illustrate the nitrogen excretion of saline-treated rats over longer post-burn periods. The same type of scald as in the last experimental series was used, but the infusion was increased to 10 per cent of the animal's body weight with the result that, on the average, 86 per cent of the rats survived. In the graph all quantities are represented as percentages of the corresponding pre-burn values for the fed state which are recorded in Table II. Note that the exogenous urea + ammonia nitrogen excretion is a measure of the food intake of the animal during the post-burn period:

$$\text{d post-burn} = \text{b post-burn} \times (\text{d/b}) \text{ pre-burn}$$

where, as in Table II, d and b designate "exogenous" nitrogen and food intake, respectively. The quantity recorded in Figure 5 is the ratio:

$$(\text{d post-burn/c fed pre-burn}) \times 100$$

c being the total daily excretion of urea + ammonia nitrogen. Prior to the burning, the ratio (d/c fed) × 100 approximated 50 per cent. Hence

* Infused intravenously at 2 and 5 hours after the scalding. The volume of each infusion (approximately 4.0 ml.) corresponded to 2 per cent of the body weights which ranged from 201 to 215 grams. The total volume (8.0 ml.) infused was approximately equal to the normal plasma volume of the rat.

in Figure 5, the 50 per cent level of the exogenous urea + ammonia nitrogen designates normal food intake.

Rat No. 4 of Table II died 10 hours after the burn in spite of the saline treatment. No urine was excreted, and the plasma nitrogen levels were as high as in the untreated controls. In rats Nos. 2 and 3 the excretion of urea + ammonia nitrogen showed the usual initial drop to the pre-burn fasting level. On the second post-burn day the excretion reached the pre-burn range for fed animals even though food consumption was still minimal. With the resumption of normal food intake (50 per cent level of "exogenous" nitrogen in Figure 5) on the fifth post-burn day, the urea + ammonia nitrogen excretion increased to about 20 per cent above the pre-burn average. It returned to normal the tenth day after the scalding. Rat No. 1 excreted during the first 24 post-burn hours 60 per cent less urea + ammonia nitrogen than during the pre-burn day of fast although the urine volume (13.0 ml.) was as high as in rat No. 3 (11.5 ml.).[5] The nitrogen excretion did not reach the pre-burn level for fed animals before the third day. Food intake remained minimal, and the animal died on the fifth post-burn day.[6]

In the rats Nos. 1 to 3 the daily excretion of undetermined nitrogen averaged 37.0, 33.0, and 42.0 mgm., respectively, during the first 4 post-burn days, *i.e.*, it was 83, 45, and 74 per cent above the fasting level and 83, 19, and 54 per cent above the average level in the fed state. The absolute quantities of undetermined nitrogen excreted were small in comparison with the total amount of urinary non-protein nitrogen. This is in keeping with the statement of Clark, Peters and Rossiter

[5] During the entire post-burn period the average daily urine output of the rats remained 2 to 3 times as high and the average fluid intake double as high as before the scalding. In contrast to the fairly constant rates of nitrogen excretion the daily fluctuations of the fluid exchange were extremely large. This phenomenon has to be re-examined since the possibility could not be excluded with certainty that the rats, whose movements were somewhat impaired owing to scar contractions, spilled drinking water into the collecting funnels.

[6] Because of the sudden death of this animal no blood for plasma analysis was secured. In rat No 2 which was sacrificed at the height of the urinary nitrogen excretion, as well as in rat No. 3 which was analyzed after the return of the nitrogen excretion to the pre-burn range, the non-protein nitrogen levels of the plasma were essentially normal.

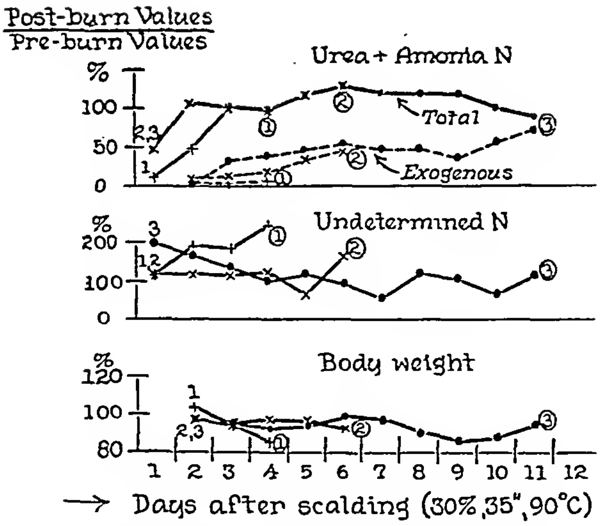

FIG. 5. DAILY NITROGEN EXCRETION AND WEIGHT CHANGES IN RATS RECOVERING FROM BURN AS A RESULT OF SALINE THERAPY

Scald: 30 per cent body surface, 90° C., 35 seconds. The volume of saline infused corresponded to 10 per cent of the animal's body weight. Infusion intervals as in Table III and Figure 1. In the graph all quantities are represented as percentages of the corresponding pre-burn values for the fed state (see Table II). Each curve shows the serial number of the rat to which it refers. Encircled numbers designate the last analysis prior to death or sacrifice of the animal.

(8) that thermal injury in the rat fails to produce the large excretion of undetermined nitrogen which has been reported (9, 10) to occur frequently in the burned human patients. It seems possible, however, that the time-course of the excretion may have some prognostic significance as rat No. 3, which recovered most rapidly from the scalding, showed the greatest initial rate of elimination of this nitrogen fraction.

COMMENT

It has been previously pointed out by us (1) that the accumulation of undetermined and amino nitrogen in the plasma of rats following scalding is probably the consequence of the thermal destruction of cells as well as of the post-burn shock. The latter leads to tissue hypoxia, increased nitrogen catabolism in peripheral tissues, decreased amino acid oxidation in the liver, and cessation of urinary excretion. It should be expected that the curative efficacy of a given type of fluid replacement therapy would be attested by the relief of any one of the 3 criteria of burn shock here examined: the anuria, the hemoconcentration, or the azotemia. While curatively effective types of fluid therapy always initiated the flow of urine and relieved hemoconcentration, curatively ineffective agents, such as gelatin infusion, were not inferior in this regard. They were, however, clearly distinguished from the effective types by the fact that they produced, in all or many animals, only a temporary reduction of the increased plasma levels of the undetermined and amino nitrogen. It seems possible that the renewed rise of the levels of these nitrogen fractions was the manifestation of a returning tissue anoxia, caused by a diminution of the actively circulating rather than of the total blood volume. Recent studies of Prinzmetal, Bergman, and Kruger (11) support the view that the shock following burns is characterized by a pronounced diminution of the circulating blood volume due to an atony of visceral blood capillaries.

SUMMARY

The effect of various types of fluid replacement therapy on the partition of the non-protein nitrogen of plasma and on the urinary water and nitrogen excretion was studied in rats subjected to standardized scalds of known lethality. The agents under comparison were physiological saline solution, gelatin solution, human albumin solution, and rat plasma. The following results have been obtained:

1. The degree of permanent reduction of the increased amino nitrogen and, especially, of the undetermined nitrogen levels of plasma provides a useful criterion of the efficacy of the treatment, whereas the reduction of the urea nitrogen is too slow and too irregular to be of use for this purpose.

2. The rates of urinary water and nitrogen excretion do not furnish a reliable index of curative efficacy. Complete failure of promoting the flow of urine proves, however, inefficiency of the treatment.

3. The effectiveness of fluid replacement therapy in permanently reducing the elevated undetermined nitrogen levels is not clearly related to the relief of hemoconcentration. It is suggested that a renewed rise of the undetermined plasma ni-

trogen levels in spite of nearly normal hematocrit values is an indication of a returning tissue anoxia due to a diminution of the actively circulating rather than of the total blood volume.

THE INFLUENCE OF DENITROGENATION ON THE RESPONSE OF ANESTHETIZED DOGS TO INTRAVENOUSLY INJECTED OXYGEN

By RAYMOND E. WESTON and LEONARD KAREL

(*From the Toxicology Section, Medical Division, Edgewood Arsenal, Md.*)

(Received for publication November 8, 1946)

INTRODUCTION

A marked clinical improvement in critically ill human subjects after the intravenous administration of oxygen has been reported by a number of investigators (1 to 5) despite the fact that only about 1.5 to 10 per cent of the calculated basal oxygen requirement was injected. However, in normal and in anoxemic experimental animals, other workers (6 to 10) have observed not only rapid, shallow breathing but also decreased rather than increased oxygen content of the arterial blood following the intravenous injection of oxygen at rates of 0.21 to 2.3 ml. per kgm. per minute. The paradoxical anoxemia has been attributed to interference with the pulmonic oxygenation of the blood by the formation of multiple oxygen emboli in the pulmonary capillaries (7). The accompanying respiratory changes, which are abolished by bilateral vagotomy, have been considered (10) as similar to the tachypnea observed in dogs after the production of pulmonary capillary emboli by the intravenous injection of starch granules (11).

Recently, in seeking a simple and effective means of extra-pulmonic oxygenation for supportive treatment in severe, acute pulmonary edema, we became interested in the possibilities of intravenous oxygen administration, and particularly in the cause and prevention of the hypothesized emboli resulting from this procedure. From theoretical considerations, it became apparent that, since the nitrogen tension of the blood and tissues normally is high (573 mm.), gaseous nitrogen present in the blood must enter intravenously injected oxygen bubbles, as in a tonometer. Consequently, if all the oxygen injected were absorbed by the reduced venous hemoglobin before the blood reached the right heart, residual nitrogen bubbles would remain to obstruct the pulmonary capillaries. In recent years, the analogous role of dissolved nitrogen in the bubble formation of decompression sickness and aero-embolism has been demonstrated and the value of prophylactic denitrogenation by inhalation of 99.6 per cent oxygen has been well established (12 to 18). To explore the interrelationship between nitrogen tension and intravascular bubble formation and the anoxemia following intravenously administered oxygen, in the present experiments, comparisons were made between the effects of oxygen administered intravenously to anesthetized dogs without prior denitrogenation and after the nitrogen saturation of the blood and tissues was reduced by continuous intratracheal exposure to 99.6 per cent oxygen before and during the intravenous administration of oxygen.

EXPERIMENTAL

Twenty-six healthy, normal, adult, mongrel dogs weighing from 7.7 to 34.1 kgm. were anesthetized by the intravenous injection of approximately 25 mgm. of sodium pentobarbital per kgm. body weight. A glass, L-shaped cannula was inserted into the exposed trachea and tied in place with heavy, silk ligatures. The femoral artery and vein were exposed bilaterally for blood sampling and for intravenous oxygen administration. The state of anesthesia was maintained by additional pentobarbital injections as required.

Denitrogenation was accomplished by continuous administration for 3 to 4 hours of dry 99.6 per cent commercial oxygen, or occasionally 95 per cent oxygen-5 per cent carbon dioxide, supplied to the animals on demand at low pressures and without re-breathing by means of an Army Air Force, low resistance, A-16 valve, attached to the tracheal cannula by rubber connections as described previously (19). In 3 experiments with very large dogs, the reducing valve leading to the demand valve offered too much resistance at peak inspiratory flows. Therefore, oxygen was supplied from a Douglas-Haldane bag, with the oxygen removed being continuously replaced from a tank connected to the bag.

The intravenously administered oxygen was bubbled through water and, then, continuously injected into the femoral veins through two ½-inch, 27-gauge needles. The rate of the injection was measured by a calibrated, capillary orifice flowmeter interposed between the water bottle and the rubber tube leading to the needles. Respiratory rates were observed before, during, and after

intravenous oxygen administration. Additional details of experimental procedure are given below.

By direct femoral arterial or venous puncture, blood samples were collected in heparinized, air-free syringes, which were immediately sealed with mercury, and stored at 0° C. Determinations of nitrogen content and oxygen content and capacity were performed in duplicate generally by the Edwards-Roughton-Scholander techniques (20, 21). Occasionally, additional checks were made by the usual Van Slyke manometric method (22). In some experiments, nitrogen contents were determined by a shorter manometric method recently described by Horvath and Roughton (23).

In an effort to avoid the pulmonary passive congestion and edema which Drinker (24) has observed in anesthetized dogs after prolonged immobilization, the animals, which were restrained in a supine position when blood samples were drawn or intravenous oxygen was administered, were moved frequently during the experiment. Despite this precaution, however, on autopsy many exhibited some congestion.

Until the day of the experiment, diets consisting of fox chow, milk, horse meat, and water *ad libitum* were permitted.

RESULTS

1. *The effect of intravenous oxygen administration on the arterial oxygen content of denitrogenated dogs*

An initial series of experiments confirmed the observations of others (6 to 10) that oxygen administered intravenously to anesthetized dogs at rates as low as 1 ml. per kgm. per minute (12 to 30 per cent of the basal oxygen requirement) rapidly produced marked increases in respiratory rates and, often, greater than 25 per cent decreases

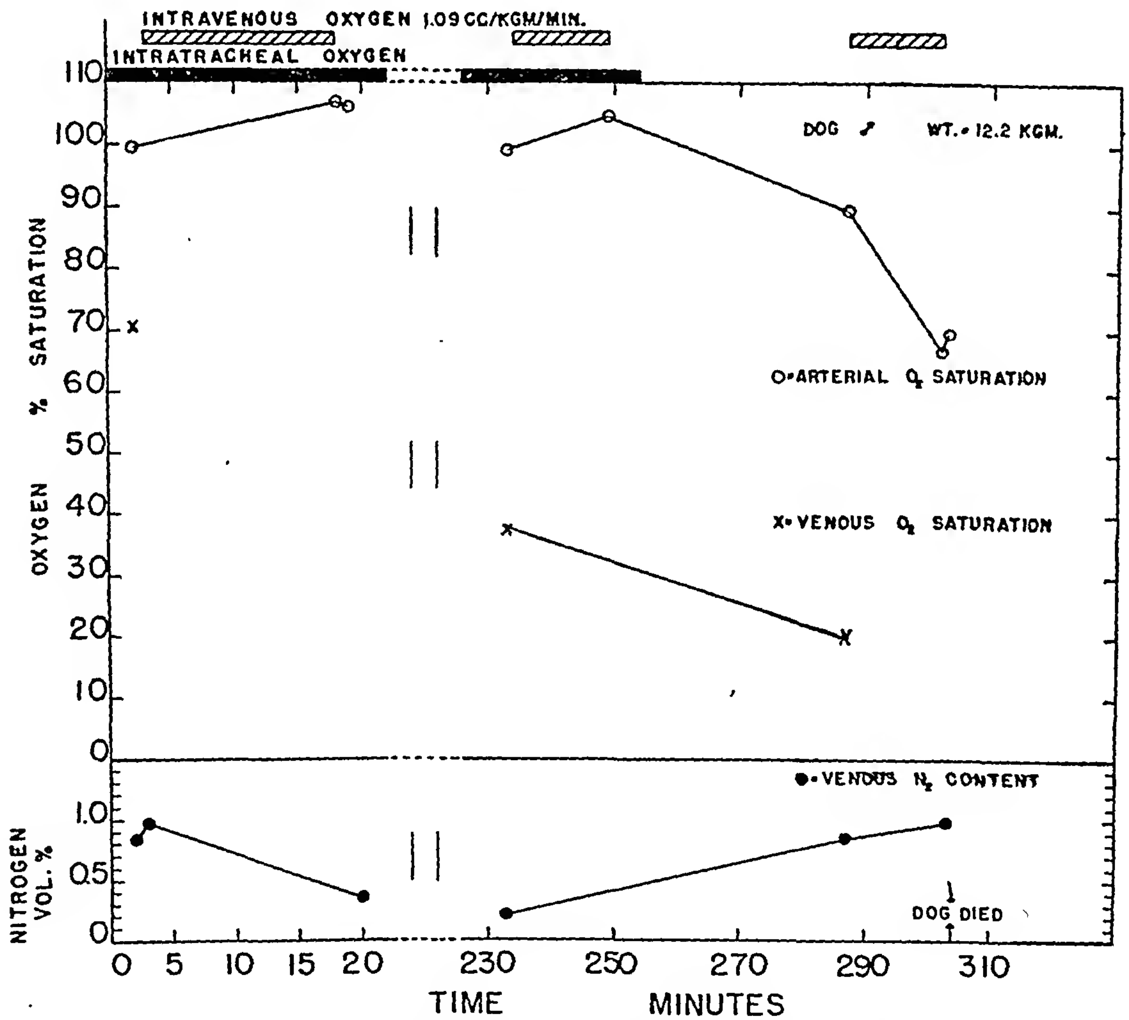

FIG. 1. ARTERIAL OXYGEN SATURATION AND VENOUS NITROGEN CONTENT IN A 12.2 KGM. ANESTHETIZED DOG BEFORE AND AFTER INTRAVENOUS INJECTION OF OXYGEN DURING AND FOLLOWING DENITROGENATION BY CONTINUOUS INTRATRACHEAL ADMINISTRATION OF 99.6 PER CENT OXYGEN

Intravenous oxygen was injected at a rate corresponding to 21.9 per cent of the calculated basal requirement.

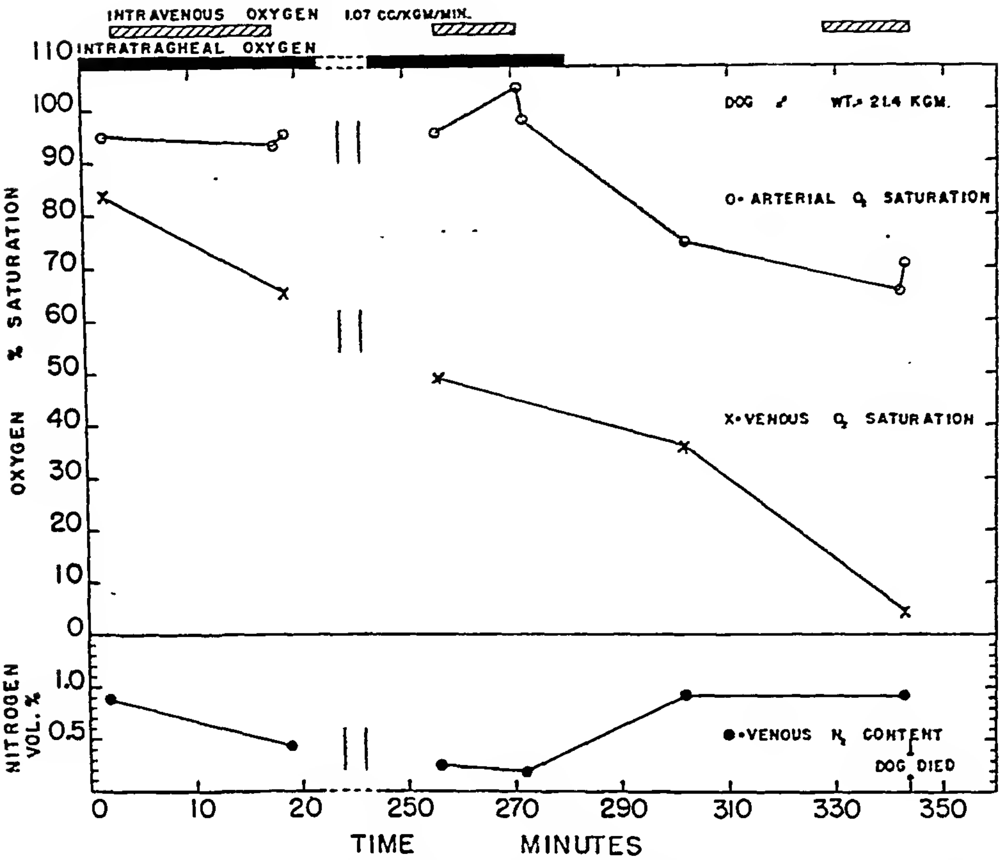

Fig. 2. Arterial Oxygen Saturation and Venous Nitrogen Content in a 21.4 Kgm. Anesthetized Dog Before and After Intravenous Injection of Oxygen During and Following Denitrogenation by Continuous Intratracheal Administration of 99.6 Per Cent Oxygen

Intravenous oxygen was injected at a rate corresponding to 24.3 per cent of the calculated basal requirement.

in arterial oxygen content. A second series of experiments revealed that intravenously injecting 1 ml. of oxygen per kgm. per minute for 20-minute periods in tracheotomized, anesthetized dogs which had been denitrogenated for from 3 to 4 hours, as described above, by exposure to 99.6 per cent oxygen usually produced falls in arterial oxygen content, frequently of the magnitude of 5 volumes per cent, although occasionally there occurred slight increases. Table I gives the pertinent data for 4 representative experiments in which venous nitrogen content was reduced to 0.18 to 0.27 volumes per cent before oxygen (12.5 to 33.1 per cent of the basal requirement) was administered intravenously.

TABLE I

Pertinent data indicating changes in arterial oxygen content following the intravenous injection of oxygen for 20 minutes in tracheotomized, anesthetized dogs, denitrogenated by continuous exposure to 99.6 per cent oxygen for 3 to 4 hours

Dog no.	O_2 Injected Expressed as per cent of basal requirement	Venous N_2 content at time of injection of O_2	Arterial O_2 content: Before injection of O_2	Arterial O_2 content: After injection of O_2
	per cent	*volume per cent*		
1	12.5	0.19	19.6	15.0
2	16.9		19.9	20.8
	17.3		17.5	18.4
3	22.0	0.18	19.6	18.0
4	33.1	0.27	21.0	16.0

2. *Effect of intravenous oxygen on the arterial oxygen saturation in dogs before and after denitrogenation by exposure to 99.6 per cent oxygen*

Binger, Brow, and Branch (11) found that inhalation of 90 per cent oxygen abolished the anoxemia observed in dogs after the production of

multiple pulmonary capillary emboli by intravenous injection of starch suspensions. Therefore, the less marked fall in arterial oxygen content of the denitrogenated dogs following the injection of intravenous oxygen may have resulted not from the prophylactic denitrogenation but from therapeutic effects of the 99.6 per cent oxygen by means of which denitrogenation was achieved and maintained. Consequently, the following experiments were performed to determine whether the simultaneous administration of 99.6 per cent oxygen intratracheally without "complete" denitrogenation would also prevent the development of the anoxemia.

Figures 1 to 4 graphically illustrate 4 representative experiments in which intravenous oxygen was administered at rates of 1.03 to 1.09 ml. per kgm. per minute to anesthetized dogs for three 15-minute periods as follows: (*1*) two minutes after the start of the intratracheal exposure to 99.6 per cent oxygen and, therefore, presumably before denitrogenation was complete; (*2*) after 4 hours of intratracheal oxygenation to achieve marked denitrogenation; and (*3*) if the animal survived the 2 earlier injections, approximately 30 to 60 minutes after discontinuing the intratracheal oxygen to permit the animals to become renitrogenated by breathing air.

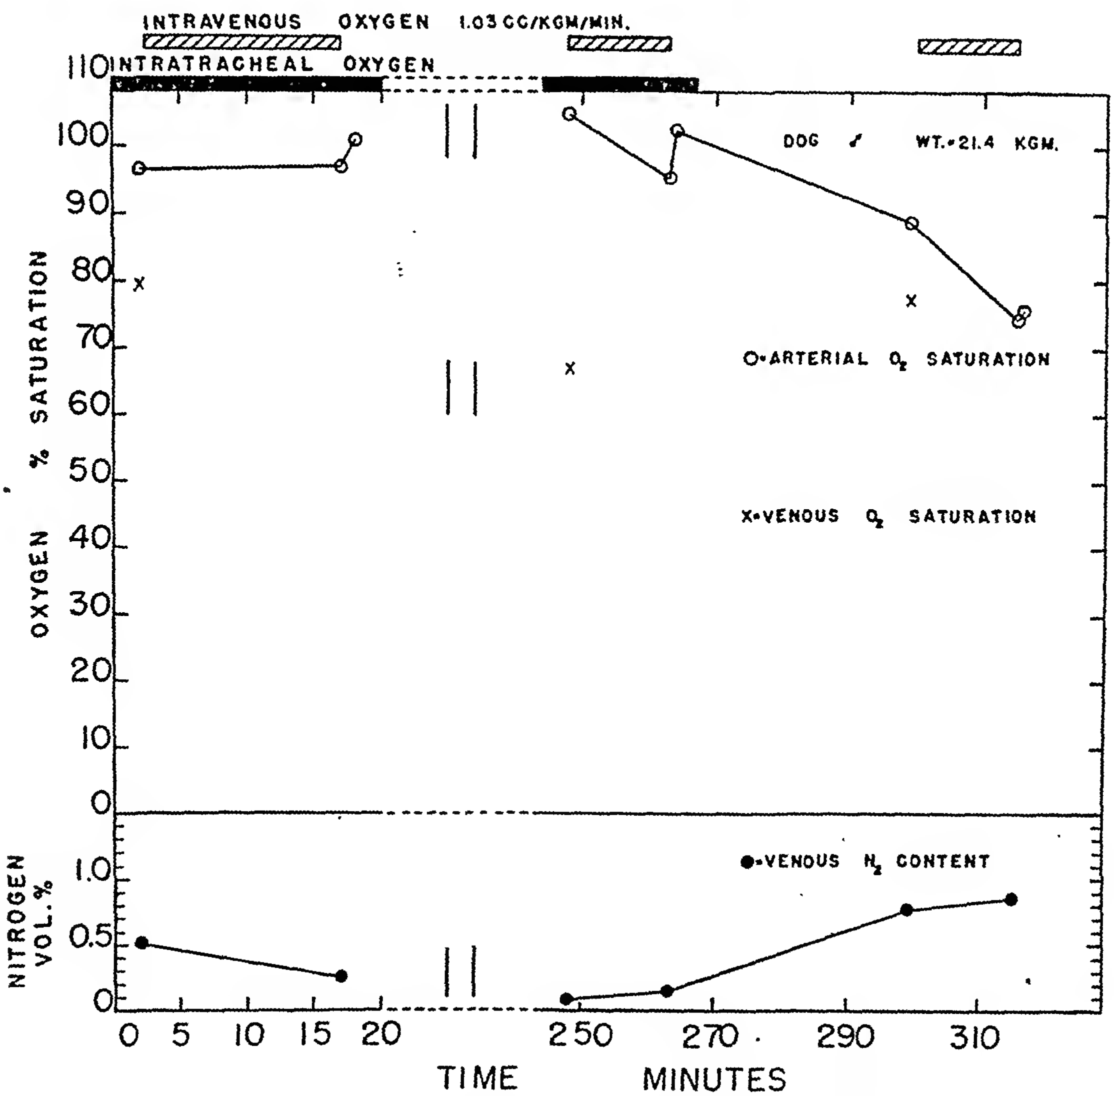

Fig. 3. Arterial Oxygen Saturation and Venous Nitrogen Content in a 21.4 Kgm. Anesthetized Dog Before and After Intravenous Injection of Oxygen During and Following Denitrogenation by Continuous Intratracheal Administration of 99.6 Per Cent Oxygen

Intravenous oxygen was injected at a rate coresponding to 23.4 per cent of the calculated basal requirement.

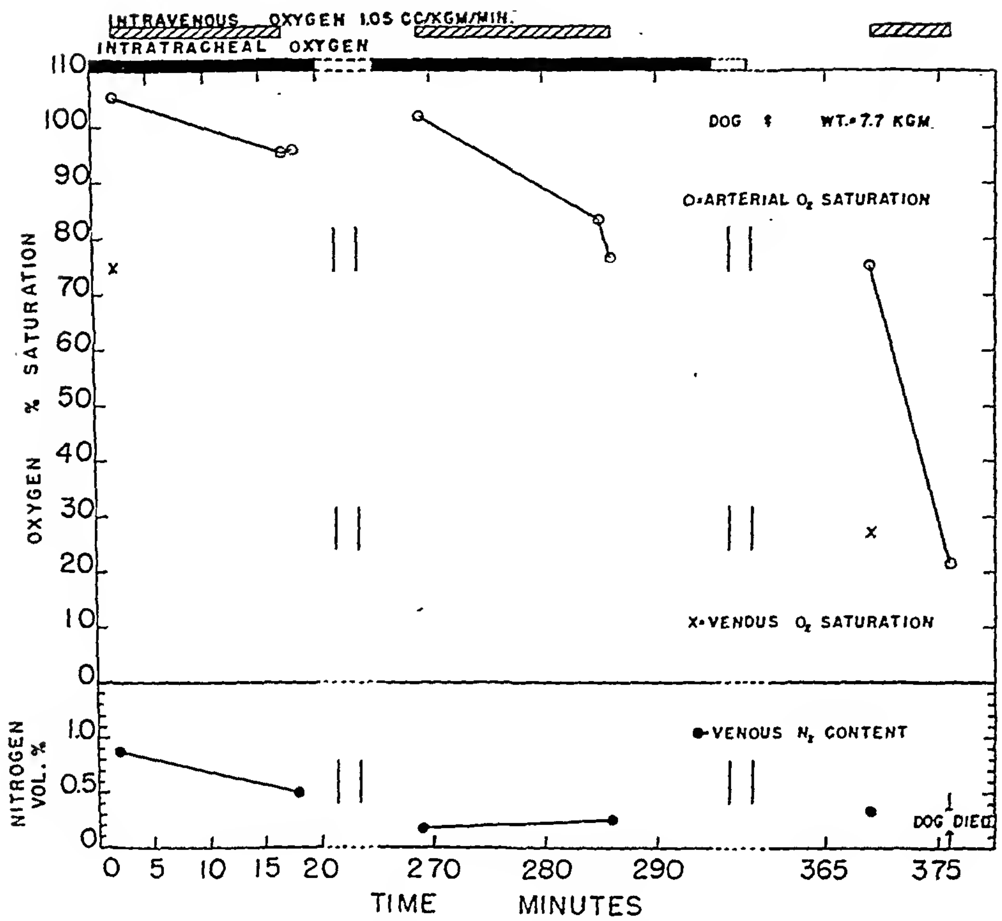

FIG. 4. ARTERIAL OXYGEN SATURATION AND VENOUS NITROGEN CONTENT IN A 7.7 KGM. ANESTHETIZED DOG BEFORE AND AFTER INTRAVENOUS INJECTION OF OXYGEN DURING AND FOLLOWING DENITROGENATION BY CONTINUOUS INTRATRACHEAL ADMINISTRATION OF 99.6 PER CENT OXYGEN

Intravenous oxygen was injected at a rate corresponding to 15.2 per cent of the calculated basal requirement.

In 2 of the animals (Figures 1, 3) administration of intravenous oxygen 2 minutes after the start of intratracheal oxygen resulted in increases in oxygen saturation of the arterial blood. However, in both of these animals, the venous nitrogen content by the end of the 15-minute injection period had fallen to values of 0.36 volume per cent and 0.26 volume per cent respectively. During the first period of intravenous oxygenation in the other 2 animals, there was a fall in the arterial oxygen saturation, and the decrease in venous nitrogen content was not so marked; *i.e.*, it fell from 0.89 and 0.87 volume per cent to 0.43 and 0.50 volume per cent, respectively (*cf.* Figures 2 and 4). Similarly, when the intravenous oxygen injections were repeated after more complete denitrogenation, in 2 of the 4 animals, there was a rise (Figures 1, 2), whereas in the other 2 there was a fall (Figures 3, 4) in arterial oxygen saturation although the nitrogen contents of the venous blood at the start of the injection periods were 0.21, 0.23, 0.09, and 0.15 volume per cent, respectively. Thus, in these experiments, there was no direct relationship between the nitrogen content of the venous blood and the response to intravenous oxygenation. However, the final intravenous injections of oxygen at the same rate, when the dogs were more completely nitrogenated and were breathing not oxygen but air, produced rapid, marked drops in arterial oxygen saturation in 3 of the animals and

a moderate drop in the fourth, with death in 3 occurring within a few minutes after the cessation of the injection (Figures 1 to 4). In all instances, the injection of oxygen resulted in a sharp rise in respiratory rate, the increases being, respectively, from 24 to 120, 40 to 70, 19 to 116, and 26 to 60. It will be noted that the least renitrogenation and greatest fall in arterial oxygen saturation occurred in the dog represented by Figure 4. This animal, at autopsy, showed appreciable congestion of the lungs.

3. *Effect of intravenously injected air on oxygen saturation in dogs*

There was no significant difference in the response to intravenous oxygen of dogs when either more completely denitrogenated or only partially denitrogenated by exposure to intratracheal oxygen for 2 minutes before and during the 15-minute period of injection. As a result, it was not clear whether the lesser drop or slight rise in arterial oxygen saturation following intravenous oxygen injection in both the partially and more completely

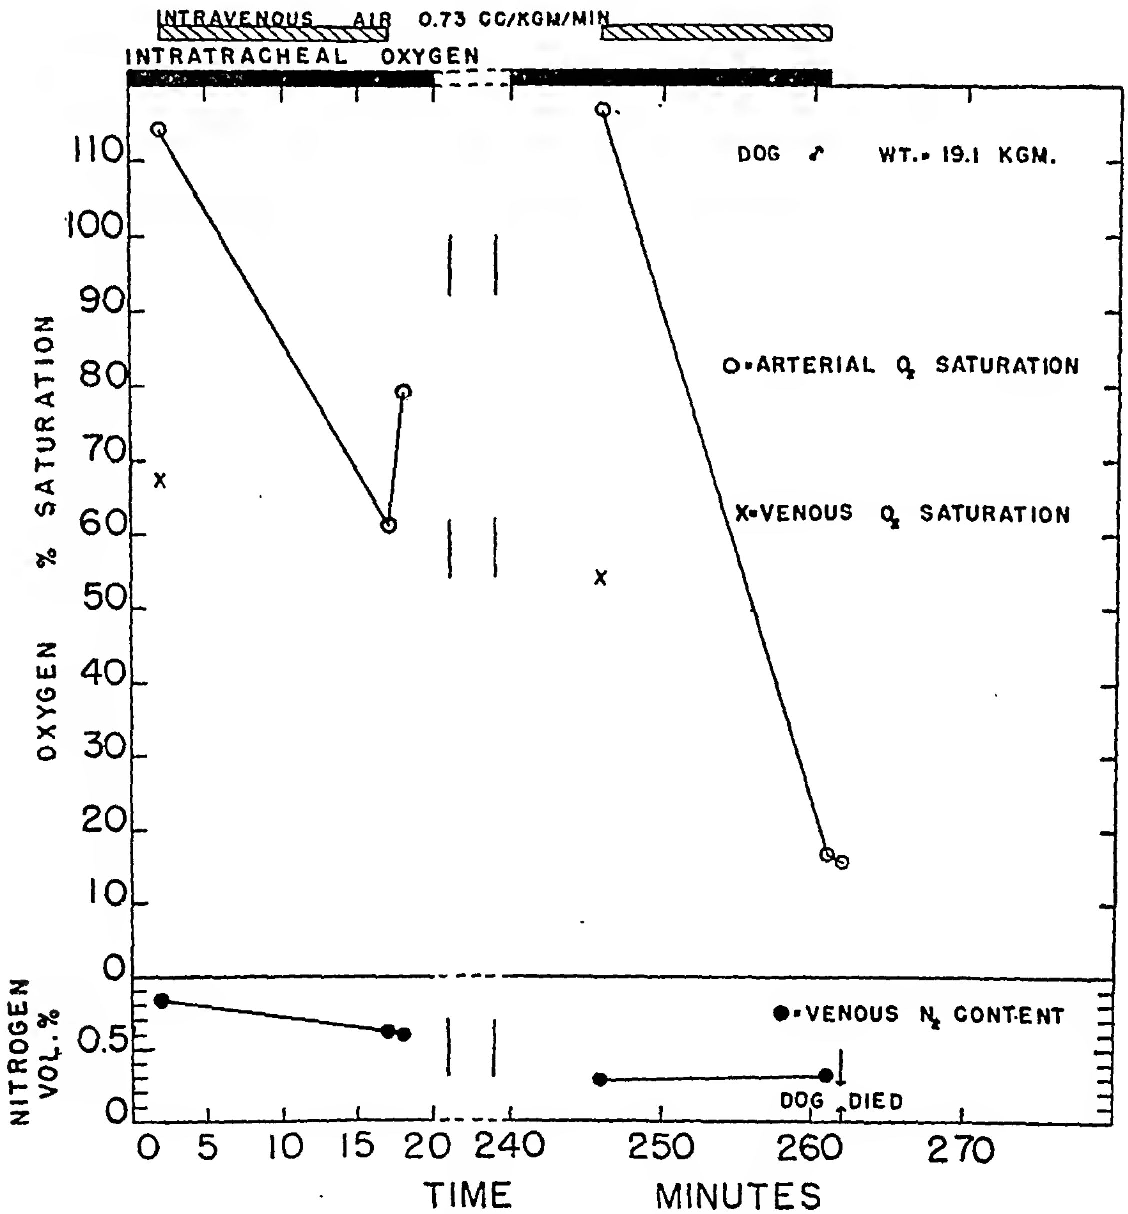

Fig. 5. Arterial Oxygen Saturation and Venous Nitrogen Content in a 19.1 Kgm. Anesthetized Dog Before and After the Intravenous Injection of Air During and Following Denitrogenation by Continuous Intratracheal Administration of 99.6 Per Cent Oxygen

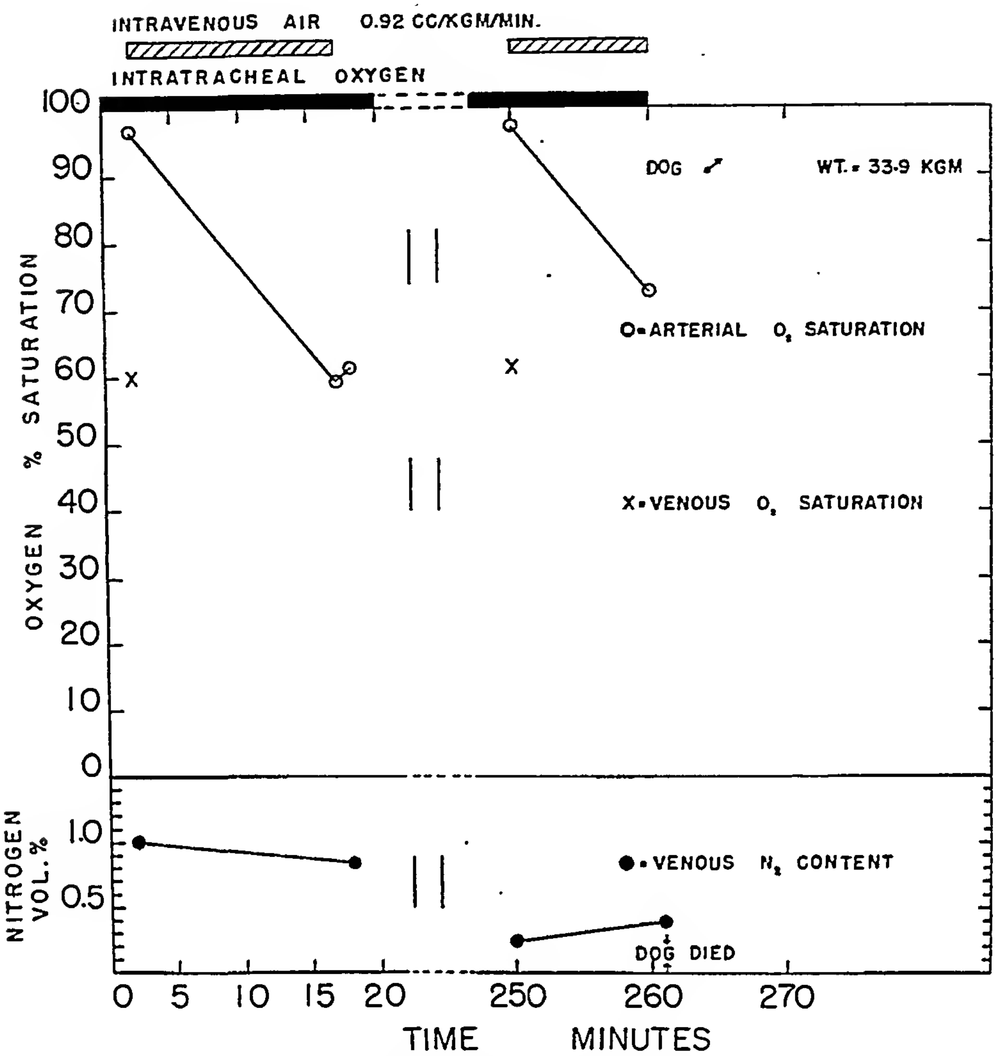

FIG. 6. ARTERIAL OXYGEN SATURATION AND VENOUS NITROGEN CONTENT IN A 33.9 KGM. ANESTHETIZED DOG BEFORE AND AFTER THE INTRAVENOUS INJECTION OF AIR DURING AND FOLLOWING DENITROGENATION BY CONTINUOUS INTRATRACHEAL ADMINISTRATION OF 99.6 PER CENT OXYGEN

denitrogenated dogs was a consequence of the beneficial effects of the prophylactic denitrogenation or of hyperventilation in the presence of the high intratracheal oxygen concentration. If the less severe reactions to intravenous oxygen resulted merely from hyperventilation due to bubble formation in the pulmonary capillaries of animals which were breathing high concentrations of oxygen, similar results should be obtained if the hyperventilation were produced by injection of an inert gas—even nitrogen itself—at comparable rates. Therefore, the previous experiment was repeated in a series of dogs in which air rather than oxygen was injected intravenously.

Figures 5 to 7 illustrate typical experiments in which air was injected intravenously at rates of 0.73, 0.92, and 1.16 ml. per kgm. per minute, respectively. In contrast to the injection of oxygen, the intravenous injection of air during simultaneous administration of intratracheal oxygen produced a rapid and extensive fall in arterial oxygen saturation both before and after considerable lowering of venous nitrogen content had been achieved, despite the marked hyperventilation which oc-

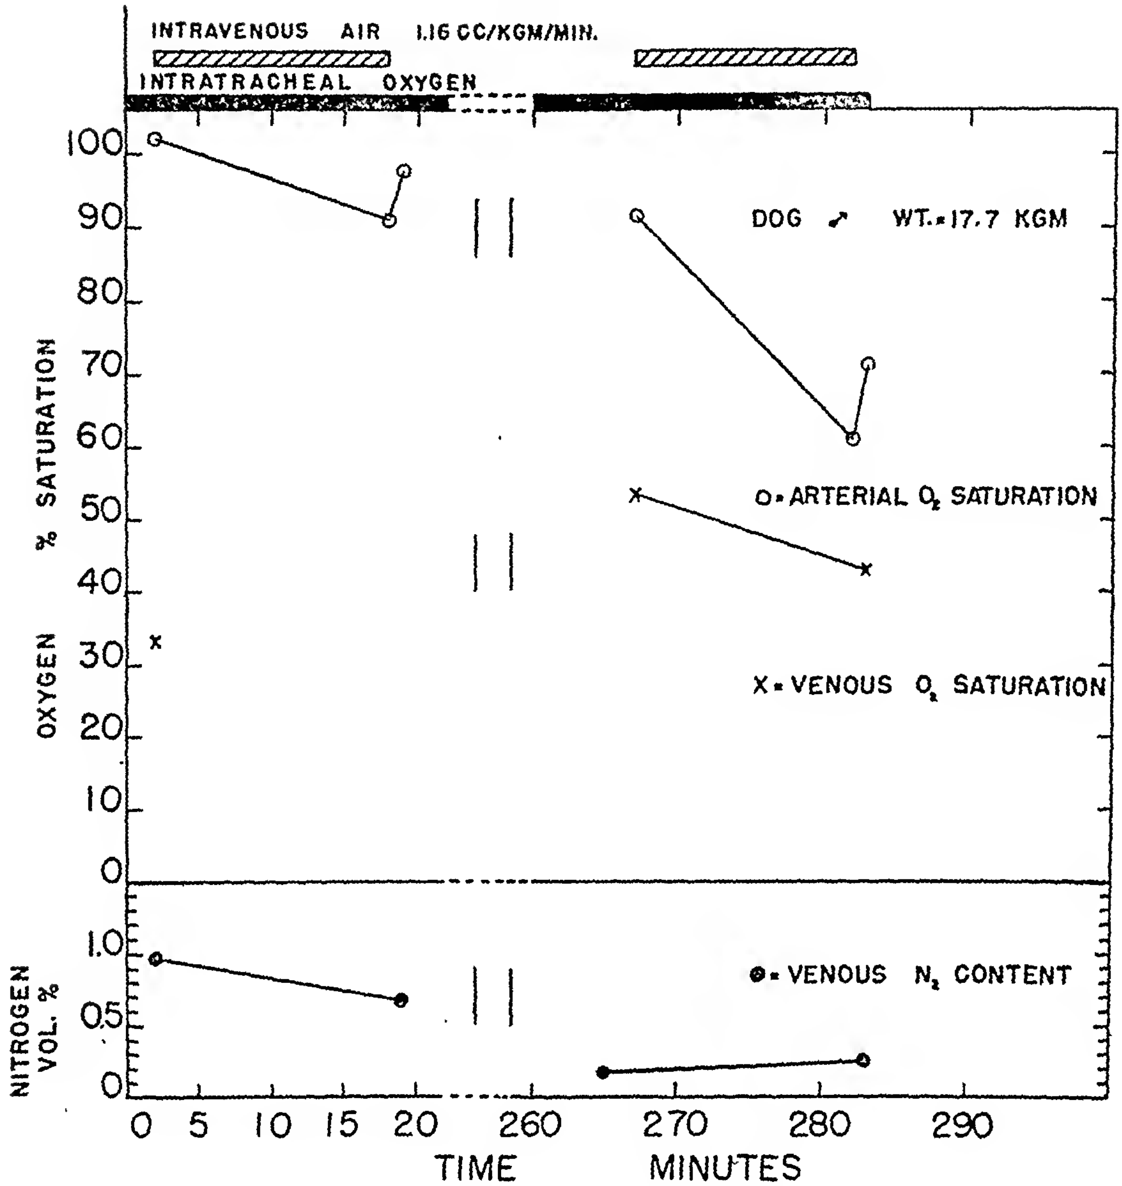

FIG. 7. ARTERIAL OXYGEN SATURATION AND VENOUS NITROGEN CONTENT IN A 17.7 KGM. ANESTHETIZED DOG BEFORE AND AFTER THE INTRAVENOUS INJECTION OF AIR DURING AND FOLLOWING DENITROGENATION BY CONTINUOUS INTRATRACHEAL ADMINISTRATION OF 99.6 PER CENT OXYGEN

curred. In no experiment could the third injection without intratracheal oxygen be made, since the animals all died after the second injection, although in some (*cf.* Figures 5, 6) the intravenous air was injected at a much slower rate than was the intravenous oxygen.

4. *The effect of injecting intravenous oxygen at very slow rates in normal anesthetized dogs without previous denitrogenation*

Inasmuch as there have been reports of marked clinical improvement in anoxemic human subjects who received prolonged intravenous injections of very small amounts of oxygen (1 to 5), arterial and venous oxygen saturations were followed in pentobarbitalized dogs during the intravenous administration of oxygen at comparable rates for periods up to 3 hours. Because of the briefer duration of these experiments, reinforcing doses of pentobarbital were not required to maintain the anesthesia. In Figure 8, 3 such experiments are graphically presented.

In all 3 animals, although the venous oxygen saturation was only 44 per cent to 73 per cent at the start of the experiment, as would be expected in deeply barbitalized animals breathing air, the

intravenous injection of oxygen at rates of 0.082 (A) to 0.345 ml. per kgm. per minute (B) resulted in continued fall of both arterial and venous oxygen saturation. In one experiment (Figure 8, B), the animal died after 150 minutes although the oxygen administered intravenously was only 7.4 per cent of the basal requirement.

The decline in oxygen saturation in all 3 animals and the death of the 1 animal must have been related to the intravenously administered oxygen for the following reasons: (*1*) generally, in pentobarbitalized animals, the blood oxygen saturation does not decrease but increases after several hours as the anesthesia tends to lighten, (*2*) the only other experimental procedure to which these large dogs were subjected was the withdrawal of a total of 30 to 50 ml. of blood over a period of about 180 minutes, and (*3*) at autopsy, no other significant contributory pulmonary pathology was found.

The results of these studies are graphically illustrated in Table II.

TABLE II

Tabular summary of the representative general effects of intravenously administered oxygen and air on the respiration and arterial oxygen saturation of denitrogenated and non-denitrogenated, anoxemic dogs

Substance administered	Denitrogenated dogs			Non-denitrogenated anoxemic dogs		
	Per cent of basal requirement	Respiratory rate	Arterial O_2 saturation	Per cent of basal requirement	Respiratory rate	Arterial O_2 saturation
i.v. O_2	15.2 to 33.1	+	−	1.9 to 7.4	++	−−
i.v. Air	−	+++	−−−	−	+++	−−−

+ = increase.
− = decrease.

DISCUSSION

The better response of dogs to the intravenous injection of oxygen at rates of approximately 1 ml. per kgm. per minute when intratracheal oxygen is administered simultaneously probably is not due solely to the beneficial effects of the inhaled oxygen. It should be recalled that when air was injected intravenously at equivalent or slower rates in dogs which were breathing 99.6 per cent oxygen after more or less denitrogenation, the fall in arterial oxygen saturation was as marked and rapid as that observed in animals given intravenous oxygen while breathing air (Figures 5 to 7, 8). This indicates that the therapeutic effect of

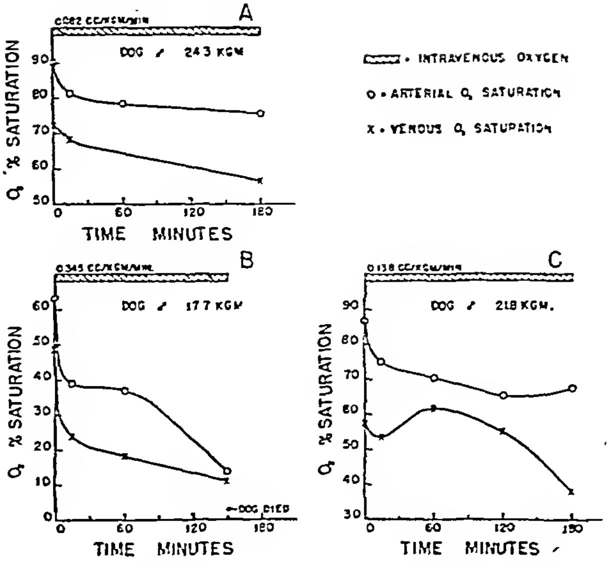

Fig. 8. Arterial and Venous Oxygen Saturation of Anesthetized, Tracheotomized Dogs Breathing Air During the Continuous Intravenous Injection of Oxygen at Rates Which Corresponded to the Following Percentages of the Calculated Basal Requirement: 1.9 Per Cent in A, 7.4 Per Cent in B, and 3.2 Per Cent in C

99.6 per cent intratracheal oxygen alone is insufficient to effect the anoxemia produced by the hypothesized pulmonary emboli. Consequently, some other factor must be involved.

As noted above, Binger, Brow, and Branch (11) found that the administration of 90 per cent oxygen could abolish the anoxemia following production of multiple pulmonary capillary emboli by the intravenous injection of starch granules in dogs. Consequently, because the anoxemia following air injections was not compensated by the simultaneous administration of 99.6 per cent oxygen it could be argued that the air injections do not constitute an adequate control and that the 2 types of experiments reported in the present study differ only in that perhaps more absorption occurred from the oxygen bubbles than from the air bubbles, leaving smaller bubbles in the former case, producing a less severe anoxemia which could be better compensated by the inhaled 99.6 per cent oxygen.

However, because of the demonstrated role of dissolved gaseous nitrogen in the genesis and perpetuation of bubbles in the blood and tissues in decompression sickness and aero-embolism, it is probable that in fully nitrogenated animals, dis-

solved nitrogen similarly enters the injected oxygen bubbles in accordance with Henry's law and that the less severe reaction to this procedure when intratracheal oxygen is simultaneously administered is a consequence of the denitrogenation achieved by the oxygen inhalations. In the denitrogenated dogs, on the other hand, as a result of the lower nitrogen tension, particularly of the blood, probably less nitrogen enters the injected oxygen bubbles which, therefore, may become smaller in size if oxygen is taken up by the reduced hemoglobin in the venous blood. In this regard, it is interesting to note that the initial and final increase in respiratory rate during intravenous oxygen injections in dogs simultaneously inhaling 99.6 per cent oxygen was markedly less than that observed during either intravenous oxygen injections in dogs breathing air or during air injections in dogs breathing 99.6 per cent oxygen, indicating that the oxygen bubbles in the denitrogenated animals possibly were of smaller size or less persistent than in the other animals.

The prolonged injections of intravenous oxygen at very slow rates in anesthetized dogs without denitrogenation reported in the present communication establish further the physiological hazard of this procedure. Despite the slow rate of injection and the initial post-barbiturate anoxemia, arterial and venous oxygen saturation continued to fall or to remain low throughout the injection period, with death occurring in 1 animal before the 180-minute injection period was completed.

Moreover, several incidental experimental observations demonstrate that even with denitrogenation and simultaneous intratracheal oxygen, intravenous oxygen constitutes an added hazard rather than a therapeutic aid in the anoxemic state. In experiments with 3 very large dogs and a smaller reducing valve leading from the oxygen tank to the demand valve, the resistance to respiration was markedly increased at peak inspiratory flows. Consequently, these animals while being denitrogenated by oxygen inhalation became progressively more anoxemic because of the inspiratory resistance which produced an inadequate respiratory flow and, ultimately, pulmonary congestion and pulmonary edema. In one animal, for example, arterial oxygen saturation was 63.5 per cent, venous oxygen saturation was 30.9 per cent, and venous nitrogen content was 0.23 per cent, when the injection of intravenous oxygen at a rate of 1 ml. per kgm. per minute (23.2 per cent of basal oxygen requirement) was begun. Within 14 minutes, respiration had stopped, and at 15 minutes no cardiac sounds were audible. Similar observations made on the 2 other animals indicate, in addition, that the failure of intravenous oxygen administration in the remaining denitrogenated dogs was not necessarily a consequence of any elevation in oxygen saturation of the venous blood, which might result from simultaneous inhalation of 99.6 per cent oxygen.

These experiments establish the practical therapeutic inadequacy of intravenous oxygen administration, even when the effect of gaseous nitrogen in the blood and tissues is minimized by prophylactic denitrogenation. Other considerations also make it evident that until some means of preventing bubble formation is developed, introduction of significant amounts of oxygen by injection into the venous blood will not be successful. For example, if oxygen is injected into peripheral vessels, the amount which can be absorbed rapidly before coalescence of bubbles occurs is limited immediately to that which will saturate fully the venous return from the areas drained. Because the peripheral blood flow is small in comparison with the total cardiac output, Goodwin *et al.* (25) attempted to inject oxygen into the inferior vena cava through a special catheter which produces small bubbles, but had no particular success in preventing the development of the usual signs and symptoms of pulmonary capillary embolization.

Moreover, as Adriani has noted recently (26), intravenously injected oxygen, like air, produces bubbles which are surrounded by a thin protein film through which neither nitrogen nor oxygen can penetrate too readily. Adriani explains the persistence of the emboli by quoting Langmuir (27) who suggested that the films are persistent and resistant, because the protein is denatured. Thus, any oxygen bubble introduced in the circulation will be only slowly absorbed even in markedly unsaturated blood. Therefore, successful extrapulmonic oxygenation probably will require not intravenous injection but some other technique for introducing oxygen into the blood without bubble formation.

Cessation of the intravenous injection of oxygen was followed within 1 minute in a number of instances by a sudden and variable, but non-persistent, rise in the arterial oxygen saturation. A similar phenomenon was observed and is more fully commented upon by Goodwin *et al.* (25).

Because of the observations made by a number of workers regarding oxygen depression, following the inhalation of pure oxygen during anoxemia resulting from deep barbiturate anesthesia, and central nervous system depression (28), the objection may be raised that the intravenous administration of oxygen to anoxemic dogs under pentobarbital anesthesia can depress or completely check respiration. It should be pointed out that although oxygen depression is readily obtained in the intact pentobarbitalized dog, it is accompanied by an almost immediate precipitous fall in respiratory rate and depth, which may happen even after only 1 breath of pure oxygen. In the series of experiments currently being reported, however, the intravenous injection of oxygen to the anoxemic dogs produced not a decrease, but an increase in respiratory rate, suggesting that the stimulus of anoxemia to the carotid and aortic bodies had not been removed.

SUMMARY

1. The observations of others that oxygen administered intravenously to dogs at rates as low as 1 ml. per kgm. per minute rapidly produced marked increases in respiratory rates and often greater than 25 per cent decreases in arterial oxygen content were confirmed.

2. Prior to the administration of intravenous oxygen, animals were denitrogenated in order to reduce the incidence of intravascular bubble formation.

3. In tracheotomized, anesthetized dogs denitrogenated by exposure to 99.6 per cent oxygen for 3 to 4 hours, the intravenous injection of oxygen at a rate of 1 ml. per kgm. per minute for 20-minute periods usually produced falls in arterial oxygen content, frequently of the magnitude of 5 volumes per cent, although occasionally there occurred slight increases.

4. In dogs which were first denitrogenated and then renitrogenated by breathing air, the intravenous administration of oxygen at rates the same as those previously used produced a rapid, significant drop in arterial oxygen saturation in most instances, and, in some cases, death.

5. In contrast to the results obtained on injection of oxygen during the simultaneous administration of intratracheal 99.6 per cent oxygen, the intravenous injection of air under similar conditions produced a rapid, extensive fall in arterial oxygen saturation both before and after considerable lowering of venous nitrogen content had been achieved, despite the marked hyperventilation which occurred.

6. The intravenous injection of oxygen for 180 minutes at very slow rates (0.082 to 0.345 ml. per kgm. per minute) in deeply anesthetized and anoxemic dogs breathing air also resulted in a continued fall of the arterial and venous oxygen saturation, although the amount of oxygen administered represented merely 1.9 to 7.4 per cent of the basal requirement.

7. It is suggested that because of the physiological and physical factors involved in bubble formation, successful extra-pulmonic oxygenation will require some technique by which oxygen can be introduced into the blood without the formation of bubbles.

8. Even with denitrogenation and simultaneous intratracheal oxygen, intravenous oxygen constitutes an added hazard rather than a therapeutic aid in the anoxemic state.

THE CONJUGATED, NON-PROTEIN, AMINO ACIDS OF PLASMA. IV. A DIFFERENCE IN THE UTILIZATION OF THE PEPTIDES OF HYDROLYSATES OF FIBRIN AND CASEIN

By HALVOR N. CHRISTENSEN, ELEANOR L. LYNCH, DAVID G. DECKER, AND JOHN H. POWERS

(*From The Mary Imogene Bassett Hospital, Cooperstown, N. Y.*)

(Received for publication January 9, 1947)

Peptides are utilized much less readily than free amino acids upon the intravenous infusion of a partial enzymatic hydrolysate of casein (Amigen), as indicated by the greater accumulation and longer persistence of peptides in plasma, and their loss to the extent of 36 to 53 per cent into the urine (1). However, a partial acid hydrolysate of fibrin twice as rich in peptides as Amigen (containing about ⅔ of its amino acids in a conjugated state) has been found to have a high biological value upon intravenous administration to dogs, as compared with fibrin given orally (2). These observations suggest a possibility of considerable interest to the subject of peptide metabolism, namely, that the peptides derived from fibrin may be more efficiently utilized than those of the casein hydrolysate. This we have found to be the case.

Five per cent solutions of the fibrin hydrolysate in 5 per cent glucose were infused intravenously into convalescent male patients and into a normal subject, in 3 different quantities—1,000 ml., 878 ml., and 485 ml.,—the latter 2 quantities supplying according to our analysis the same quantity of total α-amino nitrogen and bound α-amino nitrogen respectively, as a liter of 5 per cent Amigen. (The fibrin hydrolysate was not only much richer in peptides because of the limited hydrolysis, but also somewhat richer in total amino acids.).

With the 2 larger portions, containing 2 to 2.3 times the quantity of peptides supplied by a liter of Amigen, dialyzable amino acid conjugates (peptides [1]) reached concentrations in plasma somewhat higher than for Amigen at similar infusion rates (Table I). However, when the quantities of peptides infused were alike, the plasma levels were lower with the fibrin hydrolysate. The highest level of peptide α-amino nitrogen yet observed, 6.3 mgm. per cent, was not associated with discomfort. The infusion of either hydrolysate brought the free α-amino acid nitrogen of plasma to levels lower than were observed before the infusions. The curves picturing the removal of the conjugates from plasma show the same aspects with the 2 hydrolysates (Figure 1). Without regard to the rate or quantity of the infusion, the loss of peptides into the urine was less for the fibrin hydrolysate, 26 to 28 per cent of the peptides infused (Table II). For infusion times of 1.5 to 4 hours, losses of 40 to 53 per cent were characteristic for the peptides of 1 liter of 5 per cent Amigen. In the 2 cases where the conditions were most similar (experiment 52, reported previously [1], and experiment 14), the same quantity of peptides being infused into the same normal subject in very nearly the same time interval, the loss of peptides was 27 per cent for the fibrin hydrolysate and 53 per cent for the Amigen. The losses of *free* α-amino acids were larger during infusion of the fibrin hydrolysate than when Amigen was injected. Undoubtedly a part of the free amino acids in the urine originated from infused peptides of the hydrolysates. The over-all urinary losses of α-amino acids (free + peptide) of both preparations were in the region of 20 per cent.

The additional conjugates of the experimental urines appeared to be peptides. The optical density (at 515 mμ) given with the biuret reaction by the dialysate of experimental urine number 24 bore a relation to that given by the fibrin hydrolysate solution similar to the relation found between the conjugated amino nitrogen concentrations of the 2 solutions. Of the conjugated amino acid nitrogen of normal human urine, ordinarily about half is extracted, after acidification, by ethyl acetate and is probably due largely to acyl amino acids,

[1] The term peptides will be used here for the dialyzable amino acid conjugates, although other nonprotein conjugates besides peptides may be included.

TABLE I

Plasma amino acid changes produced by the infusion of the fibrin hydrolysate

Five per cent solution in 5 per cent glucose, containing per liter 7.2 grams N, 1.98 grams free α-amino N, 3.44 grams bound α-amino N. Experiment 6, patient with duodenal ulcer; experiment 10, patient 3 days after hernioplasty; experiment 24, patient convalescent from diverticulitis, on low residue diet; experiment 14, normal person.

† Extracted from acidified urine by 5 portions of ethyl acetate, 1.5 volumes each extraction.
** Hepatic cirrhosis; infusion in 165 minutes. See text.

mainly hippuric acid (3, 4), rather than peptides. The ethyl acetate-extractable conjugates of urine were increased by the infusion of the fibrin hydrolysate (Table II); the increases, however, represented only 9 per cent of the extra conjugated α-amino nitrogen excreted. About 1.8 per cent of the total α-amino nitrogen could be extracted from the hydrolysate itself under the same conditions. The additional extractable conjugates of the experimental urines may have arisen by preferential excretion of extractable peptides or by acylation of non-extractable peptides or amino acids.

To explore the possibility that impaired liver function might seriously handicap peptide utilization, 730 ml. of the fibrin hydrolysate solution were infused in 165 minutes into a 56-year-old male with

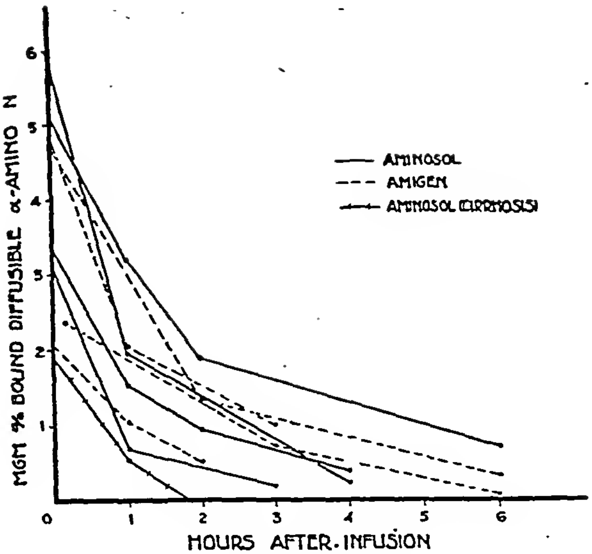

FIG. 1. REMOVAL FROM PLASMA OF THE PEPTIDES INTRODUCED BY THE INFUSION OF INCOMPLETE HYDROLYSATES OF FIBRIN AND CASEIN

The pre-experimental level of conjugated amino acid nitrogen has been deducted in each case. The term "Aminosol" refers to the experimental fibrin hydrolysate.

cirrhosis and ascites.[2] The patient yielded the following laboratory findings: bromsulfalein retention, 48 per cent after 1 hour (dose, 5 mgm. per Kilo); serum alkaline phosphatase, 9.6 King units; icterus index, 14; cephalin flocculation test, ++++; normal urea clearance. The pretest excretion of amino acid nitrogen (free and conjugated) was about a gram per day (Table II). This patient showed the smallest loss observed of the infused free amino acids and peptides (Table II). The rise in the plasma concentration of peptides at the end of the infusion was small, and these peptides were removed relatively quickly (Figure 1).

EXPERIMENTAL

The fibrin hydrolysate solution used was derived from a single lot and was supplied through the kindness of Dr. Douglas V. Frost of Abbott Laboratories. According to Dr. Frost the hydrolysis had been performed by acid at 100° for 6 hours, and the solution contained 7.2 grams of nitrogen per liter. Our analyses for this lot showed 1.98 grams of free α-amino nitrogen and 5.42 grams of total α-amino nitrogen (by acid hydrolysis) per liter, showing 64 per cent of the α-amino nitrogen to be bound. These analyses correspond quite well with those obtained by Frost for other lots.

Experimental details and analytical procedures were as described elsewhere (1).

DISCUSSION

The average sizes of the peptides of the 2 hydrolysates are similar, containing as an average, for Amigen (5), 3.4 and for the fibrin hydrolysate, 4.0 amino acid molecules per peptide molecules.[3] The difference in the availability of the peptides may be a result of differences in the 2 proteins, casein and fibrin, as to what amino acids are adjoining or may be a result of the different modes of hydrolysis, namely, by pancreatic enzymes and by acid. The first view that the difference is inherent in the proteins is supported by 2 conclusions of Frost, *et al.* (2), upon comparing the fibrin hydrolysate with a casein hydrolysate prepared in the same way by acid:

1. The superior biological value of the fibrin hydrolysate was not adequately explained by a higher content of essential amino acids.

2. Methionine in the state in which it is present in the casein hydrolysate appeared to be poorly utilized.

These observations suggest that the peptides of the hydrolysate of casein by acid, like those of the enzymatic hydrolysate, were not well utilized.

SUMMARY

Although our conclusion has been confirmed that peptides are less readily utilized than free amino acids when partial hydrolysates of protein are administered intravenously, the peptides of a fibrin hydrolysate were lost into the urine to a distinctly smaller extent than were the peptides of an enzymatic casein hydrolysate. The total amino acid losses of the 2 hydrolysates were similar. One may conclude that any partial hydrolysate of protein for intravenous nutrition offers the possibility of quantitatively or qualitatively serious losses of bound amino acids.

[2] This infusion was studied through the courtesy of Dr. Francis F. Harrison.

[3] The hydrolysis of fibrin has recently been extended to a degree of completeness similar to that of the casein hydrolysate. The term "Aminosol" is now applied to this preparation. The increased hydrolysis has intensified the difference in peptide utilization, urinary losses of peptides with the new preparation being, in 3 cases, only 16, 18, and 10 per cent—the total losses of amino acids, 8.4, 11, and 5.5 per cent.

Thanks are due to Dr. Scott P. Christensen for assistance.

THE CONJUGATED, NON-PROTEIN, AMINO ACIDS OF PLASMA. V. A STUDY OF THE CLINICAL SIGNIFICANCE OF PEPTIDEMIA

By HALVOR N. CHRISTENSEN, DAVID G. DECKER, ELEANOR L. LYNCH, THAYER M. MACKENZIE, and JOHN H. POWERS

(*From the Mary Imogene Bassett Hospital, Cooperstown, N. Y.*)

(Received for publication March 19, 1947)

Peptidemia is a recurring concept of pathological chemistry which never has been either completely established or disproved. In a literature of about 100 papers only a few studies have been based upon methods which characterized the component measured as *amino acids in conjugated forms*[1]. The reported studies appear to indicate that intermediate protein degradation products frequently enter the blood in disease, so much so as to deprive their determination of diagnostic value.

Schweriner in 1920 (1) reported little if any peptides in mercuric chloride filtrates of normal blood but substantial amounts in neoplastic disease and in some types of liver disease. Blau (2) found elevated peptide nitrogen (1 to 8 mgm. per cent) in the blood in a number of diseases including 9 cases of hypertension. Becher and Herrman (3) found normal levels in carcinoma but high levels in severe renal insufficiency. Martens (4) reported concentrations of 8 to 13 mgm. per cent in severe hepatic and renal disease. Polonovski and Driesens (5) claimed that blood polypeptides were increased by as much as 4 times postoperatively, reaching a maximum 5 or 6 days after surgery. Hannaert and Wodon (6), Kalmykoff (7), Kotschneff (8), London and Kotschneff (9), and Martens (10) have reported evidence to show that ingested proteins were absorbed into the portal circulation partially as peptides and that the peptide content of the blood was modified upon flowing through the liver.

The principal ideas as to the clinical significance of peptidemia may be classified as follows:

1. That peptidemia is characteristic of neoplastic disease.

2. That peptidemia occurs after surgery or trauma or in certain types of shock, presumably because during increased protein catabolism, intermediate protein split-products may be released into the blood stream. This does not necessarily follow. Only slight increases of blood peptides were observed in proteose intoxication (11) and in histamine shock (12) although protein catabolism was strongly accelerated. "Peptide intoxication" as a humoral syndrome occurring after surgery, trauma or burns, proposed by Polonovski and Driessens (5), has been supported by several investigations. Postoperative peptidemia has been suggested as a precipitating factor in intravascular clotting (13).

3. That peptidemia occurs in hepatic disease, presumably because of the loss of a supposed hepatic function of clearing peptides from the blood.

4. That protein degradation products in the blood stream may be toxic and etiological agents in a number of diseases, including:

   (*a*) hypertension (2, 14),
   (*b*) toxemias of pregnancy (15).
   (*c*) intestinal strangulation.

Whipple, Rodenbaugh, and Kilgore (16) concluded that the toxic agent accumulating in closed intestinal loops was a primary heteroproteose. De Negri (17) reported that ligature of the mesentric arteries of dogs gave large increases of blood polypeptides. His analytical method was not specific, however. We have not considered

[1] Certain difficulties in terminology must be considered. The investigations reviewed here, and the present study as well, measured not *peptides* but *amino acid conjugates* which yield free amino acids upon hydrolysis. Although these conjugates usually have been supposed to be peptides, they may include proteins or such substances as hippuric acid. For simplicity we are using the inexact terms "peptides" and "peptide" nitrogen for these conjugates as determined by the procedures described here. Note that the ninhydrin method used by us yields all of the α-amino groups of a typical peptide as "peptide" nitrogen, none as free α-amino nitrogen, although one (the terminal) of these amino groups is not involved in a peptide bond. With the nitrous acid method, on the other hand, a dipeptide, for example, would yield one of its amino groups as free and the other as conjugated.

here the numerous other studies which have attempted to measure peptides by the difference in content of nitrogen (or of substances chromogenic with Folin's phenol reagent) in 2 types of filtrates of blood.

Even among those studies which have employed methods possessing some degree of specificity for conjugated amino acids, highly inconsistent results have been obtained for the normal levels of blood. These results have been tabulated elsewhere (18) together with a brief statement of the methods employed. Three factors have reduced largely the validity of such studies:

1. *Inadequate deproteinizing procedures.* Tungstic acid, picric acid and trichloroacetic acid, especially the latter in low concentration, all leave in solution *non-dialyzable* amino acid conjugates, presumably proteins (19). Dialysis of plasma must be very brief if proteolysis is to be avoided.

2. *Analysis of serum or defibrinated blood.* "Peptides" are formed in the course of clotting (19).

3. *Analysis of whole blood.* Erythrocyte glutathione contributes a major part of blood peptides. Apparent changes of blood peptides may arise from changes in hematocrit or from differences in the recovery of glutathione in blood filtrates (18).

In addition, the incomplete specificities of the analytical procedures, especially of the Folin amino acid method in its unmodified form, have probably contributed to the non-agreement.

Undetermined nitrogen in azotemia. In many cases of azotemia, notably "irreversible" azotemia following severe burns (20 to 22), a substantial part of the non-protein nitrogen has not been identified. The possibility frequently has been suggested that peptides might account for much of the unidentified nitrogen.

In brief, there is a wealth of ideas as to the pathological significance of peptidemia, but the experimental support is poor because of the inadequacy of the chemical procedures used. We have investigated the question employing the manometric ninhydrin procedure for amino acids, and using for the removal of proteins a combination of chemical deproteinization and dialysis (19). Such elevations of plasma "peptides" as we observed in a varied group of diseases were by no means as large as those previously reported, and were not sufficiently remarkable to give the determination diagnostic value, nor to contribute largely to the undetermined non-protein nitrogen of plasma.

EXPERIMENTAL

Plasma from heparinized venous blood (from fasting subjects except as indicated) was at once diluted with 4 volumes of redistilled water, and 5 volumes of dilute tungstic acid (23) or of 5 per cent trichloroacetic acid were added slowly. After 30 minutes the suspensions were centrifuged and the supernatant solution filtered. Free α-amino nitrogen was determined promptly upon 6 to 8-ml. aliquots of the tungstic acid filtrates at pH 2.5, or upon picric acid filtrates, by the manometric ninhydrin procedure (24). The result was corrected for the urea found present, except when a high urea concentration was anticipated, in which case urea was removed by urease.

A 30- to 50-ml. aliquot of the tungstic acid filtrate was dialyzed in a ¾-inch cellophane tube against a single measured portion (60 to 80 ml.) of redistilled water for 24 hours at 5° C. on a slowly rotating wheel. Trichloroacetic acid filtrates were first freed of trichloroacetic acid by ether extraction (18), concentrated in vacuum, made to 25 ml. and a 24-ml. aliquot likewise dialyzed. A maximal aliquot of the dialysate was concentrated and hydrolyzed in a sealed tube at 110° C. for 24 hours in 4N hydrochloric acid. The hydrolysate was taken to dryness *in vacuo*, remoistened and dried again, 10 ml. of water added, and 3-ml. aliquots of the resultant solution were analyzed for α-amino nitrogen at pH 2.5. The difference in the 2 analyses (total diffusible α-amino nitrogen minus free α-amino nitrogen) is the *conjugated diffusible* α-amino nitrogen, due to peptides and other amino acid conjugates. It is for this category that the term *"peptide" nitrogen* is used here, with the qualifications already noted.[1]

RESULTS

Normal concentrations. Twenty-one tungstic acid filtrates of plasma from persons in the postabsorptive state contained an average of 0.9 mgm. per cent of conjugated α-amino nitrogen (18). Such filtrates, however, contained from 0.2 to 0.5 mgm. per cent of conjugated α-amino nitrogen which was not dialyzable, this presumably being due to proteins (18). Six filtrates studied consecutively in June 1946 (19) contained no measurable dialyzable conjugates ("peptides"). Fourteen samples analyzed subsequently contained an average of 0.51 mgm. per cent (S.D. = 0.07; range 0.08 to 0.89 mgm. per cent) of "peptide" nitrogen. One may conclude that "peptides" are usually but not invariably demonstrable. Trichloroacetic acid filtrates generally showed slightly

higher concentrations of these "peptides" (range, from 0.0 to 1.5 mgm. per cent "peptide" nitrogen). Most of the difference, however, in the total nitrogen content of these 2 types of filtrates is due to protein.

TABLE I

Effect of the ingestion of milk or casein upon plasma amino acids

All filtrates prepared by tungstic acid. Dialysates of these filtrates were analyzed in experiments 6 to 10. All normal subjects except experiment 6.

* Child, age 3.3 years, weight 26 pounds, cystic fibrosis of pancreas. When the test meal was 18 grams of gelatin the plasma amino acid N did not rise above 4.7 mgm. per cent.

As to the nature of these "peptides," glycine analyses indicated that hippuric acid, glutathione or serylglycylglycine made no large contribution. From acidified tungstic acid filtrates only small fractions of the conjugates were extracted by ethyl acetate.

Effect of protein ingestion. The peripheral venous plasma did not contain increased quantities of "peptides" after the ingestion of 100 grams of gelatin (25) or of 35 grams of egg white protein. The ingestion of a quart of milk, or of 35 grams of casein, led not to an increase but to a *decrease* in the "peptides" of plasma (Table I). This strange effect has been obtained 9 times in 10 experiments. This effect was not produced, in control experiments, by: (*a*) continued fasting, (*b*) the ingestion of 35 grams of starch, (*c*) drinking 1.5 liters of water in the course of an hour. No explanation of the effect of casein ingestion will be attempted.

Do surgical procedures lead to peptidemia? A preliminary study upon a patient exposed to very extensive abdominal surgery (dismantling of gastrojejunostomy, excision of marginal ulcer, hemicolectomy, transverse colostomy, enterostomy) gave the following values for "peptide" nitrogen in plasma samples taken 42, 69, and 110 hours after surgery:

(*a*) Undialyzed tungstic acid filtrate, 0.25, 0.34, 0.8 mgm. per cent.

(*b*) Undialyzed trichloroacetic acid filtrate, 0.84, 0.80, 2.0 mgm. per cent.

Detailed study (Table II) of a group of patients exposed to various major surgical procedures failed to show any definite effect upon the "peptides" of plasma (although the free amino acids were always reduced [26]) or upon the urinary excretion of free or conjugated amino acids. The preoperative and postoperative concentrations of plasma "peptides" were somewhat higher than the average for normal subjects, but not outside the normal range. The increased protein catabolism which occurs postoperatively apparently does not result in the appearance of increased amounts of intermediate degradation products in the plasma.

Peptidemia in various diseases. Table III summarizes our observations upon patients with various diseases. Peptidemia did not appear to be characteristic of neoplastic diseases, hepatic dis-

TABLE II

Effect of surgery upon free and conjugated amino acids of plasma and urine

* All urine excreted during a 72- to 96-hour period beginning just before the operation. The preoperative urines were collected during the preceding 12 hours.

† Tungstic acid filtrates of plasma. All other values for "peptide" N of plasma were determined upon 2.5 per cent trichloroacetic acid filtrates.

** Fourteenth day after surgery, free α-amino N, 4.03 mgm. per cent; "peptide" N, 0.39 mgm. per cent.

ease, even if severe, of venous thrombosis, of severe burns without azotemia, or of a number of other conditions. Somewhat elevated values appeared to occur in the nephrotic syndrome, and also in some cases of azotemia, but no level above 2.5 mgm. per cent of "peptide" nitrogen has been observed. While one cannot conclude that the rather small elevations observed in disease are without physiological significance, no indication of diagnostic value of the analysis has been obtained, nor do peptides and other conjugates appear to make any major contribution to the undetermined non-protein nitrogen of plasma.

Subjects showing the higher concentrations of "peptides" in the plasma did not regularly excrete larger quantities in the urine. On the other hand whenever the plasma peptide nitrogen is elevated by a few mgm. per cent by the intravenous injection of peptides (in the form of incomplete hydrolysates of protein) there is a massive peptiduria (27, 28). A dissimilarity is apparent in the nature of the "peptides" of plasma in the two situations.

Other body fluids. Several cerebrospinal fluid samples (by lumbar puncture) contained from 0.2 to 0.8 mgm. per cent of "peptide" nitrogen (Table IV). Tungstic acid, trichloroacetic acid and picric acid all left in solution a large fraction (15 to 50 per cent) of the protein of normal cerebrospinal fluid. Seminal plasma was unusually rich in free amino acids and in peptides, probably because of the presence of strong proteolytic activity, which led to the release of nearly 100 mgm. per cent of free amino acid nitrogen in 12 hours at 20°. Pathological accumulations of chest fluid, ascitic fluid, and synovial fluids appeared to contain "peptide" nitrogen in the range of 1 to 3 mgm. per cent.

SUMMARY

1. Factors which largely vitiate the validity of former determinations of blood peptides have been considered. The conjugated non-protein, amino acids (peptides plus other conjugates) of the plasma of normal persons and patients have been examined by procedures designed to avoid such factors.

* Analyses upon undialyzed filtrates; hence, some protein presumably is included.
† Sample supplied by Dr. Gretchen Hutchens, Children's Hospital, Boston.
** Sample supplied by Dr. Nathan Talbot, Massachusetts General Hospital, Boston. The urinary excretion of free α-amino acid nitrogen was 150 mgm. per day; of glycine nitrogen, 31 mgm. per day.

TABLE IV

Amino acids and "peptides" of some body fluids

No.	Fluid; diagnosis	α-amino nitrogen		Type of filtrate
		Free	"Peptide"	
L 27	Cerebrospinal fluid, normal	1.41	0.8	TCA
J 55	Cerebrospinal fluid, hydrocephalus, ventricular tap	1.04	0.10	TCA
K 54	Cerebrospinal fluid, normal	1.16	0.48	TCA
K 50	Cerebrospinal fluid, meningococcal meningitis	1.06	0.74	TCA
M 8	Cerebrospinal fluid, normal	1.80	0.20	Dialysate
E 72	Seminal plasma	15.8*	14.0*	Picric
	Same, after 12 hours at 20°	103.6		Picric
N 21	Chest fluid, measles, pleurisy	1.52		Picric
K 32	Chest fluid, constrictive pericarditis 7/9	4.73	1.31	TCA
K 32	Chest fluid, constrictive pericarditis 7/19	3.34	2.68	TCA
K 43	Ascitic fluid, sec. carcinoma of peritoneum	3.83	0.91	TCA
J 33	Synovial fluid, from knee, rheumatoid arthritis	4.43	1.10	TCA

* Three other experiments gave similar findings. Free glycine N 0.62 mgm. per cent; alanine N 1.4 mgm. per cent; little, if any, glutamine.

2. Tungstic acid filtrates of the plasma of normal fasting persons contained usually less than 1 mgm. per cent of conjugated, non-protein, amino acid nitrogen, and in some cases the concentration was too small to be measured. Protein ingestion did not increase the concentration of conjugates; in fact, milk or casein produced decreases.

3. Surgical procedures failed to produce increases of the "peptides" of plasma, nor were significant changes produced in the urinary excretion of free or conjugated amino acids.

4. While the plasma of patients with a variety of diseases contained as an average somewhat more amino acid conjugates than the plasma of normal persons most of the values were not outside the range encountered in normal persons. Elevated values did not appear to be characteristic of neoplastic disease, hepatic disease, or venous thrombosis. Somewhat elevated values were observed in nephrosis, but no value above 2.5 mgm. per cent of "peptide" nitrogen has been observed.

5. The free and conjugated amino acids of a few other body fluids have been reported.

STUDIES OF BLOOD VOLUME IN THE TETRALOGY OF FALLOT AND IN OTHER TYPES OF CONGENITAL HEART DISEASE[1]

By WOODROW NELSON, H. S. MAYERSON, JOHN H. CLARK, and CHAMP LYONS

(From the Departments of Physiology and Surgery, School of Medicine, Tulane University of Louisiana, New Orleans)

(Received for publication January 20, 1947)

The recent introduction by Blalock (1) of an operative procedure for the successful treatment of the tetralogy of Fallot has focused considerable attention on the various manifestations of this condition. It has also indicated the need of more information to aid in the diagnosis and prognosis, as well as in the preoperative and postoperative treatment of the patients with this disease. The present study is concerned particularly with the measurement of blood volume, hemoglobin, and plasma protein in 7 cases of tetralogy of Fallot, 4 cases of isolated septal defect, and 1 case each of Eisenmenger complex, isolated pulmonic stenosis, coarctation of the aorta, congenital mitral stenosis, and patent ductus arteriosus.

Fallot (2), in 1888, described the complex of combined congenital cardiac defects of pulmonic stenosis, right ventricular hypertrophy, patent interventricular septal defects, and dextroposition of the aorta which is commonly referred to as the "Tetralogy of Fallot." It is a common congenital defect of the heart. It constitutes 77 per cent of the 110 cases of pulmonary stenosis and 66 per cent of 40 cases of pulmonary atresia in Abbott's (3) series of 1,000 cases. The Eisenmenger complex is much less common. It differs from Fallot's tetralogy by having no pulmonary stenosis or atresia. The prognosis is somewhat better, the average life span being 16 years compared to 12.5 years in Fallot's type (4). The oldest age of survival recorded in either type is 60 years (5).

The principal extracardiac pathology of Fallot's tetralogy is a generalized vascular distention, capillary hyperplasia (3), and increased tortuosity. This is accompanied by polycythemia and increased blood viscosity. Blood arteriovenous-oxygen difference is increased, and its per cent oxygen saturation is decreased. Cyanosis, usually present at rest, is increased on exertion, when dyspnea also appears.

Although the elevated values of hemoglobin and hematocrit in the tetralogy of Fallot suggest an increased blood volume, measurements of blood volume have been recorded in relatively few cases of this disease. Meyer (6) measured the volume in 1 case using congo red, as did Blumenfeldt and Wollheim (7) using trypan blue. Both authors reported extremely low values for plasma volumes. Weber and Dorner (8), using the carbon monoxide method, obtained a value of 131 ml. per kgm. or a total blood volume of 6,040 ml. in a patient with cyanotic congenital heart disease (morbus caeruleus) as compared with the value of 77 ml. per kgm. in normal individuals measured by their method. Hallock (9) used the T–1824 blue dye in studying 2 cases. He found low plasma volumes (29.9 and 29.3 ml. per kgm.) and high cell volumes (144 and 77 ml. per kgm.).

METHODS AND PROCEDURE

Considerable care was devoted to the standardization of the procedures and methods used. All patients were studied under basal conditions. Breakfast was omitted, and the patients rested quietly in the recumbent position for at least 10 minutes before the determinations were made. Blood was drawn from an antecubital vein into syringes coated with a thin film of heparin. Total circulating plasma volume was determined by the method of Gregersen (10) using the Klett-Summerson photoelectric colorimeter. The amount of heparin which was used did not interfere with accurate determination of the plasma volume. To rule out the question of possible inadequate mixing because of slowed circulation, several successive samples were taken at 5-minute intervals after the usual 10-minute sample. In a number of cases, simultaneous samples were taken from the dorsal foot vein and an antecubital vein. All of our cases showed complete mixing in 10 minutes, and there was no evidence that the disappearance curve of the dye differed from that given for "normal" individuals. All adults were injected with 5

[1] One of series of studies being conducted under a grant from the Research and Development Division, Office of the Surgeon General, United States Army.

ml. of dye. Children were given a smaller amount of dye roughly proportional to their normal weight.

Hematocrit values were obtained by centrifuging blood in Wintrobe tubes. Since spinning for 30 minutes at 3,000 revolutions per minute gave the same results as spinning for an hour, the former interval was used in all of the experiments. Hematocrit determinations were made on the samples of blood taken before and after the injection of the dye. This served as a check on possible fluid shifts during the 10-minute intervening period.

Red cell volumes were calculated from the hematocrit values. The absolute accuracy of this procedure has been questioned by some (11) and affirmed by others (12). The suggested discrepancy between the true red cell volume and that calculated from the hematocrit, if present, would tend to make our absolute values uniformly too high by a maximum of about 25 per cent . It would have less bearing on the relationship of the actual values to standard values obtained by the same procedure.

Hemoglobin was determined as oxyhemoglobin, using the photoelectric colorimetric method of Evelyn (13). Oxygen capacity determination by the Van Slyke-Neill method furnished the necessary constants for calculation of the actual values. Specific gravity of the plasma was determined by the falling-drop method (14), and plasma protein levels were calculated from these values by the formula of Weech, Reeves, and Goettsch (15). All readings were made as soon as possible after the blood was drawn. A series of determinations made at intervals on 9 "normal" subjects over a period of 4 months showed fluctuations of not more than 10 per cent. Changes of greater magnitude have therefore been considered as significant.

The values given by Gregersen (10) were used to assign standard levels in the adult patients for blood volume, plasma volume, red cell volume, total plasma protein, and total circulating hemoglobin. These values were assembled by Gregersen from a large series and agree in

TABLE I

Tetralogy of Fallot

Patient number	Age	Obs. wt.	Date 1946	Hct.	Hb.	Hb.	Plasma protein	Plasma protein	Plasma volume	Red cell volume	Blood volume	Comments
		kgm.		*per cent*	*grams per cent*	*grams per kgm.*	*grams per cent*	*grams per kgm.*	*ml. per kgm.*

general with our findings and with those of other series (16). Standard values for blood, plasma, and red cell volumes in the children were calculated from the data given by Brines, Gibson, and Kunkel (17). Wintrobe's standard values were used for hemoglobin and hematocrit (18). Since all of our children were over 18 months old, their standard plasma protein level was assumed to be similar to that of the adult, *i.e.*, 6.5 grams per cent.

Diagnosis of tetralogy of Fallot was made principally on a basis of: (*1*) a history of cyanosis since, or shortly after, birth; (*2*) physical findings of a pulmonic stenosis-type murmur, cyanosis, finger and toe clubbing, and watchcrystal nail changes; and (*3*) X-ray findings of decreased conus pulmonus prominence. Retarded physical development was prominent in all of the children studied, and retarded mental development was observed in 1 case. Associated congenital defects were noted in 1 case. Rest cyanosis was present to a greater or lesser degree in all cases, and its presence in the absence of dyspnea and tachycardia was striking. Congestive failure was found in only 1 case (No. 206), and only 1 case (No. 212) showed marked cardiac enlargement. Right axis deviation was consistently found electrocardiographically. Circulation times, intracardiac diodrast studies, and oxygen analyses were done on some of the cases and showed markedly reduced arm-to-tongue or -face circulation time, right ventricle retention and right-to-left heart shunt, and decreased arterial oxygen saturation and increased arteriovenous oxygen difference. The aortic arch was on the left side in all cases. Two of the cases (Nos. 206 and 207) came to autopsy and presented the typical picture of the tetralogy of Fallot.

Case No. 210 was classified as an example of the Eisenmenger complex mainly on the basis of a prominent conus, lack of aortic prominence, and lack of a murmur typical of pulmonic stenosis. Since it was not feasible to employ venous catheterization, the possibility of an isolated inter-arterial septal defect was not definitely excluded. This patient manifested cyanosis only on exertion. The patient with isolated pulmonic stenosis showed a markedly prolonged retention of diodrast in the right ventricle and no evidence of septal defect. The diagnosis of patent interventricular septal defect was based primarily on the history and character of the murmur.

RESULTS

A total of 22 sets of determinations was done in the 7 cases of tetralogy of Fallot, 2 sets of determinations each in the case of the Eisenmenger complex and in the case of coarctation of the aorta. Single sets of determinations only were obtained in the cases of septal defect, congenital mitral stenosis, patent ductus arteriosus, and in isolated pulmonic stenosis.

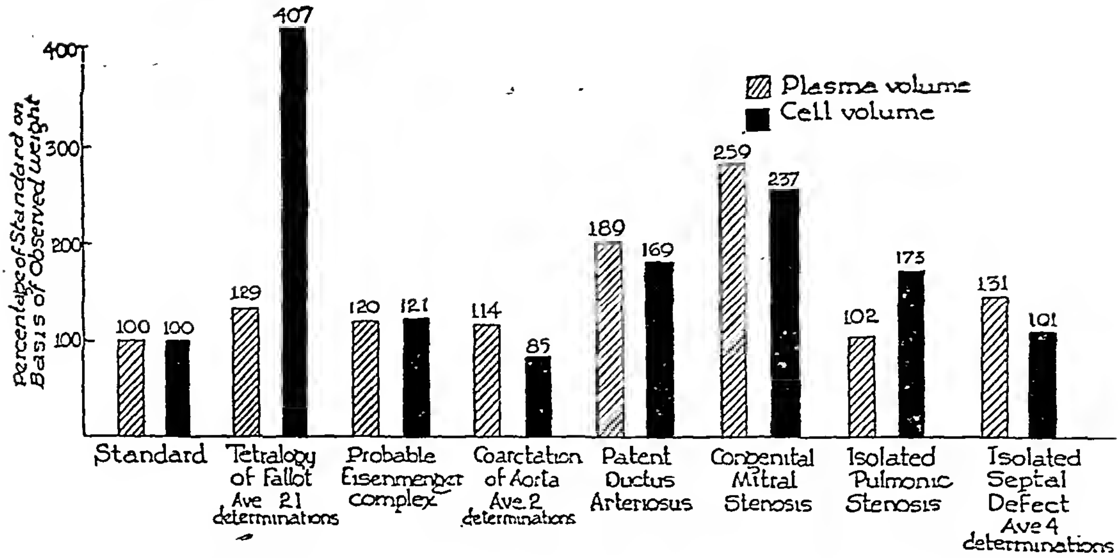

FIG. 1. COMPARISON OF TETRALOGY OF FALLOT WITH OTHER TYPES OF CONGENITAL HEART DISEASE

The results are given in detail in Tables I and II. A comparison of the plasma and red cell volumes in the various conditions is given in Figure 1. Our findings, contrary to those of previous investigators, indicate that the plasma volume is not significantly or consistently reduced in the tetralogy of Fallot.

The highest value for the total blood volume was 14,900 ml. (259 ml. per kgm.) found in the first determination in Case 208. To our knowledge, this is the largest blood volume reported in this disease, although Hallock (9) reported a case of polycythemia vera with a blood volume of over 18 liters. This case (No. 208) is of additional interest because of the dramatic response to bed rest, the blood volume dropping progressively from over 14,900 ml. to 6,300 ml. in a period of 2 months (Figure 2). This occurred without any

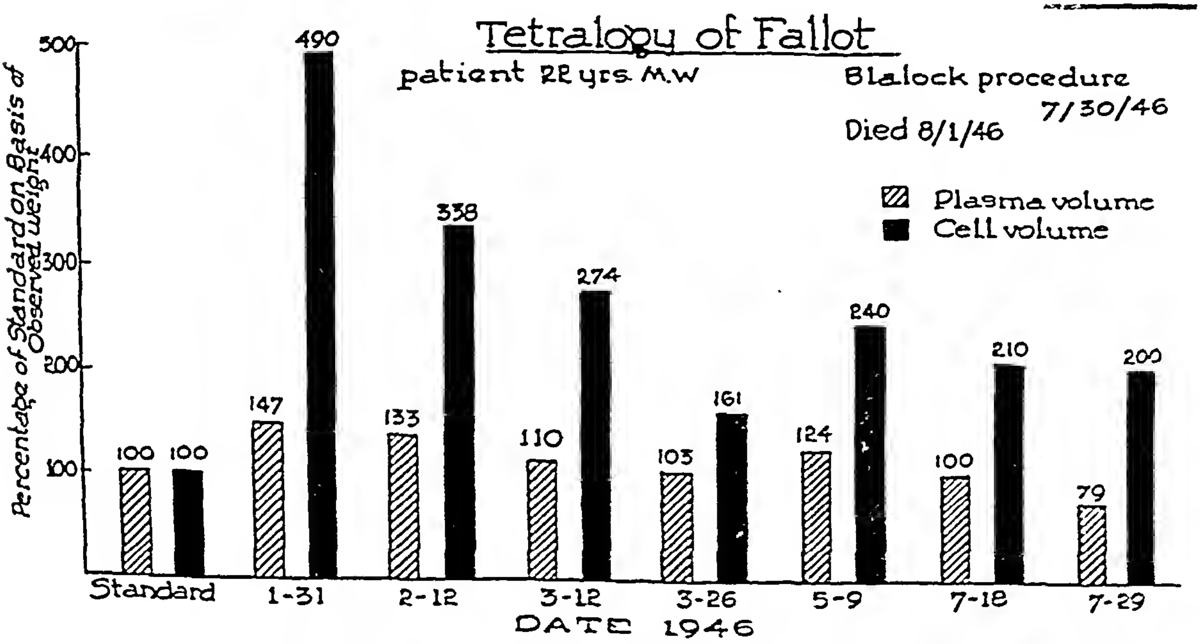

FIG. 2. SERIAL DETERMINATIONS OF PLASMA AND CELL VOLUMES IN A PATIENT 22 YEARS OF AGE (M. W.) WITH TETRALOGY OF FALLOT

hemorrhage and without clinical evidence of hemolysis. This decrease, while primarily due to a drop in the red cell volume, was accompanied by a drop in the plasma volume and total protein. This same tendency is also seen in Case 205, although the number of observations in this case is limited.

The highest total blood volume per kilogram was seen in Case 212. This child showed the most severe clinical picture of those surviving in the group. He manifested maximum cyanosis, exertional dyspnea, and cardiac enlargement. His initial blood volume was 4,215 ml. (307.7 ml. per kgm.), and a second determination some 2 weeks later showed a value of 5,268 ml. (428. 3 ml. per kgm.).

Initial values for plasma volume ranged from 51.4 to 80.3 ml. per kgm. These are 20 to 92 per cent above standard level as based on the patient's observed weights. Five of the patients were underweight at the time they were studied. We have found that in such individuals, plasma and cell volumes are more accurately predictable on the basis of optimal or usual weight. When the initial plasma volumes are calculated on this basis, the values in 4 of the 7 cases are almost exactly equal to the predicted or standard values. The remaining 3 cases (Nos. 204, 205, and 208) show values 111, 121, and 147 per cent, respectively, of the predicted levels. On the other hand, all of the patients showed strikingly increased cell volumes which varied from 104.9 to 294.3 ml. per kgm. These values are from 269 to 998 per cent of standard on an observed weight, and 220 to 639 per cent on an optimal or usual weight basis. Calculation of the total circulating hemoglobin revealed high values consistent with the elevated total cell volume. The initial values varied from 28.7 grams per kgm. to 63.1 grams per kgm. and represented levels which were from 242 to 764 per cent of the standard on an observed, and 208 to 527 per cent on an optimal or usual, weight basis.

Two of the cases of tetralogy (Nos. 208 and 211) were operated upon (see case reports). Case 208 survived only 3 days, while Case 211 has

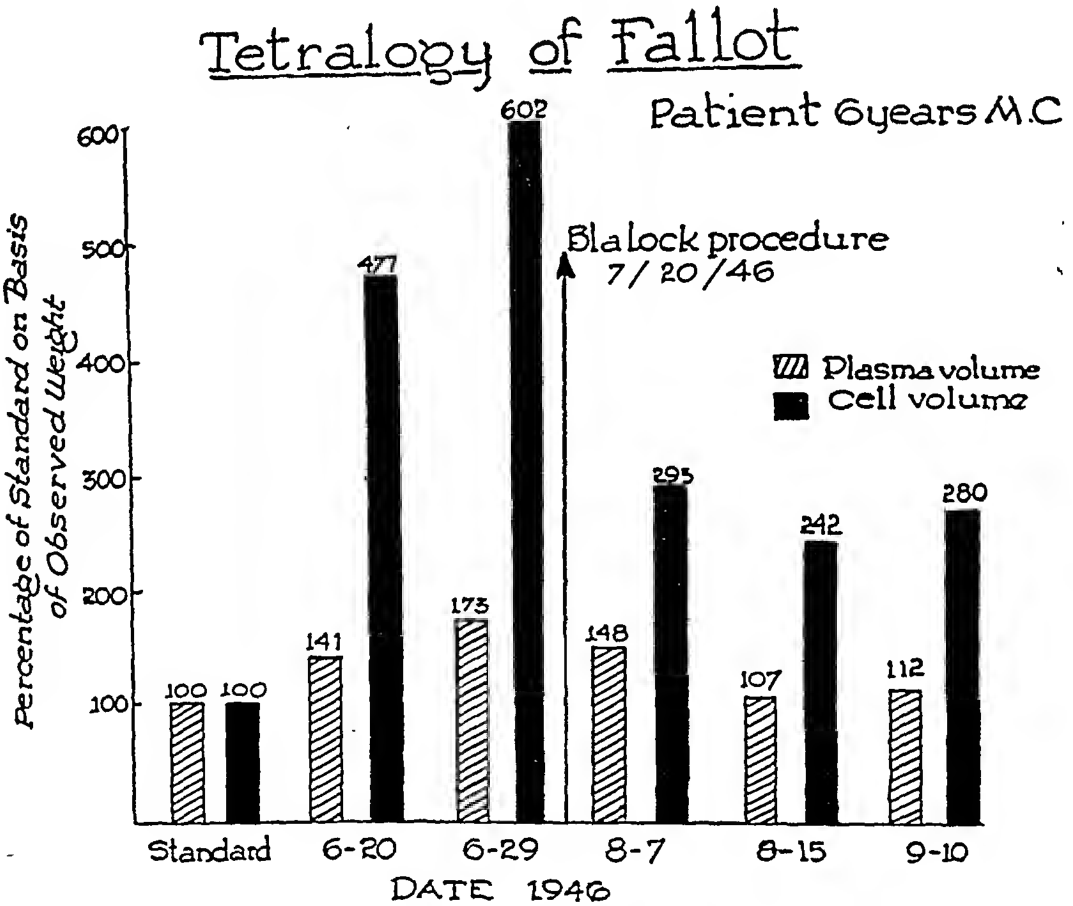

Fig. 3. Serial Determinations of Plasma and Cell Volumes in a Patient 6 Years of Age (M. C.) with Tetralogy of Fallot

shown definite improvement. Determinations made postoperatively in Case 211 showed a progressive decline in the total red cell volumes. The total blood volume 1 month after operation was only moderately increased over the standard level for the patient's observed weight but showed a slight rise following resumption of normal activity (Figure 3).

As in the tetralogy, the values for plasma volume in other types of congenital anomalies show variations which are near or slightly above predicted standard values, except for the case of patent ductus arteriosus (Case 213) and of congenital mitral stenosis (Case 215). In the latter cases, the values were 79.8 ml. per kgm. and 109.0 ml. per kgm., respectively, which are 189 and 259 per cent of standard on an observed, and 140 and 229 per cent of standard on an optimal, weight basis. Case 215, of congenital mitral stenosis, was in probable congestive failure preceding and at the time of the determinations.

In contrast to the findings in the tetralogy, however, only 3 cases showed high total red cell volumes. Again, the patent ductus arteriosus and congenital mitral stenosis show relatively high values (48.8 and 63.9 ml. per kgm.). The 3rd exception, isolated pulmonic stenosis, was the only case in which the relationship of high red cell (72 ml. per kgm.) and relatively standard plasma volume (44.1 ml. per kgm.) simulated that found in the tetralogy.

For the most part, the relative levels of plasma protein were within the standard range, as were the calculated values for total circulating plasma protein. Analysis of the data from the admittedly small number of cases fails to show any significant correlations between the total blood volume, red cell volume, total circulating hemoglobin or total circulating plasma protein and the hemoglobin percentage and hematocrit.

DISCUSSION

The findings in this study lend support to the point of view that the increased cell volume seen in the tetralogy of Fallot is due to a compensatory stimulation of the bone marrow consequent to the anoxia resulting from inadequate aeration of the circulating blood. Of the 3 prominent factors which might play a part in the development of the anoxemia, it is evident from our data that the septal defect is the least important. Thus, 2 of the cases of isolated septal defect (Nos. 221 and 223) showed significantly low hemoglobin and total cell volumes, one case (No. 222) showed approximately standard values, while the levels in the 4th case (No. 220) were only mildly elevated. The dextroposition of the aorta, on the other hand, must be considered as a possible factor, since it results in mixing of unaerated blood from the right side with aerated blood from the left ventricle. Blalock (19) has experimentally produced a similar mixing by a pulmonary arteriovenous anastomosis following lobectomy in the dog which led to anoxemia and polycythemia.

The most important factor in the production of the anoxemia and the compensatory polycythemia and hypervolemia, as seen in the tetralogy of Fallot, is probably the presence of pulmonic stenosis. This impedes the flow of venous blood into the pulmonic artery and forces the blood to pass into the systemic circulation. Talbott and his colleagues (20) have estimated that 75 per cent of the blood circulating through the heart may not go through the lungs. In addition, the increase in viscosity is a striking feature in the tetralogy of Fallot. We found, as did Talbott and his colleagues, that the blood was so viscous that it was withdrawn only with difficulty. This must impose a real burden upon the myocardium.

The combined action of these various factors results in a chronic anoxemia which resembles that seen in residence at high altitudes (21). The resulting polycythemia and hypervolemia are, in general, conditioned by the degree, duration, and continuity of the anoxic stimulus. As long as there is a marked discrepancy between the demands for oxygen by the tissues and the amount of oxygen furnished to them by the circulating blood, the stimulus continues to operate and the level of circulating red blood cells remains high. In spite of the increased hemoglobin level, the oxygen saturation in many patients is at a critical level of about 60 per cent. At this level, which corresponds to an oxygen saturation similar to that seen at an altitude of 4 miles, the margin of safety is small (19 and 20). The stimulus will be weakened when either the demand for oxygen is decreased or the supply increased. Prolonged bed rest thus

leads to a lessening of the stimulus and a decrease in the polycythemia. Likewise, the improvement in blood flow to the lungs and consequent increase in the oxygen supply to the tissues brought about by the Blalock procedure results in a decrease in the stimulus and in the polycythemia. The absence of significant polycythemia and hypervolemia in the Eisenmenger complex (Case 210) is to be expected on this basis, since in this patient much less venous blood passes into the aorta directly or by way of the septal defect; a greater portion enters the relatively wide orifice of the pulmonary artery to be oxygenated by the lungs; less cyanosis is observed, and in general the cardiodynamics more nearly approach the normal. In the same manner, no marked polycythemia or hypervolemia is found in patients with ventricular septal defects (Cases 220, 221, 222, and 223), since there is no flow of blood from the right to the left ventricle unless left ventricular failure is present. These patients, therefore, do not have arterial undersaturation and there is no stimulus to bone marrow from anoxemia. It is difficult to reconcile the finding of an increased red cell volume in isolated pulmonic stenosis (Case 209) with the fact that the arterial blood would not be expected to be undersaturated in this condition. However, the similarity of the plasma and cell volume changes in our cases of isolated pulmonic stenosis and Fallot's tetralogy suggests a possible similar etiological basis for the hypervolemia in these 2 diseases. We cannot explain the increase in plasma and cell volume in the case of patent ductus arteriosus.

The fact that the chronic anoxemia of the tetralogy of Fallot does not modify the erythropoietic activity permanently is of interest. Hurtado, Merino, and Delgado (21) have shown that normal individuals who have lived since birth at high altitudes and are brought down to sea level, show after some time, blood characteristics similar to those found in normal individuals who have always lived at sea level. Similarly, decrease of the anoxemia in patients with tetralogy by bed rest or the Blalock procedure results in a gradual change towards the blood picture found in the so-called "normal" individual. The fate of the red blood cells involved in this decrease awaits further study. The relatively gradual change and the absence of clinical icterus suggests that the superfluous red cells already in circulation are being destroyed while fewer red cells are being elaborated by the bone marrow.

The effectiveness of the polycythemia in the tetralogy seems to lie in the fact that it enables the patient to meet his resting needs for oxygen although it may not provide for much margin of safety. The large volume of viscous blood, however, imposes a rather severe strain on the heart which usually eventuates in congestive heart failure in the patient surviving to the 3rd or 4th decade, as cardiac reserve diminishes.

These studies are being continued. It would seem desirable to know much more about the underlying physiological adaptations of the circulation and respiration in congenital heart disease. Since among the most marked changes are those which occur in red cell volume, it would be of value to check further the validity of the dye-hematocrit method in these conditions by the carbon monoxide or radioactive-iron techniques. The material gathered to date, however, indicates the possible usefulness of blood volume determinations in supplementing the usual tests for the differentiation of the various types of congenital heart disease. The presence of an absolute erythrocytosis, as indicated by a significant increase in red cell volume without significant change in the plasma volume, should be interpreted as suggestive of the presence of pulmonic stenosis. The serial determination of the blood volume and total circulating hemoglobin should also serve as a valuable aid in indicating the optimal time for surgery and as a measure of the beneficial effects of surgical procedures.

CASE REPORTS

I. No. 208, W. M., 22 years

This patient gave a history of having been blue and having had clubbing of the fingers and curved nails since early childhood. Relatives stated he had been blue since birth. He had severe dyspnea and many dizzy and fainting spells occurring on slight exertion. He had an acute thrombophlebitis followed by chronic leg edema and ulceration in 1943. This responded well to treatment consisting of elimination of arterio-spasm by lumbar sympathetic blocks and compression dressings of elastic bandage or Unna's paste. In 1945 a high-low ligation for superficial varicosities was done on the right, after which the low incision healed very slowly. He was also admitted on one occasion with a diagnosis of "psychotic personality" and "gastric neurosis."

Physical examination on various admissions showed a fairly well developed adult white male. The skin was of a dusky blue color particularly marked in the ears and face. On exertion the cyanosis became more intense. No resting dyspnea was present, but exertional dyspnea was marked. Three-plus clubbing of the fingers and watch-crystalling of the nails was present. Examination of the chest revealed a loud precardial systolic murmur maximal over the pulmonic area. A systolic thrill over the same area was present. A 6-foot heart plate showed a pulmonary conus concavity and a small aortic knob. Electrocardiogram showed pronounced right axis deviation, and cardiography showed delay in right ventricle emptying. The aortic arch and descending aorta were demonstrated to be on the left when barium was introduced into the esophagus. Circulation time arm-to-tongue was 7 seconds with calcium gluconate. Determination of circulation time with ether in this patient resulted in a measurement of arm-to-face circulation time of 3.1 seconds as evidenced by severe burning of the face. The failure of this patient to smell the ether at any time after injection suggests that the amount of blood going to his lungs was very small as compared to his total blood volume. Arterial oxygen content was 18.35 per cent and venous 11.29 per cent. Venous oxygen capacity was 27.28 per cent. Venous pressure was 132 mms. of citrate; R.B.C.'s varied from 8 to 10 million. Other blood findings are given in Table I and Figure 2. Liver and kidney function tests were normal.

Treatment with semi bed rest from January to March, 1946, resulted in some improvement in exertional dyspnea and cyanosis, and resting cyanosis diminished. Attempted anastomosis of the right subclavian-pulmonary artery on May 9, 1946, by Dr. Alton Ochsner, was unsuccessful because of the relative shortness of the subclavian artery. Following 6 weeks of intermittent right carotid compression, anastomosis of the right common carotid-right pulmonary artery by the Blalock method was performed by Dr. Ochsner. Following this, the patient's cyanosis diminished for a few hours. He developed a left hemiplegia, however, and expired on the 3rd postoperative day.

II. No. 211, M. C., 6 years

The essential history on this boy, obtained from his mother, was that he had been blue since birth. The blueness was intensified by even slight exertion. He became short of breath upon slight exertion and as he became older had "falling out" spells on attempting exercise, such as running or climbing stairs. His mental development was normal and his physical development somewhat retarded. Positive physical findings were: (*1*) moderately underweight; (*2*) increased duskiness of face, ears, lips, finger-nails, markedly exaggerated on crying; (*3*) marked clubbing and watch-crystalling of fingers and toes; (*4*) loud precordial systolic murmur maximal over pulmonic area; (*5*) right axis deviation and sinus tachycardia on E.C.G.; and (*6*) R.B.C. of 6 to 8 million.

This patient was observed and treated with bed rest for a period of 2 months, during which time there was no change except questionably slight improvement of his exertional dyspnea. He, at no time, had findings suggestive of congestive failure. On July 23, 1946, a Blalock type anastomosis was done by Dr. Ochsner between the right subclavian and the right pulmonary artery. Immediate slight improvement in cyanosis resulted at this time. Little blood having been lost during the operation, it was thought advisable, in order to decrease the blood viscosity and because of danger of clotting, to withdraw 150 ml. of blood. Withdrawal of this amount caused the patient to go into severe secondary shock which was quickly overcome by re-administration of the blood.

The patient's convalescence was uneventful. Only a trace of finger and toe clubbing and watch-crystalling remains. At present he has no resting cyanosis and only slight exertional cyanosis. His exercise tolerance is much improved, his blood volume has dropped as previously noted (Figure 1). However, no murmur except the previously present pulmonic murmur can be heard.

The prompt secondary shock sustained by this patient when, following Blalock's suggestion (19), 150 ml. of blood was withdrawn postoperatively, raises the question as to the desirability of bleeding in these cases. There seems to be no reason to anticipate a sudden shrinkage of the vascular capacity so as to produce increased viscosity and clotting. In fact, as Blalock has reported and we have found, the changes towards "normal" occur gradually over a period of weeks. It is more likely that the trauma of the relatively long operation produces a widespread dilatation and temporary enlargement of the vascular bed, which certainly provides an adequate factor of safety during the early postoperative period.

SUMMARY

1. Plasma, red cell, and total blood volumes, total circulating hemoglobin, and plasma protein were studied in 7 cases of the tetralogy of Fallot. 4 cases of isolated interventricular septal defect, and 1 case each of probable Eisenmenger complex, isolated pulmonary stenosis, coarctation of the aorta, congenital mitral stenosis, and patent ductus arteriosus.

2. All patients with tetralogy of Fallot and the case of pulmonic stenosis showed a markedly increased blood volume due primarily to an increase in total red cell volume. Hematocrit and hemoglobin levels were also high. Plasma volume was at, or slightly above, standard levels.

3. Bed rest and production of a new shunt by the Blalock procedure in 2 cases resulted in a gradual decrease of red cell volume toward standard values.

4. Blood volume was at approximately standard levels in the cases of interventricular septal defect, Eisenmenger complex, and coarctation of the

aorta. The cases of congenital mitral stenosis and patent ductus arteriosus showed high blood volumes due to increases in plasma volume as well as red cell volume.

We are grateful to Miss Genie Burt and Dr. Blanche Jackson for their assistance and to Drs. V. Platou and Clarence T. Rae for their cooperation. The patients were hospitalized at Charity Hospital and Touro Infirmary.

THE RELATION BETWEEN THE SERUM UREA CONCENTRATION AND THE PROTEIN CONSUMPTION OF NORMAL INDIVIDUALS [1]

By T. ADDIS, E. BARRETT, L. J. POO, AND D. W. YUEN

(From the Department of Medicine, Stanford University School of Medicine, San Francisco, California)

(Received for publication January 28, 1947)

When a patient with renal disease is found to have a concentration of urea in his blood that is higher than usual we would like to be able to derive from the degree of increase in concentration some idea as to the degree of decrease in the urea-excreting function of his kidneys. In the individual patient this cannot safely be done. True, when we plot the blood urea concentrations of a large number of patients against their urea clearances, a general relation does emerge (1, 2). However, in any one of such a group of patients the prediction from concentration to clearance may fall dangerously far from the truth. This is inevitable because the concentration of urea in the body is determined not only by how much urea runs out of the system through the kidneys but also by how much urea runs into it from the liver. When more runs out than runs in, the concentration falls to a lower level which is maintained as long as the discrepancy persists. When more runs in than runs out the concentration level rises and remains high as long as the excess of in-flow over out-flow continues. Unlike salt, the concentration of urea is confined within no narrow zone of variation by any regulatory mechanism. Urea is a substance to which the body is chemically and physically indifferent. It is an end product of protein metabolism and participates in no chemical reactions. Except in the kidney it has no osmotic effect because it is distributed evenly through the water of all organs and tissues. So we need not be surprised when we find, as we do, that there is a wide scatter in the urea concentrations in the blood of normal individuals (3, 4). In spite of wholly normal renal function we shall continue to find this high variability until we make measurements on normal subjects who are taking the same amounts of protein in their food; and in our patients, whose renal function is not normal, we shall not be able to derive reliable judgments as to the renal significance of our blood urea determinations until we know their food protein consumption and can exclude any pronounced deviation from the usual rate of endogenous protein catabolism.

When an acutely ill patient first reaches a hospital it is generally recognized that even a quite high blood urea concentration cannot be taken as conclusive evidence of renal failure. There is always the chance that this may be an example of "extra-renal azotemia," a term used to cover any sudden and pronounced increase in urea formation by the liver, whether the amino acids from which it is derived come from the gastrointestinal tract, as in massive blood loss into the gut, or from a rapid breakdown of the protein of the body itself, as in certain patients with obstruction of the small intestine. The conditions that lead to such explosive disintegrations of large amounts of protein are not often found in ambulatory patients. In them, we may suppose, differences in the rate of urea formation arise mainly from differences in the quantities of protein they take as food. It is for this group, and particularly for out-patients with renal disease, that we might get more information from blood urea measurements if only we were able to discount this protein consumption variable. That cannot be done until we measure the effect of variation in protein consumption on the blood urea concentration of normal individuals.[2]

[1] This work was made possible by a grant from the Nutrition Foundation, Inc.

[2] In accordance with clinical usage we speak of blood urea concentrations although the determinations were actually carried out on plasma or serum. When whole blood is used the urea concentration is found to be about 1 per cent less than in serum because the red cells contain less water than the serum. This is true only when the arginase in the red cells has been destroyed by heat, before the urease is added. Otherwise determinations on whole blood give a variable plus error which we believe arises because the arginase in the red cells produces urea from arginine in the urease (5).

The data given in this paper were collected with that end in view.

Method

1. *The conditions under which the observations were made*

The experiment was made possible through the intelligent and devoted cooperation of 2 groups of people: first, the 10 medical students who were the subjects, and, second, the student dietitians who designed and prepared weighed diets containing varying quantities of protein. The effect of 3 levels of protein consumption was studied. The first contained an amount of protein not much more than is required for nitrogen equilibrium (6). This was obtained by giving each subject 0.5 gram of protein for every kilogram of his body weight (with clothes). The second represented a medium protein consumption and provided 1.5 grams of protein per kgm. The third, a high protein diet, supplied 2.5 grams of protein for every kgm. of body weight. The subject who weighed 80 kgm. thus received, first, 40 grams, then 120 grams, and, finally 200 grams of protein a day.[3] The calories in all cases exceeded 2,000 a day. There was no restriction of water. The subjects continued with their daily work. Blood was collected on the 5th and 6th days of the consumption of each level of protein. On the 5th day the first blood was taken at 7:15 a.m. before breakfast at 7:30 a.m., then at 11:45 a.m. before lunch at 12 noon, at 4:45 p.m. before dinner at 5 p.m., and at 9:45 p.m. before going to bed at 10 p.m. On the 6th day observations were made at 7:15 a.m. and at 11:45 a.m. just before breakfast and lunch. Between each diet there was a period during which whatever food the subjects wanted was taken. The 0.5-gram level was taken first, then the 1.5, and then the 2.5-gram level. After a 2-month interval the 0.5- and the 2.5-gram diets were repeated. We thus obtained 120 serum urea determinations on 0.5 gram, 60 on 1.5 grams and 108 on 2.5 grams, a total of 288 observations.

2. *The method of measurement*

A urease-aeration-titration method was used (7). In spite of constant care and reiterated checking with known urea solutions we suspect that our data may be marred by the occasional intrusion of unsuspected technical errors. We have reason also to think that there is a constant minus eror of nearly 3 per cent arising from unavoidable loss in the transfer of ammonia. In spite of these imperfections we believe the method adequate for our purpose. That this is so is indicated, though not proved, by the general agreement between our present results and the results we obtained with the same method in 1940. In these earlier measurements the subjects were different (10 residents and internes) but the protein variation was the same. Unfortunately, in 1940, blood was taken only once a day, so that the comparison has to be restricted to the measurements made at 11:45 a.m. on the 5th day of each diet in 1941 and the measurements made at the same time of the 5th day in the present series. The degree of agreement is shown in Table I.

We cannot say how much of the divergence between the 2 sets of observations shown in Table I should be ascribed to inconsistency in the technique of measurement. It is enough to observe that the sum of the technical and of all other reasons for difference do not prevent us from

[3] The body weights of our subjects varied from 65 to 83 kilograms. Unquestionably somewhat more precise results would have been obtained if we had apportioned the protein in terms of some power of the body weight. The method we used is based on the not quite correct supposition that there is a relation of direct proportionality between body weight and protein requirement. We used it because this is the simple first approximation that we

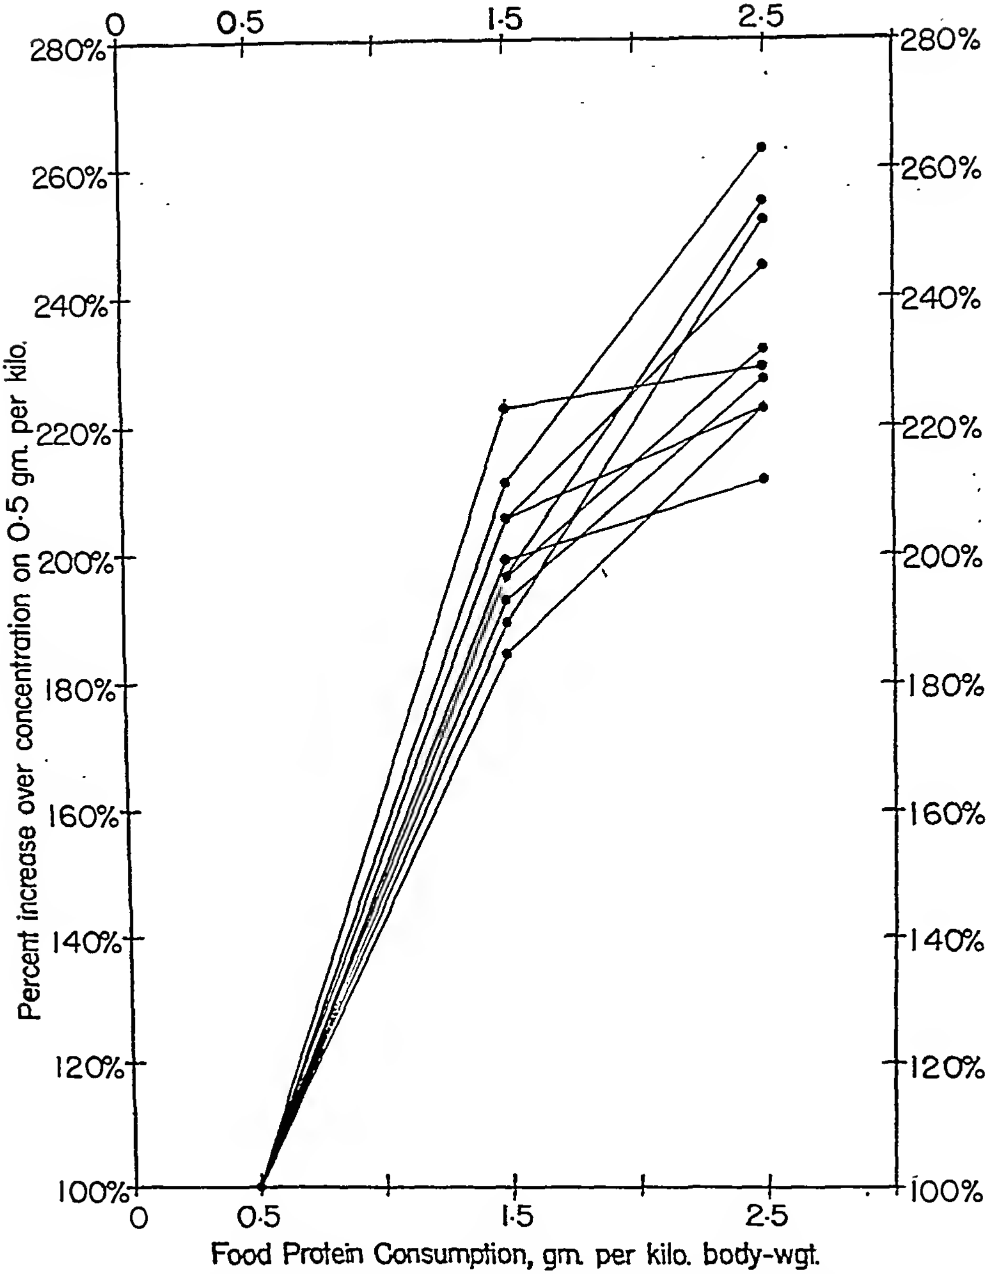

Fig. 1. The Relation between the Serum Urea Concentration and the Protein Consumption of Normal Individuals

concluding that in both of these groups of normal subjects the blood urea concentration rises as the protein consumption increases and is more than twice as high on the 2.5 as on the 0.5 gram of protein per kilogram diet.

3. *The individual variability of the subjects*

There are indications of individual peculiarities in the 20 subjects dealt with in Table I, but no conclusion can be drawn from these fluctuations because the number of observations on each subject is too small. We can get a better idea as to how much one individual may differ from another in his reaction to increase in protein consumption from the present series of observations. For each subject we have 12 measurements on 0.5 gram, 6 on 1.5 grams, and 11 or 10 on 2.5 grams of protein per kilogram. The averages for each individual are given in Table II and the percentage increases above the concentration on the 0.5-gram level are shown in graph form for each of the 10 subjects in Figure 1.

Though every subject has an increase in concentration with increase in protein, these results reveal considerable individual differences. It does not seem to us, however, that the question as to the probability that these differences arise from factors constant for each subject is one that our data can answer with sufficient dependability to give a result of practical value. For the moment it is enough to note that, if we take the concentration observed in each subject on the 0.5-gram protein diet as 100 per cent, these normal individuals responded to the 1.5-gram protein diet by increases in concentration that varied from 185 per cent to 223 per cent and from 212 per cent to 263 per cent when 2.5 grams of protein per kgm. was taken.

For clinical purposes it is most important to know how great is the individual variation in concentration in normal subjects taking the same amount of protein. This question is answered in the last column of Table II where we give the averages of 29 observations on 8 subjects, and 28 on the other 2, at all times of day and under all diets. The subjects have been arranged in the order of magnitude of their averages.

In 9 subjects there is a close concordance in blood urea concentration, with a range of from 32.3 to 35.8 mgm. per 100 ml. The subject D, however, has an average of 43.1 mgm. per 100 ml. Yet he was what we call "normal," that is, he considered his health good, he was working hard, and, in particular, was free from any sign of renal disease. There was nothing unusual in his reaction to increase in food protein, for it happens he falls close to the center of the stream of variation shown in Figure 1. It is fortunate that we happened to include this subject, for if some other student, who was like the rest of the group, had taken his place, the reported variability in blood urea concentration would have been narrowed. It is obvious that measurements of normality based on 10 subjects have only a preliminary and tentative significance.

RESULTS

We neglect all variables except the change in protein consumption and present only the averages and their standard deviations on 0.5, 1.5 and 2.5 grams of protein per kgm. body weight. This means that we include the variability arising from the fact that the blood samples were taken at various times during the two 24-hour cycles within the variation induced by the protein. We prefer to merge these 2 distinguishable effects because we intend to use our measurements for the interpretation of the urea concentration of patients no matter at what time of day we take their blood.

In Table III we give the averages and their standard deviations. In Figure 2, the averages are plotted against the protein consumption and the area lying between the averages plus or minus twice the standard deviations is indicated. This area is delimited by lines because we want to use it for the interpretation, from blood urea concentration measurements, of the renal status of patients who are taking any quantity of protein between 0.5 and 2.5 grams per kgm. The lines are broken in order to indicate that when the protein consumption is other than 1 of the 3 quantities at which our measurements were made we are dealing with assumed and not with measured variabilities.

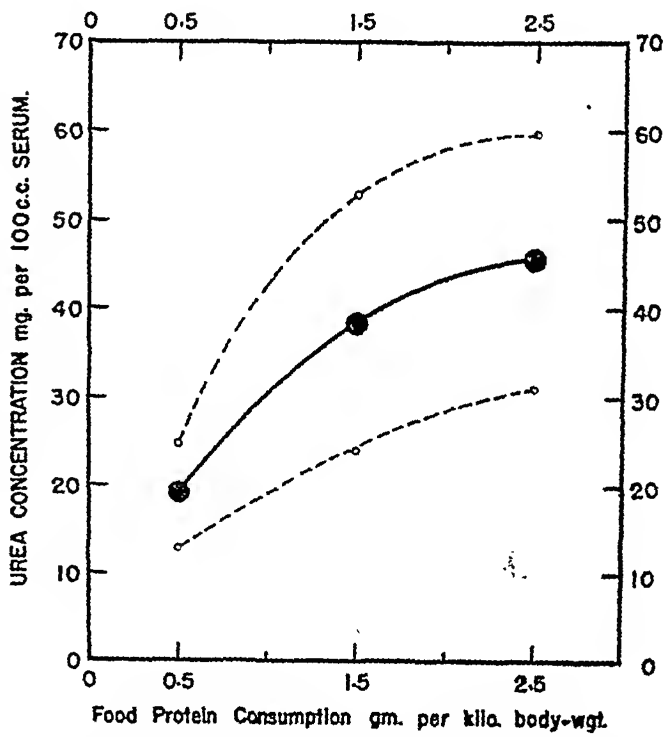

FIG. 2. THE RELATION BETWEEN THE SERUM UREA CONCENTRATION AND THE PROTEIN CONSUMPTION OF NORMAL IDIVIDUALS

DISCUSSION

The average of all the 288 measurements is 33 mgm. Of these 95 per cent lie between 7 mgm. and 60 mgm. of urea per 100 ml. of blood. This result is in conformity with what has already been observed (4, 5). All it does is to demonstrate, more precisely than before, how wide is the variability in the concentration of urea in the blood of apparently healthy young adults who present no evidence of any defect in renal function. If this were all, we should have to conclude that, even for ambulatory patients with renal disease, a measurement of blood urea concentration was of little value, apart from its use in revealing the more extreme degrees of renal failure.

Now, however, the effect of variation in protein consumption has been measured in normal individuals. As we go from 0.5 to 1.5 to 2.5 grams of protein per kgm. their blood urea concentration rises from 19 to 39 to 45 mgm. per 100 ml. At each of these levels of protein consumption the variability is much lower than the 40 per cent coefficient of variation that characterizes the whole series. It is reduced to 15 per cent at 0.5 gram, 18 per cent at 1.5 grams, and 16 per cent at 2.5 grams. This means that we now have measurements on which we can base our clinical judgments with greater assurance.

The prerequisite for the use of these standards is a knowledge of the quantity of protein the patient takes. But this is what is already known by everyone who believes that the protein consumption of a patient with renal disease is an important factor in his treatment. Many of our patients are living on self-measured diets that contain 0.5 gram of protein per kgm. We have reason to know that these measurements have a reasonable precision. That is a matter that can be verified by periodic determinations of their rate of urea excretion. If, in such a patient, we find a blood urea concentration of 40 mgm. per 100 ml. we can be almost certain that he has a urea clearance well below normal. We know that because in Figure 1 we see that on 0.5 gram of protein per kgm. only about 2 per cent of people with unimpaired renal function have urea concentrations that exceed 25 mgm. per 100 ml. If, as the months and years go by, while the same diet is maintained, we find this patient's concentration rising from 40 to 50 to 60 mgm., or falling from 40 to 30 to 20 mgm., we now have some warrant for the supposition that his urea clearance has changed in an approximately proportionate inverse manner.

Whatever average quantity of protein a patient loses in his urine is added to his diet. In some this may amount to 10, in others to 15 and in still others to 20 grams of protein a day. Thus the protein taken by an 80-kgm. patient may be increased from 40, to 50, to 55 or to 60 grams of protein a day, that is from 0.5 to 0.63, to 0.69, to 0.75 gram of protein per kgm. In such patients there are reasons, and some of them are more than statistical, why we cannot have the same assurance in the interpretation of urea concentrations measured at levels of protein consumption other than those at which our determinations were made. Until we have more extensive information, however, our best guess is to assume smooth curves between the measured points in Figure 1. Then, if a patient is taking 0.75 gram of protein per kgm., we shall be guided in the estimation of the urea-excreting function of his kidney by the supposition that, with unimpaired function, the average concentration would be 25 mgm. and that in only 2 per cent of all such instances would the concentration be more than 33 mgm. per 100 ml.

In theory, we can now predict the urea clearance of any ambulatory patient whose protein consumption is known. In practice, however, we have to remember that 10 medical students are not an adequate sample of all people whose renal function is supposedly intact. More than that, the theory involves the assumption that the rate and variability of "endogenous" protein catabolism in patients with renal disease is similar to that which existed in our normal sample. That is a supposition that has never been tested. Nevertheless we find these normal standards useful, even though we are aware that our "predictions" are not much more than clinical judgments, influenced in an indeterminate manner by considerations arising from a concrete knowledge of the particular circumstances that surround each one of our patients.

CONCLUSIONS

1. The average of 288 determinations of the urea concentration in the blood of 10 medical students was 33 mgm. per 100 ml. The range of variation

that included 95 per cent of the measurements went from 7 to 60 mgm. of urea per 100 ml.

2. When the subjects took 0.5 gram of food protein per kgm. body weight the average of 120 blood urea concentration determinations was 19 mgm. per 100 ml., and 95 per cent lay between 13 and 25 mgm. per 100 ml. On a diet containing 1.5 grams of protein per kgm. the average of 60 determinations was 39 mgm., and 95 per cent fell between 25 and 53 mgm. per 100 ml. When 2.5 grams of protein per kgm. was taken, the average of 108 determinations was 45 mgm. and the same proportion was included in a range from 31 to 60 mgm. per 100 ml.

THE SERUM CREATININE CONCENTRATION OF NORMAL INDIVIDUALS [1]

By EVALYN BARRETT and T. ADDIS

(From the Department of Medicine, Stanford University School of Medicine, San Francisco, California)

(Received for publication January 28, 1947)

In the preceding paper (1) it is shown that the blood urea concentration of subjects with intact renal function increases as their protein consumption increases. The conclusion is drawn that a relatively dependable inference from urea concentration to renal function requires a knowledge of the amount of protein a patient is taking and, in addition, a clinical situation that warrants us in excluding any sudden and pronounced increase in protein catabolism. In general, this second requirement is met when we deal with ambulatory patients, but at the first visit of every new patient the first requirement is lacking. Under the circumstances it would be well if we could measure some substance, other than urea, the concentration of which is uniquely determined by the functional capacity of the kidney. Unlike urea, this substance should have a rate of formation that is constant and that is unaffected by variation in food consumption. Creatinine may be such a substance. Its rate of flow into the blood stream is said to depend on the rate of transformation of creatine into creatinine (2). Its rate of excretion is independent of the amount of food protein that is eaten (3) and remains the same whether the muscles are active or at rest (4). We have therefore measured the variability of serum creatinine concentrations in individuals without proteinuria whose renal function was presumably unimpaired.

METHOD

1. *The conditions under which the observations were made*

The same subjects, the same diets, the same blood collections were used for the serum creatinine as for the blood urea concentration measurements (1). But within this identity of conditions there is concealed a difference that exists for creatinine but not for urea. At all levels of protein intake the food was devoid of preformed urea, but it was not free from preformed creatinine. When 0.5 gram of protein per kgm. was taken there was no meat in the diet and so the food was creatinine-free. But on the 1.5-gram and still more on the 2.5-gram level there was an increasing consumption of meat, fish, and chicken. In cooking, some of the creatine of muscle is converted into creatinine, in an amount that varies, presumably, with time, temperature, and pH (5). Since the unaltered creatine of the meat does not appear in the urine as creatinine (6) and since an increase in protein consumption does not increase creatinine excretion (3) we may derive from the 24-hour rates of creatinine excretion of our subjects an indication as to the quantity of creatinine formed from creatine in cooking. These rates are given in Table I.

TABLE I

Rate of creatinine excretion on a creatinine-free diet (0.5 gram protein per kgm.) and on diets containing increasing amounts of cooked muscle tissue (1.5 and 2.5 grams protein per kgm. body weight)

Averages from groups of 10 subjects. Rates corrected for a body weight of 70 kgm.

	0.5 gram per kgm. creatinine	1.5 grams per kgm. creatinine	2.5 grams per kgm. creatinine
	mgm. per 24 hours		
1940 observations	1638	1766	1903
Present observations	1597	1743	1835

If we take the average of both rates of creatinine excretion on the 0.5-gram diet as representing the endogenous creatinine, we note in Table I that this is increased by 137 mgm. on the 1.5-gram and by 252 mgm. on the 2.5-gram protein diet. This increase we may reasonably attribute to the addition of exogenous creatinine formed in cooking. The point is worth mentioning because it may seem unfortunate that the conditions we chose for our observations include a variable that may prevent us from obtaining a true measure of the variability of serum creatinine concentrations in normal individuals. This would be true enough if the variability determination were our end, instead of being a means to our end of establishing a standard of normality for new patients, many of whom will certainly have taken varying amounts of cooked meats before we see them.

With the exception of the 9:45 p.m. collection, blood was drawn just before breakfast, lunch, and dinner, that is to say at as long a period as possible since the preceding meal. Preformed creatinine is rapidly excreted

[1] This work was made possible by a grant from the Nutrition Foundation, Inc.

and so the maximum increase in serum creatinine concentration may have occurred before we got our blood samples. We measured the serum creatinine concentration in 32 nurses about an hour to an hour and a half after a lunch that contained soup and meat. The average concentration was 0.98 mgm. per 100 ml. The average obtained in 16 nurses who had taken no soup or meat was 0.91 mgm. per 100 ml. From the standard errors of these means it was calculated that such a difference would arise from chance in about 5 of every 100 repetitions of the experiment. It is thus probable that a somewhat greater variability than the one we report in Table IV would have been found if we had made our observations at times other than those we selected.

We shall restrict ourselves to the present series of observations in determining the variability of serum creatinine concentrations. The group involved was distinguished from the 1940 group by the fact that one of the subjects was a woman. Though the point has never been established beyond reasonable doubt there is some indication that creatinine concentrations are a little lower in women than in men (7). In our series we have 257 observations on our 9 male subjects and 29 on E, our single woman subject. The mean for the men was 1.03 mgm. per 100 ml. and for subject E 0.95 mgm., but, from the standard errors of these means, it can be shown that the difference between them might readily arise by chance. We conclude that, for our particular purpose, we may include subject E and use the total variability in judging the significance of observed concentrations in both male and female patients.

2. *The method of measurement*

The photoelectric cell has facilitated the measurement of the color of creatinine picrate but even so the order of precision is not high for normal serum creatinine concentrations. When tungstate filtrates are used, the color is so faint that the limit of capacity of the photoelectric cell in the Evelyn colorimeter is approached. In 1940 we used the standard Folin Wu method (8) except that we used an Evelyn instead of a Duboscq colorimeter. In the present series of observations 2 modifications were introduced. We took note of Peter's (9) statement that a 1.175 per cent solution of purified picric acid was preferable to the saturated solution usually used. At the suggestion of Phillips (10) all the reagents were brought to the same temperature before the reaction was started in a water bath that varied between 24.5° and 26.2° C., and this temperature was maintained until the color was read exactly 10 minutes after the reaction was initiated. When we compare those of the 1940 measurements with those of the present measurements which are strictly comparable it becomes clear that there is a difference between them which we can attribute only to these changes in technique.

The difference becomes apparent when we use the information given in Table IV. All of the examples of our present measurements fall within the range given by the average, 1.02 mgm., plus and minus twice the standard deviation of 0.118 mgm.; but 5 of the 29 measurements

made in 1940 exceed 1.26 mgm., which is the upper limit of this range. For our purpose this is important because it is apparent that the standard we have set up is applicable only to measurements made with the particular technique we have described.

We have made these color determinations because we believe they measure creatinine. But if all we have been doing is to determine the variability of a color produced by various unknown chromogens there is no reason that we should suppose the resulting color to have any necessary reference to the kidney nor need there be any propriety in our proposal that we should take an increase in this color as a ground for questioning renal creatinine-excreting capacity. What direct evidence we have on this point, though of necessity it is neither statistically convincing nor wholly conclusive, is due to the development by Miller and Dubos (11) of 2 bacterial enzyme systems that specifically destroy creatinine. Having found an average serum or plasma "creatinine" concentration of 1.09 mgm. per 100 ml. in 15 normal individuals, they observed that these enzymes did away with a color equivalent to that produced by 0.99 mgm. of creatinine per 100 ml. There is so little difference between 1.09 and 0.99 mgm. that we are left free to suppose that all of the color might have been due to creatinine[2] But, however that may be, our principal reason for confidence in a relation between the color and renal function is the indirect evidence provided by the, for the most part, unrecorded experience of a multitude of clinicians who have watched

[2] It should be noted that in the serum of uremic patients Miller and Dubos found that not all of the color could be accounted for by creatinine (12). If this is confirmed we shall have to remember that at the higher levels of creatinine retention we cannot expect any direct relation between the degree of renal failure and the degree of the color we measure.

the "creatinine" concentrations of their patients' sera gradually rise as the functional capacity of their kidneys slowly fell.

3. *The individual variability of the subjects*

In Table III we give the averages for each subject, derived usually from 12 determinations on the 0.5-gram, 6 on the 1.5-gram and 12 on the 2.5-gram level of protein consumption. The averages for each subject for all 3 diets is given in the last column of this table, arranged in order of ascending magnitude. There is a gradual increase from 0.93 mgm. to 1.10 mgm. per 100 ml. and no one subject stands out as singular. Subject D, whose blood urea concentration was so high relative to the others (1), falls here well within the range of individual variation.

TABLE III

Individual average serum creatinine concentrations from observations made at all times of day on varying levels of protein consumption

Subject	Food protein consumption			
	0.5 gram protein per kgm.	1.5 grams protein per kgm.	2.5 grams protein per kgm.	Individual averages for the 3 diets
	mgm. per 100 ml.			
G	0.92	0.92	0.95	0.93
H	0.96	0.88	0.94	0.93
E	0.91	0.96	0.99	0.95
J	1.05	0.98	0.98	0.98
A	1.06	1.03	1.01	1.03
B	1.08	1.01	1.05	1.05
C	1.07	1.11	1.09	1.09
D	1.07	1.14	1.08	1.09
F	1.13	1.04	1.08	1.09
I	1.05	1.13	1.13	1.10

RESULTS

The measurements given in Table IV show quite decisively that variation in protein consumption has no effect in the serum creatinine concentration. Our standard can therefore rest on all the 286 determinations. The average is 1.02 mgm. per 100 ml. and the standard deviation is 0.118 mgm. If we add twice the standard deviation to the average we have an upper range from 1.02 to 1.26 mgm. within which all but about 2 per cent of determinations will lie unless some other factor intervenes that did not exist in the subjects or in the conditions that we observed. The nature of the factor remains, of course, a question for clinical judgment.

TABLE IV

Averages and variabilities of serum creatinine concentrations on varying and on all levels of protein consumption

	Food protein consumption			
	0.5 gram protein per kgm.	1.5 grams protein per kgm.	2.5 grams protein per kgm.	All observations on all 3 diets
	mgm. per 100 ml.

	per cent			
Coefficient of variation	12.4	12.1	10.3	11.5

DISCUSSION

Figure 1 contrasts the behavior of creatinine and urea as the protein consumption of normal individuals is increased.

With creatinine-concentration measurements we are delivered from the effect of a variable that obscures the significance of the urea or non-protein nitrogen determinations. We thus have a measure that we can use with assurance in the numerous clinical situations in which we have no precise information as to the rate of urea formation.

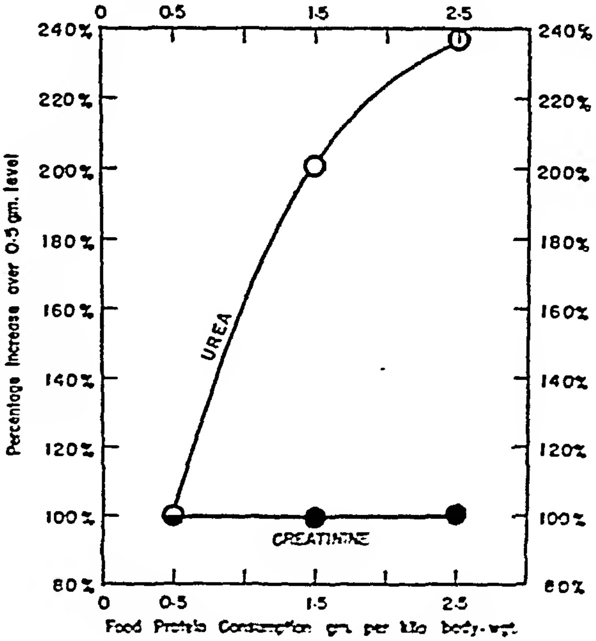

FIG. 1. FOR SERUM CREATININE CONCENTRATION OF NORMAL INDIVIDUALS

CONCLUSIONS

1. The average of 286 determinations of creatinine concentration in the serum of 10 medical students was 1.02 mgm. per 100 ml. The range of variation that included 95 per cent of the measurements extended from 0.78 mgm. to 1.26 mgm. per 100 ml.

2. Variation in protein consumption from 0.5 to 2.5 grams protein per kgm. body weight had no effect on the serum creatinine concentration.

We are indebted to Dr. Horace Gray for advice and help in the statistical treatment of the data.

A CLINICAL METHOD FOR THE APPROXIMATE DETERMINATION OF SERUM CREATININE CONCENTRATION

By T. ADDIS, EVALYN BARRETT, AND JEAN T. MENZIES

(*From the Department of Medicine, Stanford University School of Medicine, San Francisco, California*)

(Received for publication January 28, 1947)

In our two preceding papers (1, 2) we have given measures of the variability of blood urea and serum creatinine concentrations in normal individuals who were taking known amounts of food protein. These standards have been found useful in forming an opinion as to the renal status of ambulatory patients with proteinuria. As time goes by and successive measurements are made we are able to judge the direction of change in the functional capacity of their kidneys. Such data are of primary clinical value because they are elements in the more complex judgments on which therapeutic decisions depend. But our own experience has forced us to conclude that these methods require supplementation by some procedure more in consonance with the immediate and practical requirements of day to day clinical work. Every day, in every clinic for renal disease, there are apt to be several new patients in whom an answer to the question as to the extent of their renal lesion is needed. This is not usually obtainable from their histories and physical examinations or from the state of their urines. At best these methods may suggest the existence of suburemic or uremic states, but at times they fail us altogether. It is the determination of the concentration of creatinine in the serum that transforms these indications into knowledge on which treatment can be based. Now, in theory, there is no reason why a precise measurement of creatinine cannot be obtained within half an hour or so of drawing the patient's blood. But this determination involves a complete separation from the patient and an absorption in technique that may be inadvisable or impossible. It is then that we need a quick approximate measure of the serum creatinine level to be used for the purpose of general orientation and immediate preliminary treatment.

We happened one day to observe that when the alkaline sodium picrate used for the determination of creatinine was added to whole serum the mixture remained quite clear. As the tube was watched, the orange color of creatinine picrate was seen to appear but as time went on the color deepened so that a few hours later it had become a deep orange, far deeper than the color derivable from the creatinine in the serum we were using. It seemed that there must be some chromogen other than creatinine in whole serum. The two colors can, however, be distinguished. The creatinine color develops quickly, even faster in serum than in a protein-free filtrate from the same serum, whereas the non-creatinine color develops very slowly. In Figure 1 it is shown that within 6 minutes after the addition of alkaline picrate to serum the rate of color formation has already become asymptotic. By making the determinations at 6 minutes we were thus able to measure the quantities of creatinine we added to serum.

In the clinical method we describe, the creatinine color in the serum is read against potassium dichromate standards. The comparison is facilitated by diluting the standard alkaline picrate solution with an equal volume of water. This solution is conveniently prepared by adding 1 ml. of 10 per cent sodium hydrate to 5 ml. of 1.175 per cent picric acid, and diluting with water to 12 ml. If care is taken to avoid parallax errors this can be done in a 15-ml. graduated centrifuge tube, adding the required volumes to the mark by means of capillary pipettes. One ml. of the thoroughly mixed alkaline picrate is then added to 0.5 ml. of serum and an interval timer is set to ring at 6 minutes. The mixture of serum and picrate is then poured into a 4- by ½-inch test tube similar to the sealed tubes in which the potassium dichromate standards are kept. Tubes that have the same or almost the same diameter, by caliper measurement, and that are made of the same colored glass are selected. In comparing the colors we use a 3-slot comparator with a ground glass background illuminated by a daylight bulb. After 3 or 4 minutes the comparison with the standards may be started, but the final decision must be made

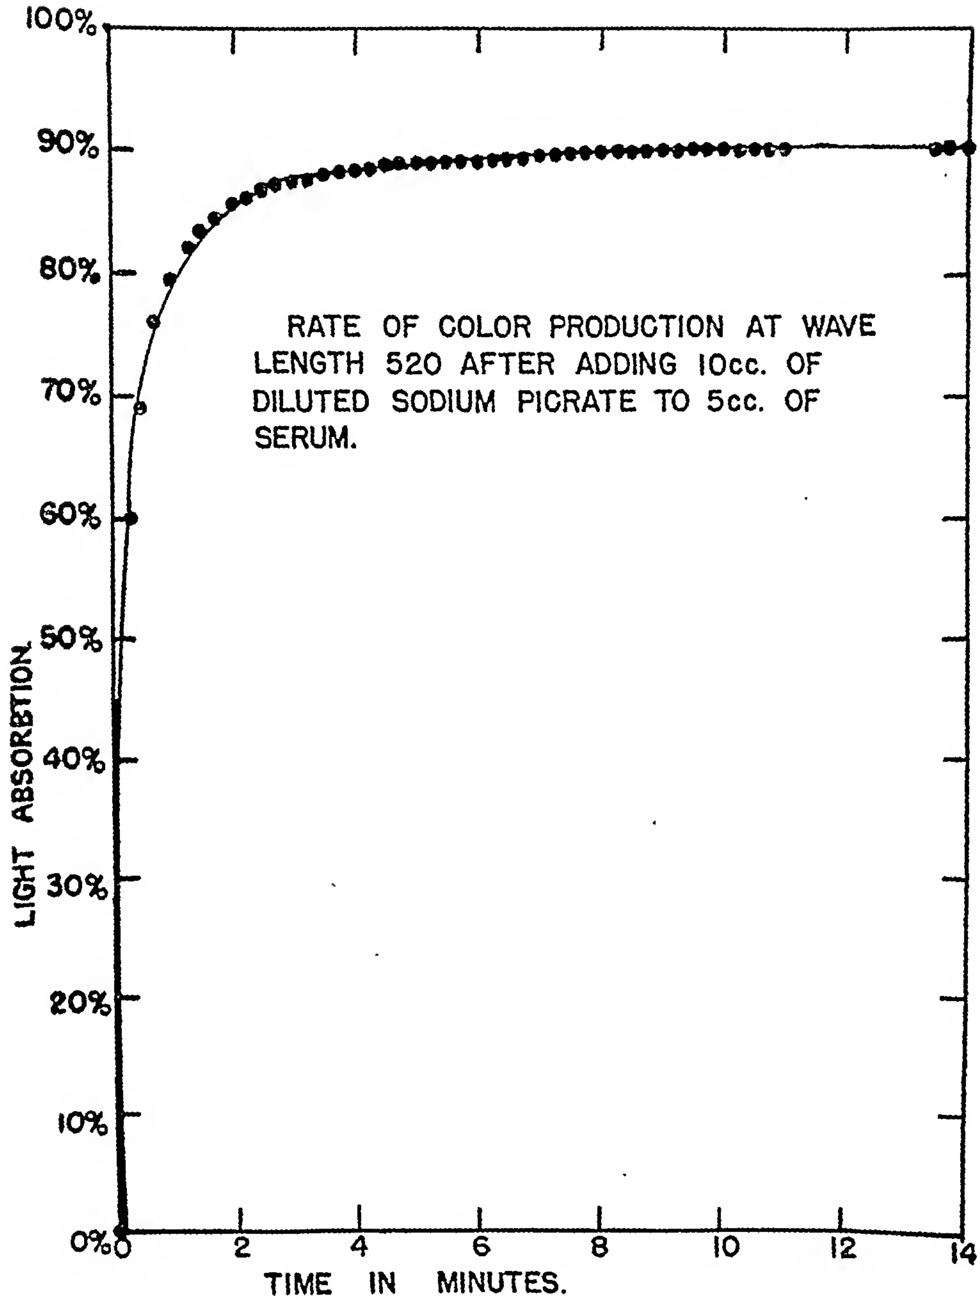

Fig. 1

when the bell rings 6 minutes after the picrate is added to the serum.

It is curious and fortunate that the colors of certain concentrations of potassium dichromate and of creatinine picrate in sodium picrate should be indistinguishable by eye and should give almost an identical light absorption when a 520 filter is used. It was potassium dichromate that Folin used as a standard in his first creatinine determinations (3). Not only do potassium dichromate solutions give a perfect match but, once evaporation is prevented, they remain unchanged for years. In Table I we list the quantities of potassium dichromate that, when dissolved in water and brought to a volume of 100 ml., give colors corresponding with the colors that develop in 6 minutes in sera containing the designated creatinine concentrations (mgm. creatinine per 100 ml. of serum).

Provided that the few measurements are made with care and granted that the user has the capacity to distinguish shades of yellow and orange, it has been found by many that this method is of value in the immediate management of new patients. It cannot give, of course, a continuous series of creatinine concentrations for classification, but it does afford grounds for the division of our pa-

TABLE I

Potassium dichromate concentrations (mgm. potassium dichromate dissolved in water and brought to 100-ml. volume)

These concentrations have colors that are equivalent to the colors obtained by the direct and filtrate clinical methods from sera containing the given concentrations of creatinine (mgm. creatinine per 100 ml. of serum).

Direct method		Filtrate method	
Potassium dichromate	Serum creatinine	Potassium dichromate	Serum creatinine
mgm. per 100 ml.		*mgm. per 100 ml.*	
200	0.47	50	0.27
250	0.64	100	0.57
300	0.80	200	1.14

		9000	22.17

tients into 4 categories: those who may have concentrations within the normal range, and those with a slight, a moderate, or a pronounced elevation of concentration.

There are conditions in which the color of the serum is altered and then we cannot use the direct method. Bilirubinemia is an example, though one rarely seen in ambulatory patients with renal disease. Hemoglobinemia is more common, but it is almost invariably an artifact.[1] Lipemia constitutes our almost sole source of difficulty. The fat alters the quality of the color and when we try to read it against the dichromate tubes we find that we somewhat overestimate the creatinine concentration. As might have been anticipated, we failed to find any fat solvent, and we have tried many, that is able to clear these lipemic sera. In such cases, or when the serum is colored with bile pigment or hemoglobin, we can get water-clear filtrates by precipitating the color along with the serum proteins. We take 1.5 ml. of serum in a graduated centrifuge tube, add 3 ml. of 0.5 M. sodium acetate-acetic acid buffer at pH 5 to the 4.5 ml. mark, mix, close with a vaccine stopper through which a hypodermic needle is inserted, and place the tube in a beaker of boiling water for 5 minutes. The coagulum is then emptied onto a small filter and, when a litle more than 1 ml. of filtrate has run into a graduated centrifuge tube, the filter is removed and the volume reduced to exactly 1 ml. by a capillary pipette. Then we add 0.5 ml. of undiluted alkaline picrate (1 ml. of 10 per cent sodium hydrate plus 5 ml. of 1.175 per cent picric acid). The interval timer is set to ring at 10 minutes and the comparison is made with the dichromate standards given in Table I for the filtrate method.

This filtrate method was the one we first developed. It was conjoined with a similar method for the determination of the rate of creatinine excretion in the urine. Desiring a method requiring no more apparatus than graduated centrifuge tubes and capillary pipettes, and avoiding the need for color standards, we diluted the urine color until it matched the color of the serum and thus derived an approximate "creatinine clearance." However, by comparison with results obtained on the same serum and urine by precision methods, and through experiments on rats from which known proportions of the total renal tissue had been removed, we learned that, as a rule, a decrease in creatinine clearance arose not from any diminution in the rate of creatinine excretion but from an increase in the concentration of creatinine in the serum. So when we found that we were able to approximate the serum creatinine concentration without removing the protein and usually learn as much from it as we could from a clearance, we felt that we had probably reached that maximum of rapidity and ease of operation that is an indispensable prerequisite for a clinical as contrasted with a laboratory method.

It seems to us that this distinction between what we call laboratory and clinical methods necessarily involves a differentiation in the criteria by which they should be judged. A laboratory method belongs to science. It is an instrument for an exact description, under isolated and controlled experimental conditions, of what is measured. For this purpose a high order of average precision is ad-

[1] We draw the blood into a vaselined syringe. The needle is detached before transferring the blood to a centrifuge tube in which it is allowed to clot. When the blood is forced through the needle, some lysis of red cells may be induced.

vantageous. Often this precision requires a considerable complexity of mechanism. Occasionally a fault in one or other of the elements involved may lead to large error. The scientist accepts this possibility with equanimity. He knows that in the end such errors will reveal themselves as gross deviations from the general law he intends to derive from his measurements. A clinical method, on the other hand, is a doctor's tool. Reliability in each and every observation rather than average precision is its virtue. It is best, therefore, if the method has such a transparent simplicity that any error in its operation is at once apparent. The clinician is looking not for that which is general and abstract but for that which is individual and concrete. Every patient is for him an end. So he cannot afford to use a method, no matter how precise, that may at times mislead him with respect to the individual. What he wants is a universal dependability within known limits of error that need not be so very narrow.

We have evaluated this clinical method in terms of its greatest errors. In 93 patients the serum creatinine concentration was estimated by the standard Folin-Wu method, using the Evelyn colorimeter as well as by the direct addition of sodium picrate to serum (the clinical method). The series was divided into 4 groups: first, those in whom the serum creatinine concentration was not certainly abnormal, and the other 3 into those with slight, moderate, and pronounced increases in concentration. In Table II we give the maximum minus and plus errors of the direct clinical method for each group on the assumption that the photoelectric measurement gave us correct values.

In Table II we give the minus errors first because it is they that are dangerous. Even in these worst examples there is no case in which we were seriously misled. Always we were able to pick out the patients who had an increase clinically important to recognize. We believe, therefore, that this is a dependable method in the clinical sense, for in many hundreds of observations made since this series was completed there has been no single patient with serious renal failure that we have failed to detect by this simple procedure.

TABLE II

The largest errors incurred in the District Clinical Method as derived from comparison with determinations made by the precision method

Clinical subdivision	No. of patients	Minus errors	Plus errors
		mgm. per 100 ml.	
Possibly normal	63	0.6 instead of 1.2	2.1 instead of 1.1
Slight retention	15	3.0 instead of 3.3	3.0 instead of 2.3
Moderate retention	9	7.1 instead of 7.9	8.6 instead of 7.6
Marked retention	6	7.9 instead of 9.3	9.3 instead of 8.1

CONCLUSIONS

1. A clinical method designed to reveal the existence of varying levels of increase in serum creatinine concentration is described.

2. A modification of the method is given for use when the serum is lipemic or colored with bilirubin or hemoglobin.

THE CORRELATION BETWEEN THE ALBUMIN AND ALPHA GLOBULIN CONTENTS OF PLASMA [1]

By BACON F. CHOW

(From the Division of Protein Chemistry, The Squibb Institute For Medical Research, New Brunswick, N. J.)

(Received for publication January 28, 1947)

The hypoalbuminemia which accompanies insufficient protein intake has come to be generally accepted as a diagnostic sign of protein deficiency (1). Experimental study of dogs depleted in protein by low protein diet feeding, manifests the same marked decrease in the plasma albumin, but not in the plasma globulin (2). Further study has shown this condition to be also characterized by an increase in the concentration of alpha globulins (3, 4). This loss of albumin, if expressed as total protein in circulation, becomes more apparent, since protein depletion is commonly accompanied by a decrease in plasma volume (4, 5). On the other hand, the total circulating alpha globulins remain essentially constant and other globulins decrease slightly. It would seem possible from these considerations that the decrease in the concentration of albumin and the increase in the concentration of alpha globulins might together furnish an index of the degree of protein depletion more valuable than that obtained from the albumin alone.

Were such a relationship to hold for man, as it would appear to hold for dogs under experimental conditions, then it would permit the utilization of the ratio of the two moieties of plasma protein as a measure of depletion.

The possibility has been examined by determining the concentration of plasma albumin and alpha globulins in the plasma of a number of patients with several types of diseases and with different levels of plasma protein concentration. The estimations were based upon data derived from electrophoretic patterns of plasma. A limited number of patients were also studied before, during, and after the administration of several protein hydrolysates to ascertain whether an increase of the percentage of plasma albumin is accompanied by a reciprocal change in the plasma alpha globulins. The results of these studies are the subject of this communication.

EXPERIMENTAL

Twenty ml. of blood from each patient under investigation were introduced into a centrifuge tube containing solid sodium oxalate as anti-coagulant. After centrifugation about 8 ml. of the plasma were diluted with an equal volume of diethylbarbiturate buffer of pH = 8.4 and ionic strength of 0.10 and then dialyzed against the same buffer for 24 hours or longer. After adequate dialysis the bag was opened and the solution was electrolyzed according to the technic of Longsworth (6). The electrolysis was carried out for a sufficient length of time (3 hours) to permit a clear-cut separation of alpha globulins from the albumin. The total plasma protein concentrations were determined by micro Kjeldahl.

RESULTS

One hundred ninety-eight samples of plasma taken from patients with several diseases were analyzed. The results are illustrated in Figure 1, in which per cent of plasma albumin is plotted against per cent of alpha globulins and a curve is fitted to the data. The distribution of the data about the mean is reasonably normal as indicated by the lines in the figure demonstrating the areas of 1 and 2 standard deviations. A correlation co-

[1] The author is indebted to Shirley DeBiase for her technical assistance in electrophoretic analyses.

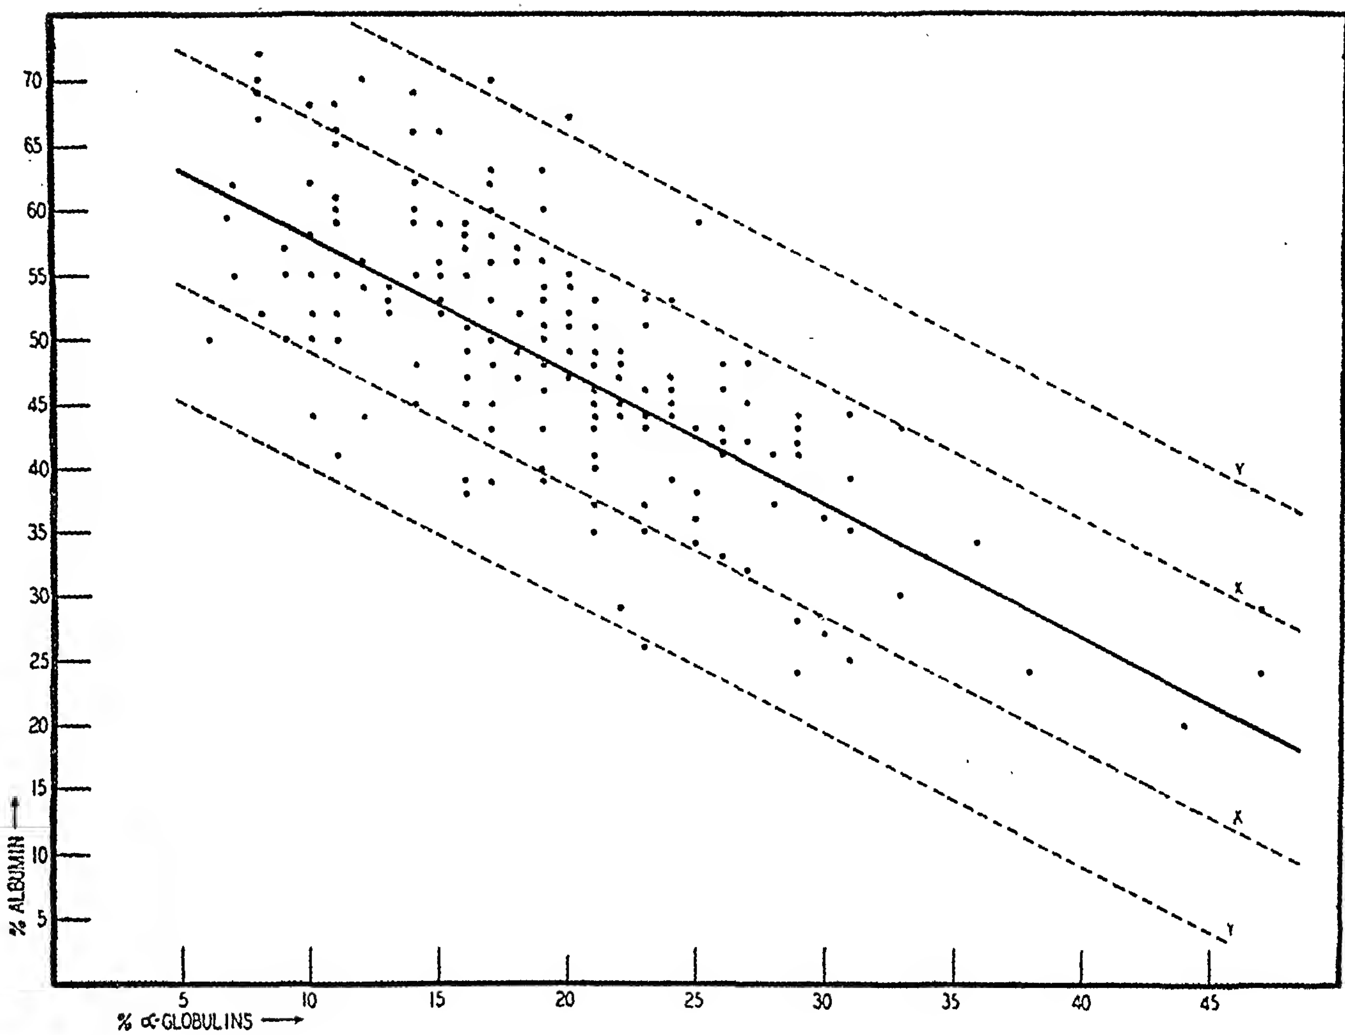

FIG. 1. THE RELATIONSHIP BETWEEN THE PERCENTAGES OF ALBUMIN AND ALPHA GLOBULINS

efficient (7) of −0.63 with a standard error of ±0.04 was also obtained by arranging the data according to the albumin levels grouped at intervals 5 per cent apart (Table I). A negative correlation coefficient of 0.4 or greater is commonly considered statistically significant; consequently the results demonstrate an inverse relationship between the concentrations of albumin and alpha globulins. However, the correlation is not sufficiently close to provide useful information when one considers a single sample of serum.

A similar attempt was made to establish a correlation between the per cent albumin and total plasma protein concentration. However, the data reveal no relationship with statistical significance. Twenty-five samples with total protein concentrations of 6.5 grams per cent or even higher, have albumin levels between 30 per cent and 40 per cent. At the same time, 33 samples of plasma with a protein concentration of 6.5 grams per cent or less have protein concentrations as high as 50 per cent or above. Thus, there appears to be no relationship between per cent albumin and plasma protein concentration. Unfortunately the plasma volumes of these patients are not available.

A casein hydrolysate [2] or other commercially available hydrolysates (at a dose of about 5 to 6 grams per kilogram body weight per day) were administered orally to 11 patients for several weeks. The first 8 patients (column I, Table II) were hypoalbuminemic. The 9th patient (Urban) had low protein concentration (4.8 gram per cent) but normal albumin content before treatment. The remaining 2 patients (Migut and Kjaer) had normal plasma protein concentration and normal albumin content.

The data do not constitute a comparison of the relative effectiveness of the various hydrolysates

[2] The casein hydrolysate was supplied by E. R. Squibb & Sons.

used. However, they do demonstrate that the administration of an adequate protein hydrolysate brings about plasma albumin regeneration despite differences in the state of hypoproteinemia. As is to be expected, this is most marked where the hypoalbuminemia is severe. Also, the increase of per cent of albumin is accompanied by a drop in alpha globulins. It is interesting to note that the albumin content of Summelensky was 39 per cent before treatment, was increased to 65 per cent after 3 weeks of treatment, but dropped to 43 per cent after 8 weeks of treatment. During the corresponding periods, the per cent of alpha globulins dropped when the albumin increased and increased when the albumin decreased.

The relationships between the concentrations of plasma albumin and alpha globulins in the second samples from these 11 patients were plotted in the same manner as the random samples in Figure 1. The relationships between these two moieties at different levels of protein concentration in the individual patient were generally closer than that of the random samples shown in Figure 1. This fortifies the view that an inverse relationship between the two usually exists, but again it is to be emphasized that the ratio of the two fractions is not useful in the evaluation of the nutritional status of any single patient. The compositions of the other plasma protein components are recorded in Table II, but the effects of administration of the hydrolysates on these components are erratic and no conclusion can be drawn.

TABLE II

DISCUSSION

Electrophoretic analysis is a useful tool for the determination of the composition of plasma proteins. During the past few years, numerous investigations were made to correlate the change in plasma protein pattern with a specific disease. It has been found that diseases such as hyperthyroidism (8), malaria (9), pneumonia (10), streptococcus infections, relapsing fever, and scarlet fever (11) are accompanied by a rise in alpha globulins, some depression of albumin, and occasionally a rise in other globulins. These findings have usually been attributed to the disease rather than, as seems likely, the protein deficiency which is incidental to the disease.

The data presented include sera from 76 patients with peptic ulcer, 51 patients with tuberculosis, 25 patients with malnutrition, and 37 with miscellaneous conditions. These show that a lowering of albumin is generally accompanied by a rise in the alpha globulin. This increase, although statistically significant, is not sufficiently close for clinical use in the evaluation of the state of protein nutrition of the individual patient. The relationships are sufficiently similar to those observed in simple protein depletion to lead one to conclude that the alterations of normal plasma pattern are in fact due to the same fundamental mechanism, *i.e.*, inadequate protein retention as an incidental phenomenon in each of the diseases studied. It is not surprising then that the patients with a low albumin content of the plasma are treated by the administration of an adequate protein hydrolysate, thus correcting the protein deficiency; a rise of albumin occurs quite promptly and this is accom-

panied by a decrease in the concentration of alpha globulins.

SUMMARY

One hundred ninety-eight samples of plasma from patients with several diseases were analyzed electrophoretically. There appears to be a correlation between the decrease in albumin and the increase in the per cent of alpha globulins. The significance of this relationship with respect to diseases is discussed.

BIOCHEMICAL AND HEMODYNAMIC CHANGES FOLLOWING THE SUBCUTANEOUS INJECTION OF GLUCOSE SOLUTION [1]

By T. S. DANOWSKI, A. W. WINKLER,[2] AND J. R. ELKINTON

(From the Department of Internal Medicine, Yale University School of Medicine, New Haven, Connecticut)

(Received for publication January 30, 1947)

It is well known that the loss of extracellular electrolyte may contribute to or even produce cardiovascular collapse. This is manifest in its most striking form in the crisis of Addison's disease (1), in diabetic acidosis and coma (2, 3) and in patients losing large amounts of fluid from the gastrointestinal tract (4, 5). In these conditions the losses of the sodium ion, the chloride ion, and water are often the primary and sole cause of circulatory collapse. The chain of events which ends in clinical shock following salt depletion has been experimentally studied (6, 7). Abstraction of salt from a healthy animal via the peritoneal route according to the Darrow-Yannet technique (8) produces hypotonicity of the extracellular fluid. Water then moves into the cells in response to osmotic forces. The consequent decrease in extracellular fluid volume occurs in both the interstitial fluid and the plasma. Diminution in the latter is readily detected by the rise in the hematocrit and in the concentration of the total serum protein. It is of particular significance that some of the circulating plasma protein is lost and that in terms of proportionate change, the plasma volume diminishes much more than does the extracellular fluid as a whole (7). These alterations in the composition of the fluid in the extracellular and intracellular compartments are an invariable accompaniment of salt depletion. If acutely induced, and of sufficient magnitude, the loss of salt results in a shock state akin to that seen following burns, trauma, or hemorrhage (9). The circulation slows and the venous pressure falls. These changes are associated with a diminished cardiac output (7). If untreated, death ensues.

It seems highly probable that during absorption of a glucose hypodermoclysis salt is removed from the circulation in a manner identical with that observed following the injection of fluid intraperitoneally. Moreover, it has been recognized clinically that the subcutaneous administration of non-electrolyte-containing fluid to certain patients may precipitate circulatory collapse and death. This has been noted in particular in patients with mercury poisoning and with diabetic coma (10, 3). Inasmuch as these conditions are known to be frequently associated with some measure of antecedent salt and water loss, it is possible that the shock state is precipitated by further salt depletion during glucose hypodermoclysis (11). Since the parenteral administration of glucose solutions to all types of patients, even those on the verge of cardiovascular collapse, is a commonly accepted procedure, the biochemical and hemodynamic changes which occur have been studied experimentally and are reported in this paper. It has been found that the subcutaneous administration of a sufficient volume of non-electrolyte-containing fluid usually produces salt depletion, and that this can result in peripheral vascular collapse.

MATERIALS AND METHODS

The effects of glucose solutions on circulatory efficiency have been studied in animals and in human patients in the post-absorptive state.

Two healthy female dogs weighing 7.96 and 10.86 kilograms were given 5 per cent glucose solution by subcutaneous injection, 720 ml. and 1,000 ml. respectively, during a 10- to 15-minute period. In the first experiment, measurements were made prior to and at 2.0 hours after the injection of the glucose solution. In the second, observations of cardiovascular function were made at intervals during 2.5 hours. These included determination of the direct arterial blood pressure, the circulation time, the cardiac output, and the volume of urine elaborated. The methods and the calculations employed have been described in a previous paper together with the procedure employed for measurement of changes in the plasma volume, extracellular fluid volume, and the circulating plasma proteins (7). These involve the determination of the whole blood hematocrit and non-protein ni-

[1] Aided by a grant from the Fluid Research Fund of Yale University.

[2] Dr. Winkler died June 26, 1947.

trogen, the concentration of serum protein, and the balance of serum chloride.

Glucose hypodermoclyses have also been given to 4 patients in amounts ranging from 32 ml. to 72 ml. per kilogram of body weight. In 2 of these subjects, and in one other, the effects of intravenous glucose solutions on circulatory efficiency have been determined in control experiments as well. The studies with patients differed from the animal experiments in that the parenteral fluids were administered over a period of several hours, and the cardiac output was not measured. In 2 of the experiments the nitrogen clearances were followed as well as the changes in effective renal plasma flow as measured by the clearance of para-amino hippurate (PAH)[3] (12).

RESULTS

At 2.0 and 2.5 hours, respectively, following the administration of glucose solution subcutaneously in dogs 110A and 55P, profound circulatory collapse was present. The circulation time rose to 12 and 15 seconds from initial values of 8 and 7 (Table I). The mean arterial blood pressure declined 25 and 35 mm. Hg, respectively. The cardiac output diminished to ⅓ or ½ of the predepletion values.[4] Urine elaboration ceased almost entirely.

The biochemical changes were equally definite. The concentration of chloride in extracellular fluid decreased by more than 10 meq. per liter. Hemoconcentration appeared as indicated by the increase in hematocrit and serum protein content; plasma volume diminished.

In patient L. M., equally striking biochemical and hemodynamic changes followed the subcutaneous administration of glucose solution (Table II). Hypochloremia, hemoconcentration, diminution of plasma volume, loss of circulating plasma protein, hypotension, and lengthening of the circulation time occurred. In this patient, therefore, the injection of glucose solution, 72 ml. per kgm. of body weight, produced unequivocal circulatory collapse which responded to treatment with plasma and physiological saline.

In patients C. M., W. O., and M. W. the biochemical changes at the end of 4.0 to 5.6 hours were less pronounced, but nonetheless definite. The hematocrit, the hemoglobin, and the serum protein concentration all rose. The concentration of serum chloride fell in 2 of these subjects and was unchanged in 1; the plasma volume fell in all 3 subjects; plasma protein left the circulation. The effects of these changes on circulatory efficiency were either minimal or absent. The circulation time was prolonged in only 1 of these subjects (patient C. M.). Nitrogen clearance declined temporarily in 1 of the 2 patients in whom it was measured (patient M. W.). Renal plasma flow as measured by sodium para-amino hippurate did not change significantly (patients W. O. and M. W.).

In the control experiments, on the other hand,

[4] In dog 110A a preliminary determination of cardiac output was not done. If the mean value for cardiac index, as determined by us in a large series of normal dogs, of 5.45 ± 1.43 liters per minute per square meter is taken as the initial value (7), the final value represents a decrease in cardiac output of 56 per cent.

administration of comparable amounts of glucose solution intravenously failed to induce hypochloremia, hemoconcentration, and loss of circulating plasma protein, or to affect adversely the circulatory dynamics (Table III). Urine volumes were maintained, or actually increased, throughout the periods of observation.

DISCUSSION

These studies with animal and human subjects provide unequivocal proof that the subcutaneous injection of fluid which does not contain electrolyte may produce a form of salt depletion. Even though the electrolytes which diffuse into the subcutaneous pool of fluid are still within the body as a whole, they have been removed from the circulatory system and from the usual confines of interstitial fluid. Such segregation depletes the rest of the body of salt. This can produce circulatory collapse.

In the studies reported here, definite impairment of circulatory efficiency occurred in the dog experiments and in 1 of the 4 experiments with humans. Salt depletion definitely was present, however, in 5 of the 6 subjects given glucose solution by subcutaneous injection. Hence, in the patients who failed to develop evidences of cardiovascular collapse the salt depletion was either of insufficient magnitude or only a transient phenomenon. The 2 dogs received 92 ml. and 90 ml. of glucose solution per kgm. of body weight. If none of the injected fluid had been absorbed and if chloride had diffused into it to the point of equilibrium with the body fluids, 32 and 33 per cent respectively of the total body chloride would have been segregated.[5] On the other hand, even though all 4 patients received approximately 3 liters of fluid subcutaneously at comparable rates of flow, the per kilogram doses varied widely. Patient L. M. who developed shock received 72 ml. per kgm.; 33 per cent of the chloride was thereby removed from the rest of the extracellular fluid. The other 3 patients were given only 32 to 41 ml. per kgm. As a consequence, a distinctly smaller amount of body chloride, 16 to 19 per cent, was segregated in the subcutaneous pool. This was enough to produce the typical biochemical changes but not sufficiently great to result in cardiovascular collapse. These are apparently the limits of the changes in most patients, since a glucose hypodermoclysis is usually a benign procedure. Under these circumstances the abstraction of body electrolytes is both minimal and temporary, since the salt is returned to the extracellular fluid as a whole as the clysis is absorbed. This salt depletion may, however, be augmented and cardiovascular collapse produced, as evidenced in the dog experiments and in 1 of the 4 studies with human subjects, by increasing the relative volume of the glucose solution.

Shock may develop, however, even after a comparatively small hypodermoclysis. This is particularly true in patients who already have some measure of salt depletion as a consequence of their illness, and in those who are on the verge of circulatory collapse because of trauma, burns, etc. In these patients even a relatively small loss of extracellular electrolyte may plunge them into manifest shock. This has been noted clinically and reported (3, 10). In patients such as these, with the efficiency of the circulation already partially compromised, subcutaneous fluid is poorly absorbed and the salt depletion ordinarily produced by small volumes of fluid is magnified and prolonged. Shock is, therefore, not only precipitated, but perpetuated as well.

It cannot be assumed, therefore, that glucose solution can be administered subcutaneously with impunity to all patients. Particular care must be exerted toward the identification of patients in imminent circulatory collapse, with or without salt depletion. In subjects such as these it is imperative that the subcutaneous administration of glucose solution be either preceded or accompanied by measures to prevent or combat shock. It should be an invariable rule that, whenever subcutaneous parenteral fluid is to be administered, the saline fluids precede salt-free glucose solutions. If incipient shock is suspected the patient should be treated with blood, plasma, or gelatin and by res-

[5] Undoubtedly these assumed conditions were not realized; the degree of absorption of the fluid and its chloride concentrations were not measurable. But the values for chloride segregation obtained on these assumptions indicate maximum limits and are valid for comparison between experimental subjects. The initial extracellular fluid volume is also assumed to be 25 per cent of the body weight in dogs and 20 per cent of the body weight in humans.

toration of salt deficits prior to the use of subcutaneous glucose.

Experimental studies provide a logical basis for therapy of patients in whom shock has developed through the inadvertent use of glucose solution subcutaneously. It has been shown that, within certain limits of time, shock produced by acute salt depletion can be completely, or almost completely, reversed by the simple replacement of the salt deficit with hypertonic solutions of saline (13). It has been found, however, that the use of colloid solutions together with replacement of salt provides a distinct margin of safety (14). Hence blood or plasma should be administered in addition to salt solutions in treating salt depletion shock.

The lack of adverse effects following intravenous glucose solutions in the control experiments in Table III does not indicate that this is invariably a safe procedure. The patients studied had no demonstrable disorder of the cardiovascular-renal system and were not salt-depleted. The extra fluid merely increased the volume of urine. No data are available to indicate whether such a procedure would be equally benign in patients with antecedent salt depletion, on the verge of circulatory collapse, and unable to excrete water.

SUMMARY AND CONCLUSIONS

1. Five per cent glucose solution was administered by subcutaneous injection to dogs and to human subjects. The changes induced in the body fluids and circulatory dynamics were studied.

2. The subcutaneous injection of glucose solution usually produced transient salt depletion.

3. Large or rapidly administered hypodermoclyses of glucose solutions resulted in marked salt depletion and circulatory collapse.

4. It seems probable that circulatory collapse may be precipitated even with small glucose hypodermoclyses in patients with incipient shock.

ON THE CONCENTRATION OF PROTEIN IN SAMPLES OF NORMAL URINE MEASURED BY ITS SURFACE ACTIVITY

By R. GUNTON and A. C. BURTON

(*From The Department of Medical Research, Faculty of Medicine, University of Western Ontario, London, Canada*)

(Received for publication February 3, 1947)

INTRODUCTION

The appearance of albumin in quantity sufficient to give "positive" results by well known "clinical" precipitation tests, has long been regarded as a reliable indication of kidney dysfunction. The reliability, of course, depends on the assumption that in normal physiology, the glomerular "filter" is wholly impermeable to protein molecules. Direct evidence of this came from the beautiful experiments of Richards and his co-workers. Walker, *et al.* (1) found that in some of their samples of capsular fluid in the mammalian kidney the protein was less than 30 mgm. per cent, although the smallest degree of mechanical trauma resulted in the appearance of large amounts of protein. The question of resorption of protein in the tubules has been raised, though Bott and Richards found no evidence of this in amphibia (2). Some textbooks state that protein is not a normal constituent of urine (3). Other textbooks are content to state that "normal urine usually contains a trace of albumin too small to be detected by regular tests" (4). Again a "faint trace" by these tests is variously estimated from 30 mgm. per cent to as much as 100 mgm. per cent of protein (5a and b), and quantitative information as to the amount of protein found in normal urine is hard to find in the literature. Even though there have been discussion and work on the so-called "normal" or "benign" albuminurias (6a and b), quantitative measurements even in this field are lacking.

Bodansky (7) states, without reference, that normal urine contains 2 to 5 mgm. of protein per cent; Kolmer and Boerner (8) give figures that indicate an average of 5 mgm. per cent, and Everett (5) says that normal urine contains 1 to 6 mgm. per cent. Most references are to the classical work of Mörner (9), who found from 2.2 to 7.8 mgm. per cent protein. However, he was more concerned with the chemical nature of the protein and related substances than with a statistical evaluation of the quantity normally present.

The quantitative methods of measurement of protein in urine are capable of measuring much smaller amounts, down to perhaps 5 or 10 mgm. per cent but this is only if relatively large samples are available. Thus, they are not suitable for quantitative studies on the time-course of albuminuria, produced experimentally or pathologically.

It is evident that there is a possibility that a given sample of urine might contain protein in amounts too small to be detected by the commonly used methods, yet this amount could be much greater than the amount found in truly "normal" urine. It becomes of importance to establish in a quantitative and statistical manner, what amount of protein is to be expected in a sample of normal urine. The method to be described is an adaptation of one first demonstrated to us by Dr. J. B. Bateman, for measuring the amount of protein in cerebrospinal fluid, and so used by Bazett and Burton (10). It is essentially the method of Gorter and Grendel (11), for serum proteins, simplified for clinical use and applied to urine.

APPARATUS

The apparatus required is very simple and inexpensive. (See Figure 1.) Surface films are formed on buffer in a plastic tray (of lucite) 36 by 11.5 by 2 cm. over-all, with a well which is accurately 10 cm. wide and 0.5 cm. deep. Black plastic is used for the bottom of the tray, as this greatly facilitates seeing the oil-drops used in the method. Several "barriers" of plastic, 12 cm. long and ¼ inch square in cross section, are required, and one of these is rigidly fixed at right angles to a long guide piece, carrying a scale which shows the area of the well enclosed between the barrier and the end of the tray. All other apparatus (a 5-ml. burette, pipettes, etc.) is standard in chemical laboratories, except perhaps the platinum wire set in a glass handle. The total cost of apparatus is certainly less than $10.00.

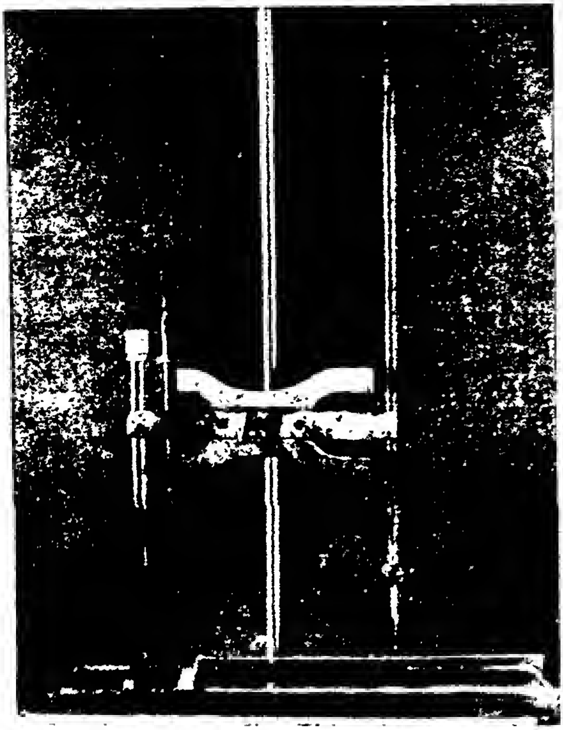

FIG. 1

METHOD

The method consists of measuring the total surface activity of a sample of urine and then the residual activity after protein has been precipitated. The difference gives the activity due to protein. This divides itself naturally into several successive steps:

(*a*) *Preparation of trays and barriers*

The tray and barrier must first be cleaned with distilled water and rendered hydrophobic. We have found that paraffin wax is much less satisfactory as a hydrophobic agent than is ferric stearate. This, though difficult to purchase, is very easily made. The following instructions are given by Dr. A. DeLuca who kindly made the ferric stearate we used:

To some hot water (80° C.) add a quantity of stearic acid. The latter melts forming a layer above the water. Next, add a solution of $FeCl_3$ drop by drop until the water layer is a deep brown. Continue the heating for 15 to 30 minutes with stirring. Let the mixture cool, after which the ferric stearate forms a solid sheet above the liquid. Wash the impure compound by adding it to hot distilled water, and again allowing it to cool. The ferric stearate which reforms on cooling is then broken into small pieces and dropped into a test tube. The latter is placed in a water bath to melt the compound. After cooling the ferric stearate may be removed from the test tube in the form of a solid stick. It may be necessary to pass the test tube momentarily through a flame in order to cause the stick to fall out readily.

All surfaces that will be in contact with the liquids are rubbed with a stick of ferric stearate, then rubbed to a hard polish with paper tissue (Kleenex). This surfacing with stearate should be repeated at frequent intervals, certainly after each day of use of the apparatus.

(*b*) *Buffer used*

A buffer of pH 6.4 (307 ml. of 0.1 M citric acid added to 693 ml. of 0.2 M disodium phosphate) has been routinely used. This pH was chosen as the result of experiments on the surface activity of a given urine sample on buffers of various pH values. The method is most satisfactory from pH 6.0 to pH 7.0. The buffer is poured into the tray until it stands well above the edges, the shape of the meniscus indicating the "unwettable" nature of the stearate-treated plastic material.

(*c*) *Removing contamination*

Contamination by surface-active substances either from the tray and buffers or from the air is inevitable. It is minimized by "sweeping" the surface of the buffer with the barriers repeatedly and wiping the barriers clean between each operation with a fresh piece of paper tissue. This "sweeping" was first discovered by Pockels (12). We routinely have swept the tray 3 times before each "blank" or urine determination.

(*d*) *Forming the protein monofilm*

Protein is so active in forming surface films that for the range of concentration of interest in the research, namely from 0 to 80 mgm. per cent, the sample of urine is first diluted in the ratio of 10 to 1 with distilled water. (One ml. urine was added to 9 ml. of distilled water.) The diluted sample was then placed in the 5-ml. burette. The stop-cock of the burette should have a minimal amount of stop-cock grease, which is itself surface-active. Unless solutions containing organic solvents are left for long periods of time in the burrette, we have found little trouble from contamination with stop-cock grease. Where there is trouble from this source, it can be avoided altogether by using a dropping-pipette having no stop-cock.

To form the protein film, all that is needed is to allow the diluted urine in the burette to drop slowly (at the rate of 1 drop every 2 or 3 seconds) from a small height into the surface of the buffer (method of Gorter and Grendel [11, 13]). The top of the burette should be just high enough so that the drops do not touch the surface but fall on to it. Any surface-active substance tends to form a "skin" on the surface of the drops and when these reach the flat surface of liquid in the tray the material spreads rapidly. It will be noted that the drops persist for 2 or 3 seconds on the top of the buffer before they [illegible]

(e) Measuring the area covered by the film

A barrier pushed along the tray will carry the protein film before it and, after all available space on the surface of the buffer has been occupied by the film, further compression will raise the film pressure as the area decreases. The measurement of area has meaning only if it be made at a definite pressure. To indicate the pressure, the simple device is used of an indicating oil drop, as developed by Blodgett (14), Langmuir and Schaeffer (15). The platinum wire is cleaned by holding in a flame, is then dipped in a test tube of lubricating oil (crank-case oil), and touched briefly to the surface containing the protein film. The oil spreads to a small colorless disc which should not be more than 1 cm. in diameter. As the barrier is pushed up to diminish the area of the film, the area of the oil disc also decreases and its thickness increases, until it is thick enough to show interference colors. These are seen much better in diffuse daylight than in artificial light. The first tint is a straw color, followed with more compression by a first-order blue color, then complicated colors of higher order follow in quick succession as the thickness of oil increases. The oil will always reach a definite thickness, and show a characteristic interference color, at a definite film pressure. We have found that the first-order blue color gives the best critical endpoint. The barrier is therefore pushed steadily along the tray until this color is seen in the oil. Calibration of the particular oil used must be made on a surface balance, of the type now well known, to find the film-pressure corresponding to the endpoint used. In the case of our oil this is 9 dynes per cm. By mixing some "oxidized" (dirty) [1] oil with clean oil, indicators can be obtained that show critical colors at pressures from 5 to 15 dynes per cm. It will be seen that for the purpose of measuring protein in urine, it is not necessary to know the exact critical pressure of the oil used, except within wide limits, since calibration on standard protein solutions is employed. However, if the areas of film are measured under a different pressure, the calibration curve of the method will, of course, be different from that found in our case.

It will be found that when the endpoint of the critical color is first reached, the color will fade and the area will have to be reduced slightly to produce a permanent indication of endpoint. This is due to viscous properties in the elasticity of the protein film, and the endpoint used in the measurement is that which persists for at least 30 seconds without further movement of the barrier. The area, at this critical point, is then read from the scale.

Since the measurement is made at a film-pressure of 9 dynes per cm., the measured area is considerably less than it would be if made at "zero" pressure, *i.e.* than the limiting area at zero compression. If the amount of protein dropped on to the surface is too great, the total available area of the tray may be inadequate to accommodate it, and the later drops will not be able to form a monomolecular film. It is important, therefore, to ensure that when the film is formed, the area available is adequate. It was found by repeated tests that if the final area, measured under 9 dynes per cm. pressure, was less than half the total area of the tray, the area was proportional to the volume of diluted urine put on the tray, but if the final area were greater, the measured area was less than would be expected from the amount put on (Figure 2). This indicates that the limiting area (at zero pressure) is about twice that at the pressure of 9 dynes per cm. used in the measurement. A rule was therefore made that if the measured area was greater than half the area of the tray (say with 1 ml. of urine), the determination was repeated using a smaller quantity (say 0.6 ml. of urine), until the final area was sufficiently small. Alternately, the urine may be further diluted (say to 20 to 1 instead of 10 to 1) and the 1 ml. used as previously.

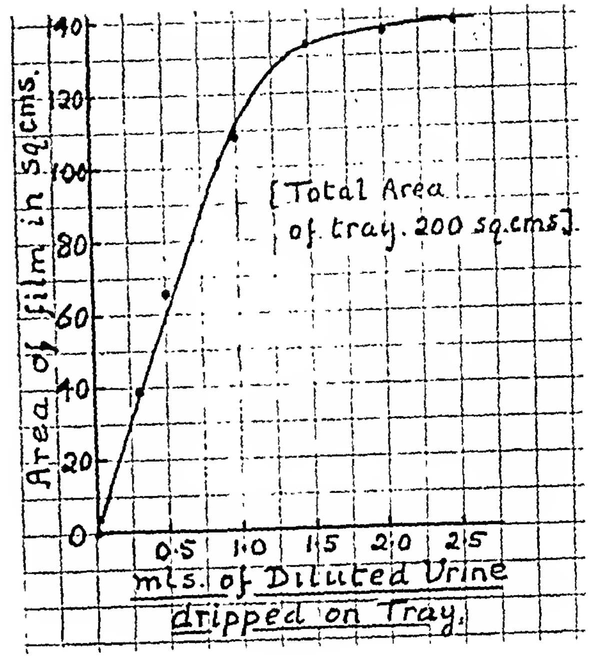

FIG. 2

(f) Precipitation of the protein

Several of the well-known precipitation methods were tried before one was found that was satisfactory. Some, such as trichloracetic acid, while precipitating the protein will markedly increase the residual activity of the non-protein surface-active substances in urine, probably by the release of more active groups. Other reagents, such as tungstic acid and lead acetate, produce a copious flocculent precipitate, and the residual surface activity is greatly reduced, presumably by the absorption of all surface-active substances on the precipitate. Finally, it was found that Tsuchiya's [2] reagent was satisfactory.

[1] "Oxidized" oil can be easily produced by heating clean oil in an open dish for a few minutes.

[2] Tsuchiya's reagent is: Phosphotunstic acid — 1.5 grams
Concentrated HCL — 5.0 ml.
95 per cent ethyl alcohol — 93.5 ml.

The activity of urine, freed from protein by precipitation by the reagent, was measured, a considerable amount of egg albumin added to increase greatly the measured activity; the added albumin was precipitated again by the reagent, the pH adjusted to neutrality with ammonia, and the activity finally measured. After correction for the dilution due to the added reagent, the final activity was consistently about the same as at the start. The success of this reagent is probably due to the use of alcohol which produces a compact precipitate of small surface area, and the absorption of surface-active substances on the precipitate is correspondingly low. It will be seen that in most cases, for clinical determinations, the precipitation and second measurement of activity after precipitation may be omitted.

(g) Routine of measurements

The sequence of measurements on the tray is illustrated by the table below (Table I) which is for a typical sample of normal urine diluted 10 to 1. It will be seen that "blank determinations" are made between each "test" measurement. In these the tray is "swept" 3 times, but nothing is added from the burette before the area of film is measured. The areas of "blanks" represent the inevitable contamination. The mean of the "blank" determinations is subtracted from the mean of "test" values to give the area due to the substances added from the burette.

TABLE 1

Urine sample diluted 10 times

Before precipitation			After precipitation		
Ml. added	Cm. on scale	Corrected values	Ml. added	Cm. on scale	Corrected values
0	1.3		0	1.4	
1.0	9.7	8.4	1.0	2.9	1.5
0	1.2		0	1.5	
1.0	9.5	8.2	1.0	3.1	1.7
0	1.4		0	1.2	
Mean		8.3			1.6 cm.

Area per ml. of urine = 830 (8.3 × width of tray × dil.) = 160 sq. cm.

Area due to protein = 830 − 160 = 670 sq. cm. in 1 ml. of original urine.

The whole procedure can easily be completed in 20 minutes.

CALIBRATION OF THE METHOD

Calibration was made by measurement of the surface area, due to protein, of a number of samples of urine containing increasing amounts of protein, the amount of protein being also measured by the quantitative gravimetric method of Folin and Denis (16). It was felt that in the calibration, urinary protein, rather than any other albumin, should be used. The urine of a patient, which was found, by the gravimetric determination, to contain

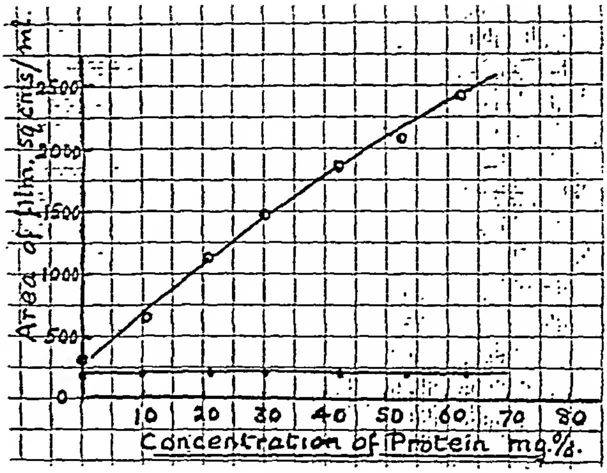

FIG. 3

240 mgm. protein per cent was, therefore, after neutralization, added in different proportions to normal urine which had been rendered free from protein by precipitation. The amount of protein in each of the samples was calculated from the proportions of a mixture of the normal and the protein-containing urines. Results are given in Figure 3, where the open circles represent surface area of film per ml. of original sample before, and the closed circles after, protein precipitation.

RESULTS

(a) The non-protein or "residual" surface activity in normal urine

The nature of the "residual" surface-active substances is the subject of a separate research now in progress. In normal urine, the residual activity, found after the protein has been precipitated, is a major part of the total surface activity. The substance or substances responsible for the residual activity are not yet identified, but their activity in normal urine is very constant. In 30 normal subjects, the residual activity from subject to subject, and in the same individual, had a mean from day to day of 206 sq. cm. per ml. of urine with a standard deviation of ±41 sq. cm. Reference to the calibration curve, Figure 3, shows that this amount of variability could correspond to a variation in protein of only ± 1 mgm. per cent. On the other hand, where there is an amount of protein greater than normal, even as little as 20 mgm. per cent, the residual activity is a small part of the total activity. Thus for most clinical purposes, the second step of precipitating the protein and remeasuring the surface activity (unless the presence of bile salts

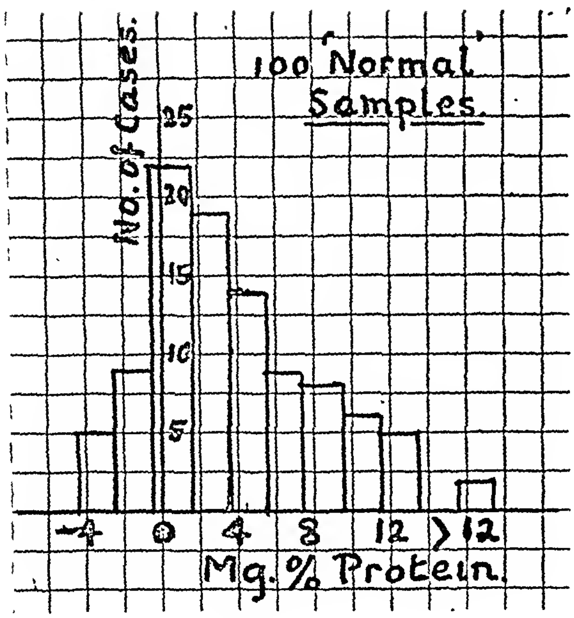

FIG. 4

is suspected), is unnecessary, especially if the total activity indicates a protein concentration within the normal range. To verify this, in 4 cases picked at random, the estimate of protein concentration from the total activity and from Figure 3, was compared with the value from the difference in activity before and after precipitation of protein. In no case did the 2 estimates differ by more than 3 mgm. per cent.

(*b*) *The concentration of protein in samples of normal urine*

Samples of urine were examined by the method described for 100 normal male subjects, most of them students of the Medical School, University of Western Ontario. The criterion of normality was that the blood pressure was within the normal range, with systolic pressure not greater than 140 mm. Hg and diastolic pressure less than 95 mm. Hg and that there was no known history of kidney dysfunction.

Results are shown in the histogram Figure 4. The negative values are to be expected because, as in all methods, there is an experimental error; and the true mean value is close to zero. A negative value means that the "residual" surface activity after precipitation was greater, instead of less, than the total activity before precipitation. In the case where the protein concentration is deduced from the total surface activity alone, without performing the precipitation, it means that the total activity of that particular sample fell below the "residual" activity on the standard curve.

The mean protein concentration is 3.7 mgm. per cent but it should be noted that the distribution is decidedly "skew," and the most frequently occurring concentration (the mode) in normals is between 0 and 2 mgm. per cent.

(*c*) *The concentration of protein in urine from patients with higher blood pressure than normal*

The amount of protein in the urine of normals turns out to be so very low that it seemed worthwhile to see if an appreciable number of patients with hypertension, but with no "clinical" evidence of proteinuria, would prove to have concentrations of protein significantly above normal, though below the limit of the normal clinical tests. The group of 50 patients from Victoria and from the Westminster Hospitals, London, Ontario, include 14 who had had some history of heart failure or some degree of decompensation but were free of such conditions at the time of this experiment. Most of the rest were diagnosed as "labile hypertensives," and the clinical tests had shown albumin in amounts described as a "very faint trace" or "insignificant." The group includes some with systolic pressure up to 200 mm. Hg, but diastolic pressures were in most cases less than 120 mm. Hg.

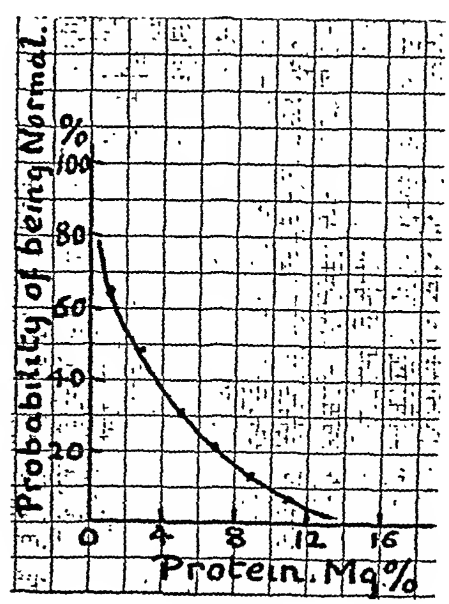

FIG. 5

Results on this group are shown in Figure 6 in the form of a histogram. Where the protein concentration falls outside the normal range (as judged from Figure 4), the blocks are shaded. In 5 cases where the protein concentration was greater than 80 mgm. per cent, these would presumably be noted by the usual clinical tests as having a "trace" of albuminuria. In the 45 other cases, Figure 5 shows that in 15, or 33 per cent, the protein concentration is significantly greater than the normal.

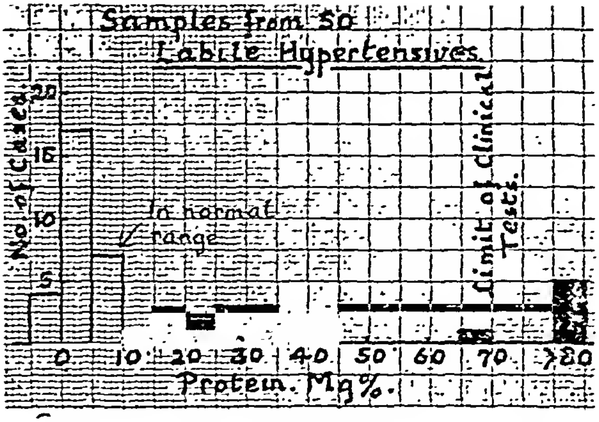

Fig. 6

DISCUSSION

The curve Figure 3 shows that the area of the protein film is not strictly proportional to the amount of protein present, but there is a slight curvature of the graph. This may be attributed to a "concentration effect," which means that, when protein is more concentrated in the liquid in the burette, the ability to form a film is slightly decreased. This is easily understood, since the more competition there is for the surface of the drops as they are formed, the less completely will the protein be adsorbed on the surface of the drops.

The method of measurement of protein concentration by means of the surface activity is widely adaptable to biological fluids other than urine, such as cerebrospinal fluid, blood serum, or lymph. The initial dilution of these fluids should be such that the concentration of proteins in the fluid dropped in the tray is in the same range as in these measurements, *i.e.* not greater than 10 mgm. per cent. This would require an initial dilution of cerebrospinal fluid some 50 times and of blood serum some 200 times. Since different proteins may differ markedly in their surface activity, calibration should be made with standard solutions of the particular protein concerned.

The specificity of the method in measuring protein, and not other substances, is of course the same as the specificity of the precipitation by Tsuchiya's reagent.

From the results on normal urine, a statistical prediction curve can be constructed as in Figure 5 This shows that if a sample of urine is found to contain more than 12 mgm. per cent of protein, the chance that this sample is from a "normal" is less than 5 per cent, and for greater amounts, the chance is insignificant. This gives a statistically valid basis for the use of the term "insignificant" in connection with albuminuria, whereas, on the basis of the usual clinical tests, "insignificant" really referred to the appearance of the precipitate in the particular test used and not to the degree of albuminuria.

The amount of protein in normal urine is so small that it would be extremely difficult to establish that what little was present was not extraglomerular in origin, rather than having passed through the glomerular filter. The view that the normal glomerular membrane is "completely" impermeable to protein is not contradicted by these experiments.

The results on the small group of hypertensives are included merely to indicate that a more sensitive method of measurement of urinary protein is of clinical usefulness. The sensitivity of a clinical test should be at least sufficient to give a definite indication with the amount of substance found in normal physiology so that the degree of deviation from the normal can be judged.

SUMMARY AND CONCLUSIONS

1. Since protein is highly active in forming monomolecular surface films, its concentration in urine can be found by a measurement of the total surface area occupied at a definite surface force, compared with the surface area occupied after protein has been precipitated. For clinical use, it is seldom necessary to take this second step of the precipitation of protein.

2. A simple method, using relatively inexpensive

apparatus, is described. Less than 1 ml. of a sample of urine is required, and the measurement is completed in less than 20 minutes.

3. The method has been used to find the concentration of protein in samples of 100 normal urines. The most frequently found concentration is less than 2 mgm. per cent, the mean is 3.7 mgm. per cent, and the probability of finding more than 12 mgm. per cent in normal samples is less than 5 per cent.

4. When the method is applied to a group of 50 hypertensives, most of them of the labile type, where there was no evidence of albuminuria by the usual clinical tests, amounts of protein significantly greater than normal were found in 33 per cent of these cases.

5. It is concluded that the usual clinical tests for proteinuria applicable on small samples of urine, have a sensitivity which is inadequate to their use. The method employing the surface activity of protein is rapid, easy to perform, requires a very small sample, and is accurate to 2 or 3 mgm. per cent. It can be adapted readily to the measurement of the concentration of protein in other biological fluids.

ACKNOWLEDGMENT

A major part of the technical work was done by Mr. Milton Walsh, and he also contributed a great deal in the development of the method. Thanks are also due to the Medical Staff of the Victoria Hospital and of the Westminster Hospital, London, for their cooperation.

THE EFFECT OF CYTOCHROME C UPON THE METABOLISM OF RAT TISSUES

By WILLIAM C. STADIE and JULIAN B. MARSH

(*From the John Herr Musser Department of Research Medicine, University of Pennsylvania, Philadelphia, Pa.*)

(Received for publication February 4, 1947)

Recently, Proger and his co-workers have published papers dealing with the effects of parenteral injections of cytochrome C on conditions associated with tissue anoxia (1 to 8). They found, in man, that the changes in the visual acuity, electrocardiogram, and electroencephalogram associated with anoxia were partially or completely prevented by the antecedent intravenous injection of relatively small amounts of cytochrome C.

These phenomena were explained by Proger by assuming that in anoxia essential oxidative processes were limited by the low concentration in the cells of cytochrome C *relative* to cytochrome oxidase. By parenteral injection the concentration of cytochrome C within the cells was increased, the limitation of oxidative processes was removed, and tissue function restored toward normal.

Proger discussed further experiments bearing on the problem of the role of cytochrome C in tissue anoxia: (*1*) He reported (5) that the adenosine triphosphate (ATP) of heart and kidney of rats subjected to anoxia was markedly reduced. The antecedent parenteral injection of cytochrome C significantly prevented this reduction. It is well known that the organic phosphates, particularly ATP, play important roles in tissue metabolism. The regeneration of these energy rich phosphate bonds is dependent upon oxidative processes. Presumably, then, increase of cellular cytochrome C by injection removed the limiting factor of its naturally occurring low concentration, increased oxidative processes associated with the regeneration of ATP, and thus prevented the decrease otherwise accompanying anoxia. (*2*) He also found that cytochrome C together with hydroquinone (4) increased the oxygen uptake of *homogenized* tissues *in vitro*.

These 2 experiments were considered by Proger to support his concept of the role of parenterally administered cytochrome C in combating tissue anoxia. There are, however, theoretical difficulties in the acceptance of this explanation, viz.: (*1*) How can the large molecule of cytochrome C (molecular weight approximately 13,000) enter into the interior of the cell in order to function? (*2*) Is the cytochrome C concentration of tissues so low that it is a limiting factor in metabolism under normal extraordinary physiological demands?

In this paper the interesting problem of the possible beneficial effect of parenteral injections of cytochrome C in anoxic states was studied in 3 ways: (*1*) The adenosine triphosphate (ATP) concentration of kidney tissue in rats in the normal state, in anoxia, and in anoxia subsequent to cytochrome C administration was studied. (*2*) Experiments were performed to determine the effect of cytochrome C on the oxygen uptake *in vitro* of diaphragms, liver and kidney slices from rats. (*3*) Using a recent value for the turnover number of cytochrome C together with cytochrome C concentrations of various tissues, the limiting values of oxygen uptake imposed by these 2 factors was calculated and compared with the physiological range of oxygen uptake of the respective tissues.

METHODS

The concentration of inorganic phosphate, ATP, and total phosphate in the acid-soluble fraction of the kidney was determined by the methods of Kaplan and Greenberg (9). One hundred-minute hydrolyzable phosphate was determined by hydrolysis in 1N H_2SO_4 at 100° C. All phosphate determinations were by the method of Fiske and Subbarow (10), using a Klett-Summerson photoelectric photometer with a 6,600 A° filter.

The rats were made anoxic for 5 minutes by means of a 3 per cent O_2 − 97 per cent N_2 gas mixture passed through a funnel held over the animal's head. Cytochrome C was injected intravenously 10 minutes prior to the anoxic period in the manner reported by Proger *et al* (5).

The kidney was frozen with liquid air as quickly as possible following decapitation of the rat. The frozen kidney was ground to a powder under liquid air in a mortar, and this powder was added to a tared centrifuge

tube containing 7 per cent trichloroacetic acid, following the procedure of Kaplan and Greenberg (9).

The cytochrome C was prepared according to the technique of Keilin and Hartree (11). The concentration was determined spectrophotometrically, using the constant 26.1 at λ 550 mμ for a millimolar solution of cytochrome C, with a cuvette depth of 1 cm. This concentration is referred to pure cytochrome C with 0.43 per cent Fe (Mol. wt. = 13,000). In addition the biological activity of the preparation was demonstrated by its ability to increase the oxygen uptake of rat liver homogenates in the presence of 0.01M succinate. The increment was of the order of 1 mole of O_2 per mole of cytochrome C per minute, which is comparable to that obtained by Schneider and Potter (13) with their preparations of cytochrome C.

In the experiments dealing with tissue slice respiration, the organs were removed immediately following decapitation and slices 0.35 mm. in thickness were cut. The slices were placed in Warburg vessels containing 2 ml. of a medium of the following composition: Na_2HPO_4, 0.020M; NaH_2PO_4, 0.020M; KCl, 0.005M; $MgCl_2$, 0.002M; $CaCl_2$, 0.001M; NaCl, 0.09M; glucose, 0.011M; pH = 6.7. Where noted, the glucose was replaced by succinate.

RESULTS

The effect of cytochrome C on the ATP content of kidneys from normal and anoxic rats

The results presented in Table I show that the anoxia caused a 74 per cent decrease in the ATP content of the kidneys of the normal, non-injected rats. The 100-minute minus the 7-minute easily hydrolyzable phosphate, representing mainly hexose diphosphate, was decreased 52 per cent. There was no significant change in the inorganic and total phosphate content.

The rats made anoxic following injection of cytochrome C showed a similar reduction in the ATP and hexose diphosphate content of the kidney. There is no statistically significant difference in the data of the untreated and treated rats.

TABLE I

Partition of the organic acid-soluble phosphates (mgm. P per 100 grams wet weight) of kidneys from normal rats, anoxic rats, and rats previously injected with 5 mgm. of cytochrome C

Condition of rat	Inorganic phosphate	7-minute hydrolyzable phosphate (ATP)	100-minute minus 7-minute hydrolyzable phosphate	Total phosphate
	mgm. P	*mgm. P*	*mgm. P*	*mgm. P*
Normal	41.9	12.4		89.4
	31.6	5.6	10.8	90.7

The effect of cytochrome C upon oxygen uptake of tissues in vitro

It is well known (*e.g.*, Elliott [12]) that the addition of cytochrome C (together with some reductant such as hydroquinone or ascorbic acid) to *homogenized* tissue *in vitro* increases the oxygen uptake. The currently accepted explanation is that the cytochrome oxidase is in excess compared to cytochrome C. Hence in the homogenate, in which both cytochrome oxidase and cytochrome C are *free*, the further addition of cytochrome C saturates the cytochrome oxidase to a greater extent and oxygen uptake is enhanced. Proger (4) repeated experiments of this kind with homogenates and used them to support his general concept of the effect of cytochrome C on anoxia in the intact animal. It seems to the authors of this paper that such a phenomenon in homogenates has little or no meaning with respect to the problem at hand unless it can be shown that parenterally administered cytochrome C enters the intact cell. Elliott (12) was unable to find any influence of cytochrome C upon the O_2 uptake *in vitro* of intact tissue and concluded that cytochrome C does not penetrate into intact cells.

To test whether the addition of cytochrome C to the medium would have any effect upon the oxygen uptake, we used relatively untraumatized tissue preparations such as kidney or liver slices, or whole rat diaphragms rather than homogenates. We found, in the presence of glucose or succinate, that cytochrome C has no significant effect. The evidence is presented in Table II.

TABLE II

The effect of cytochrome C upon the oxygen uptake in vitro *of diaphragms, kidney and liver slices from rats*

* Medium I contained *glucose*, 0.011M; Na_2HPO_4, 0.02M; NaH_2PO_4, 0.02M; KCl, 0.005M; $MgCl_2$, 0.002M; $CaCl_2$, 0.001M; NaCl, 0.09M. pH = 6.7. Medium II contained sodium *succinate*, 0.01M in place of the glucose in Medium I. Total vol. 2.5 ml. Cytochrome C 1.7 mgm. t = 38° C.

The limiting cellular oxygen uptake imposed by cytochrome C content

Proger (8) emphasized that the concentration of cytochrome C in tissues is below that required for maximum activation of cytochrome oxidase with which it is coupled in metabolic reactions. This, however, does not indicate that cytochrome C is necessarily a limiting factor in cellular oxygen consumption. From the data of Rosenthal and Drabkin (14) the turnover number of cytochrome C expressed in terms of oxygen uptake is 2.3×10^7 μM of O_2 per gram (dry weight) per hour. On the basis of this figure we have calculated the values shown in Table III. These calculations indicate that the cytochrome C concentration of various rat organs is considerably beyond that required for the estimated physiological demand.

TABLE III

The calculated maximum oxygen uptake of various tissues calculated from the turnover number and tissue concentrations of cytochrome C compared to physiological ranges of oxygen uptake

Organ	Cytochrome C	Calculated oxygen uptake	Approximate physiological range of oxygen uptake
	*per cent of dry weight**	Q_{O_2}	Q_{O_2}
Kidney cortex	0.14	720	10–50
Liver	0.06	309	10–30
Brain cortex	0.04	206	10–40
Striated muscle	0.05	257	5–110
Heart	0.22	1133	3–60

* From data from rats by Rosenthal and Drabkin (15). Expressed in terms of oxygen uptake the turnover number of cytochrome C used was 2.3×10^7 μM of O_2 per gram dry weight per hour. The calculation of the Q_{O_2} is: $2.3 \times 10^7 \times 22.4 \times 10^{-3} \times P \times 10^{-2}$ where P is the per cent (dry weight) of cytochrome C in the respective tissue. Q_{O_2} = cu. mm. O_2 per mgm. dry weight per hour.

In the brain, for example, there appears to be a 5-fold reserve factor, and in striated muscle, the factor is 2 even under the demands of excessive muscular work. In the heart the factor of safety appears to be still greater, viz. 20. It is difficult, therefore, to understand, on the basis of the current concept of the function of cytochrome C in tissue oxidations, how the parenteral addition of a relatively small amount of cytochrome C, even if it could enter the cell, can affect oxidative cellular metabolism.

SUMMARY

1. The decreased adenosine triphosphate (ATP) content of anoxic rat kidney reported by Proger *et al* (5) has been confirmed. The prevention of the lowered ATP content of anoxic kidney by the antecedent intravenous administration of cytochrome C, reported by these authors, has not been observed in the present experiments.

2. No alteration in the oxygen consumption of rat diaphragm and rat liver and kidney slices was observed following the addition of cytochrome C to the medium *in vitro* either with glucose or succinate as substrates.

3. Using the turnover number of cytochrome C and known values of tissue cytochrome C, the maximum oxygen uptake of various tissues was calculated. Comparison of these calculated values with the range of oxygen requirements lends no support to the concept that the cytochrome C con-

tent of tissues is a limiting factor in cellular oxidations within physiological ranges.

We are indebted to Dr. David L. Drabkin of the Department of Physiological Chemistry for the spectrophotometric standardization of the cytochrome C solutions.

THE RENAL CLEARANCE OF PENICILLINS F, G, K, AND X IN RABBITS AND MAN[1]

By HARRY EAGLE and ELLIOT NEWMAN

with the technical assistance of ARLYNE D. MUSSELMAN, MARGOT ROBINSON, and MARION BIRMINGHAM

(From the Laboratory of Experimental Therapeutics of the U. S. Public Health Service and The Johns Hopkins School of Hygiene, and the Department of Medicine of the Johns Hopkins Medical School, Baltimore 5, Maryland)

(Received for publication February 6, 1947)

The factor which most seriously limits the therapeutic efficacy of penicillin is its rapid urinary excretion. Thus, the renal clearance of commercial penicillin in man has been found (1, 24) to vary between 755 and 1,120 ml. per minute, approximating the total renal plasma flow; and when crystalline penicillin G or X is injected intramuscularly in aqueous solution at average therapeutic dosage (0.6 mgm. per kgm.), approximately 60 per cent is excreted in the urine in the first hour (2 to 4). Largely because of that rapid excretion, the blood level of *e.g.* penicillin G falls off, after its intramuscular injection in aqueous solution, at an average rate of 70 to 80 per cent each succeeding hour, or 2 to 3 per cent each minute (4, 19). It is apparent that even a minor decrease in the rate of renal excretion would be reflected in significantly prolonged blood levels and a correspondingly enhanced therapeutic efficacy.

There is considerable evidence that penicillin is secreted by the renal tubules, and by the same secretory mechanism as diodrast and p-aminohippuric acid. Thus, the excretion of penicillin is said to be depressed by the simultaneous administration of either of these 2 compounds in amounts sufficient to saturate the common tubular mechanism (5 to 10). Restriction of the water or salt intake (11) and the administration of benzoic acid or pitressin (12) are also reported to curtail the excretion of penicillin and to prolong the blood penicillin curve correspondingly.

Since the 4 penicillin species known to be produced by penicillium (F, G, K, and X) vary markedly in their pharmacological behavior and bactericidal activity (2 to 4, 13, 14), it was of interest to determine the renal clearance of each, over a widely varying range of plasma concentration, and with varying rates of urine flow. As is shown in the following, in both rabbits and man penicillins F, G, and X were found to have a renal clearance corresponding to the total renal plasma flow. The ratio of the glomerular filtration rate, simultaneously determined with inulin or thiosulfate, to the renal clearance of penicillin did not vary significantly over a wide range of plasma concentrations and was independent of the rate of urine flow. In rabbits, the tubular secretory mechanism was found to have been saturated by serum concentrations on the order of 100 to 1,000 micrograms per ml.

The apparently anomalous renal clearance of penicillin K is discussed later in the text.

At least in the case of penicillins F, G, and X the nature of the side chain which differentiates the several species of penicillin, and which significantly modifies their bactericidal activity, thus has no demonstrable effect on their renal clearance. Further modification in that prosthetic group may nevertheless be a promising approach to the development of penicillins with low renal clearances and correspondingly enhanced therapeutic activity.

EXPERIMENTAL METHODS

Penicillins: The purified penicillins used in these studies were generously provided by the following pharmaceutical firms:

G—Squibb (Lot CRA-214-20)
F—Upjohn (Lot 175-EANW-6)
K—Abbott (Lot RP 309 P2)
Pfizer (Lot 5/2/46)
X—Lederle (Lot CA-3242-IC)

Penicillin assay: The blood and urine concentrations were determined by a modified Rantz-Kirby (1) serial dilution technic (cf. [4, 13]), using the inhibition of hemolysis by streptococci (C-203 strain of Streptococcus pyogenes) as the endpoint. The use of 5 tubes for each

[1] Study supported in part by the Life Insurance Medical Research Fund.

2-fold difference in concentration (*i.e.*, 0.8, 0.72, 0.6, 0.48, 0.4, etc. ml. of the unknown specimen in a total volume of 0.8 ml.) permitted a reasonably accurate and reproducible assay.

The technic was further modified in that the assays were removed from the incubator after 6 to 9 hours, by which time hemolysis had begun, and were then allowed to remain at room temperature overnight before reading. With this technic, contaminated urine specimens could usually be assayed without preliminary filtration, since the heavy streptococcus inoculum initiated hemolysis at 37° C. before it had been overgrown by the contaminant, and bacterial growth in the following 10 to 15 hours at room temperature was usually too slow to obscure the results.

Calculation of results: The average serum concentration over the time period represented by the successive urine samples was obtained in the usual manner by graphic interpolation (log of serum level plotted against time).

Calibration of glomerular filtration and renal plasma flow: In some of the experiments, the rate of glomerular filtration was simultaneously determined by the administration of inulin or sodium thiosulfate, given either as a single injection, or as a constant infusion following a priming dose. In some of the subjects, the renal plasma flow was determined with para-aminohippuric acid several days before or after the administration of penicillin. The methods used for the determination of inulin and para-aminohippuric acid were those suggested by Goldring and Chasis (16). Thiosulfate was determined by the method of Newman (17).

EXPERIMENTAL

Group I. Human subjects continuously infused with penicilllin F, G, K, or X

The results in 6 experiments are given in detail in Table I and are graphically summarized in Figures 1 to 3.

In subject G. J., the renal clearance of penicillin G averaged 525 ml. per minute. This is to be compared with a calculated renal plasma flow of 717 ml. per minute and an observed clearance for para-aminohippuric acid of 619 ml. The parallelism between the renal clearance of penicillin G and the glomerular filtration rate simultaneously determined with inulin (*cf.* last 2 columns of Table I and Figure 1), and the constancy of their ratio (0.19 to 0.24, averaging 0.23) are particularly to be noted.

The renal clearance of penicillin G in this subject was independent of the blood level and the rate of urine flow, within the experimental range. Periods in which the blood levels averaged 2.4 and 0.25 micrograms per ml. gave clearances of 498 and 416 ml. per minute, respectively; and periods in which the urine flow was 12.5 and 2.1 ml. per minute gave penicillin clearances of 588 and 416 ml. per minute, respectively.

When the same subject was infused with penicillin X (bottom of Table I), the renal clearance averaged 652 ml. per minute, in satisfactory agreement with both the calculated renal plasma flow (717) and the observed clearance of para-aminohippuric acid (619), and 4.6 times the calculated glomerular filtration rate of 135 ml. per minute. The renal clearance was again largely independent of the absolute serum concentration and rate of urine flow. With a 10-fold difference in serum concentration (3.6 and 0.37 microgram per ml.), the renal clearance varied from 456 to 699 ml. per minute; and in periods in which the urine flow averaged 10.3 and 4 ml. per minute, the renal clearances averaged 787 and 722 ml., respectively.

Subject E. W. is of particular interest (Figure 1 and the second section of Table I). This subject was a woman with long-standing hypertension, in whom the urea clearance was 58 per cent of normal, and the phenolsulfaphthalein excretion was 60 per cent in 2 hours. Corresponding to the obvious impairment of renal function, the renal clearance of penicillin G averaged 242 instead of the calculated value of 617, or 40 per cent of normal. Significant also is the fact that as her blood pressure fell from 218/112 to 158/114 during the first 80 minutes of the experiment, the inulin clearance increased from 52 to 97, and the penicillin clearance from 158 to 308, indicative of an increased flow of blood to the kidney. Meanwhile, the ratio of glomerular filtration to total renal clearance remained essentially constant at the abnormally high level of 0.31. As in patient G. J., the rate of urine flow had no significant effect on renal clearance, which varied only from 276 to 230 ml. per minute as the urine flow increased from 2.0 to 7.4 ml. per minute in 5 successive experimental periods.

Penicillin F gave results essentially the same as penicillins G and X. The renal clearances averaged 550 and 900 ml. per minute in 2 patients in whom the calculated renal plasma flow was 750 ml. per minute. The clearance was again independent of the absolute blood level and of the rate of urine flow over the entire experimental range (*cf.* Figure 3 and Table I).

In patient M. B., injected with penicillin F, midway through the experiment the blood flow to the kidney apparently decreased sharply for a period of approximately 40 minutes. This was manifested by a simultaneous and parallel decrease in the renal clearance of *both* penicillin

TABLE I

The renal clearance of penicillins F, G, K and X in man

Experiments with continuous intravenous infusion at a falling rate. Most of the patients received a priming dose of 2.5 mgm. per kgm. and the rate of infusion was slowly reduced from an initial level of 1 mgm. per kgm. per min. to 0.16 mgm. per kgm. per min. over a period of 2 to 3 hours. In all but 2 patients, the urine specimens were collected by catheterization.

and thiosulfate and a significant increase in the ratio of glomerular filtration to total renal clearance. All 3 values returned to normal levels in the last 2 experimental time periods.

Contrasting with the values obtained for the clearance of penicillin G and X, the renal clearance of penicillin K in 2 normal subjects averaged 272

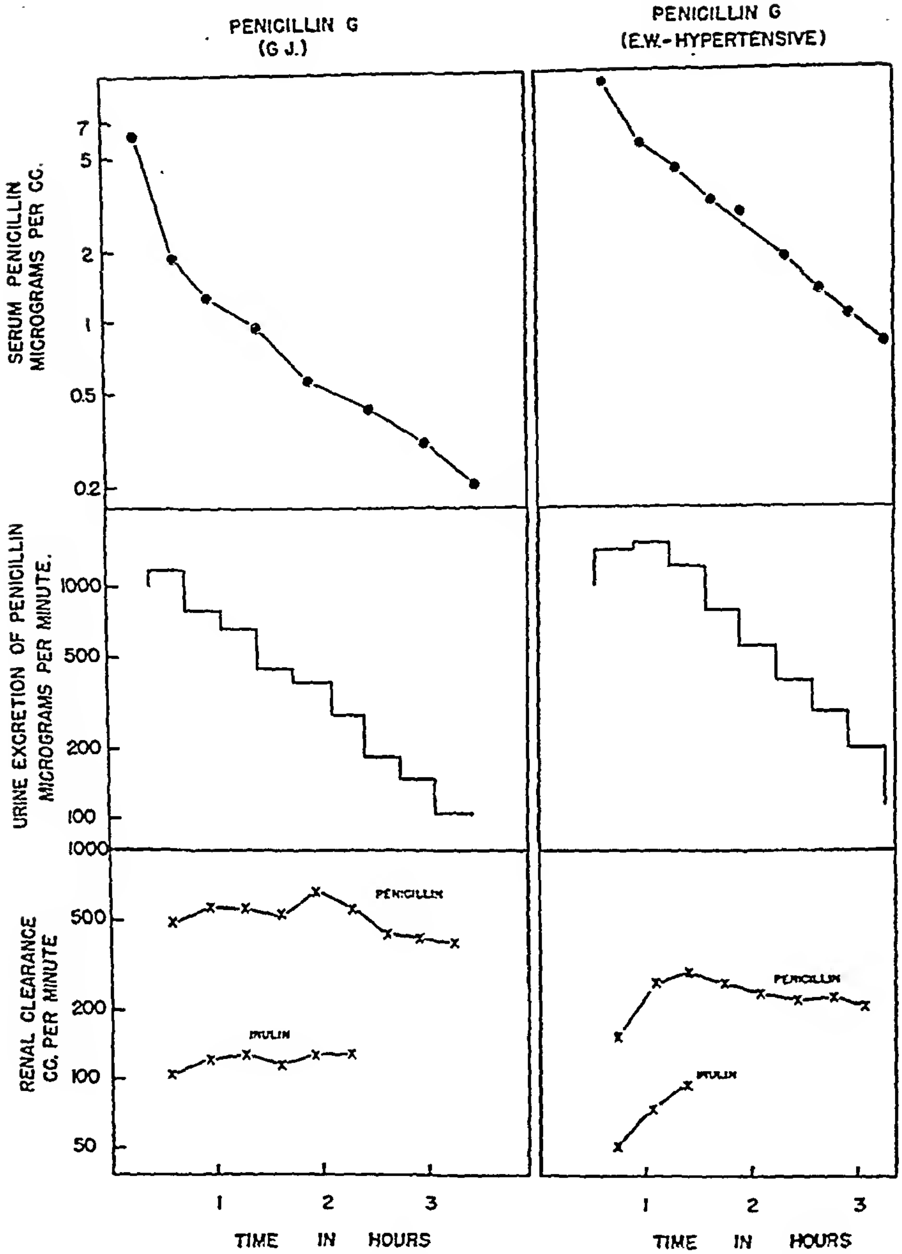

FIG. 1. THE BLOOD LEVEL, URINE EXCRETION AND RENAL CLEARANCE OF PENICILLIN G IN SUBJECTS G. J. AND E. W.
Continuous intravenous infusion at a falling rate (After data of Table I).

and 269 ml. per minute. Within each experiment, however, the results in individual time periods varied widely, the renal clearances varying from 110 to 406 in one subject, and from 128 to 362 in the other. These variations had no demonstrable relationship to either the blood level or rate of urine flow. In these 2 subjects, the calculated renal plasma flow was 850 and 665 ml. per minute, 3 and 2.5 times greater than the clearance of penicillin K. The low values for the renal clearance of penicillin K, which were confirmed in the larger group of patients discussed in the following section, are significant in relation to the low urine recovery of that penicillin species as compared with that of penicillins F, G, or X (*cf.* page 914).

Group II. The renal clearance of penicillins G, K and X in human subjects receiving a single intravenous or intramuscular injection of an aqueous solution

The determination of the renal clearance of penicillin in subjects receiving a single injection of the aqueous solution was far less accurate than the continuous infusion technic used in the experiments of the previous section. The rapidly falling blood level made the "average" value over a given time period of dubious quantitative significance, while a relatively small amount of residual urine in patients who voided voluntarily, or incomplete bladder washing in patients who were catheterized, introduced a large error in the following sample. Despite these limitations, it is clear from the data of Table II that the renal clearance of penicillins G and X generally approximated the total renal

plasma flow and averaged 4 to 6 times the glomerular filtration rate.

Patient W. B., an apparent exception, was a hypertensive with a blood pressure of 210/135. The penicillin clearance of G in this patient was considerably less than the calculated normal renal blood flow, and the results in successive time periods were highly variable. However, the ratio of the glomerular filtration rate, experimentally determined with inulin, to the total renal clearance of penicillin was fairly constant, averaging 0.23. The low average clearance in this patient is probably attributable to renal damage associated with long-standing hypertension, and the variability in successive periods can probably be related to the patient's apprehensiveness and incomplete voiding.

Penicillin K again gave results differing from those obtained with penicillins G and X. In the 5 patients studied, the observed renal clearance of K averaged 0.3, 0.2, 0.9, 0.5 and 0.25 of the calculated renal plasma flow. It is particularly to be noted that of these 5 patients, one (D.), when tested with G, gave a normal clearance of 850 ml. per minute, 4 times the value obtained with K; and a second patient (J. W.), who gave an average clearance of 165 ml. per minute with penicillin K, gave clearances of 600 and 1010 ml. per minute when tested with X.

Group III. The renal clearance of penicillin G in in man after its injection as a suspension in peanut oil and beeswax

In 2 patients, the renal clearance of penicillin G was determined after its injection as a finely divided suspension of the potassium salt in peanut oil and 4.8 per cent beeswax (Romansky formula [15]). The prolonged and slowly falling blood levels obtained with this preparation proved admirably suited to the study of renal clearances. In 2 such experiments, summarized in Table III, the average renal clearances were 687 and 471 ml. per minute, to be compared with the calculated renal plasma flows of 796 and 632. These clearances were 4.2 and 3.3 times the glomerular filtration rate as determined with sodium thiosulfate.

Group IV. The renal clearance of penicillin in rabbits

The results obtained in rabbits injected intramuscularly with the crystalline penicillins are summarized in Table IV. The renal clearance of penicillins F, G, and X, studied in a total of 17 rabbits which received 0.35 to 60 mgm. per kgm., varied from 18 to 100. In 4 rabbits receiving penicillin F, the renal clearance averaged 32 ml. per minute (15 to 46 ml. per minute), in 8 rabbits receiving penicillin G at dosages of 0.6 to 60 mgm. per kgm. the average clearance was 59 ml. per minute (17 to 111 ml. per minute), and in 5 rabbits receiving penicillin X the average clearance

was 36 ml. per minute (23 to 54 ml. per minute). These results are to be compared with a reported (18) renal plasma flow in rabbits of 1.5 to 4.8 ml. per minute per gram kidney, or a range of 24 to 77 ml. per minute in rabbits with a total kidney weight of 16 grams.

One can only speculate as to the degree to which the technical manipulations of repeated catheterization and cardiac punctures affected the blood flow to the kidney, and contributed to the discrepant results sometimes obtained in successive time periods in the same animal. In most of the experiments the renal clearance of penicillin probably approximated the renal plasma flow; while the significantly lower values sometimes obtained may reflect a decreased blood flow to the kidney under the conditions of the experiment.

Five rabbits were injected with penicillin K at 0.6 mgm. per kgm. However, the speed with which the blood levels fell and the short periods of

time for which penicillin remained at measurable levels precluded a precise measurement of the average blood level during the period of urine collection, and the figures in Table V with respect to the renal clearance of penicillin K are of dubious significance.

In an attempt to saturate the tubular secretory mechanism, rabbits were injected intravenously with 6, 60 and 600 mgm. per kgm. of penicillin G, and blood and urine specimens were obtained for assay in the usual manner. As is shown in Table IV, after injection at 6 or 60 mgm. per kgm. the renal clearance of penicillin remained at a high level which did not vary significantly over the entire range of plasma concentration studied, and approximated the total renal plasma flow. Saturation of the tubular excretory mechanism was, however, achieved by a single intravenous injection of penicillin G at 600 mgm. per kgm., which corresponds to 60 million units in the average human adult. As is shown in Table V, in 2 rabbits so injected, with initial blood levels 5 to 7 minutes after the injection , of 2,667 and 3,200 micrograms per ml., the renal clearance of penicillin in the first hour after the injection was abnormally low (9.0, decreasing to 3 ml., in rabbit 5791, and 7 ml. per minute in rabbit 5939). These values are of the same order of magnitude as the normal rate of glomerular filtration reported by Walker and his associates (18). The renal clearance remained at this low level until the plasma concentration had fallen in 1 instance to approximately 1,500, and in the other to approximately 1,000 µg. Thereafter, the renal clearance rose, in 1 instance sharply,

* Experimentally determined with sodium thiosulfate.

and in 1 progressively, to reach peak values of 18 to 28 and 23 to 57 ml. per minute. As is shown in Figure 4, the rate at which penicillin G disappeared from the blood of these 2 rabbits paralleled its renal clearance. During the phase of tubular saturation, the blood level fell slowly; but as the renal clearance increased toward normal levels there was a parallel accelerating drop in the serum concentration, particularly evident in rabbit 5791.

In the latter rabbit the glomerular filtration rate and renal plasma had been determined experimentally with sodium thiosulfate and para-aminohippuric acid, 2 days before the injection of the penicillin. The observed glomerular filtration rates of 6.0 and 6.4 ml. per minute agree with the renal clearance of penicillin during the period of tubular saturation (3 to 9 ml.); while the para-aminohippuric acid clearances of 17.5 and 18.0 ml. per minute are in reasonably good agreement with the penicillin clearances of 18 to 28 ml. per minute, obtained when the plasma levels had fallen below the level of tubular saturation.

The results in a number of rabbits' experiments in which the animals received varying amounts of commercial sodium penicillin (of unknown composition with respect to penicillins F, G, K, and X), given as a single injection, are summarized in Table V. In 7 rabbits injected at dosages of 4,000, 8,000, or 150,000 units per kgm., the average renal clearances were 53, 57, 40, 28, 42, 24, and 43 ml. per minute. In these experiments the blood level varied from a peak of 45 µg. per ml. to a low of 0.044 µg.

In rabbit 5660, injected with commercial penicillin at 1,200,000 units per kgm., the renal clearance was abnormally low, with observed values of 10, 13, 5.7, and 4.9 ml. per minute in successive time periods. As had previously been found with penicillin G, the tubular secretory mechanism had been saturated by the high blood levels, which in this animal ranged from 580 to 800 µg. per ml.

DISCUSSION

1. The data here presented indicate that in both rabbits and man, penicillins F, G, and X are secreted into the urine by the kidney at a rate which corresponds essentially to their total removal from the blood reaching that organ. The normal renal clearance of penicillin so closely approximates the renal plasma flow as determined experimentally with para-aminohippuric acid that it may be used as a test of kidney function. Indeed, penicillin has

certain unique points of superiority over diodrast, para-aminohippuric acid, or any other substance currently used for that purpose. The plasma concentrations of the latter compounds cannot exceed a level of 3 to 5 mgm. per cent, as higher concentrations may so overload the tubular mechanism responsible for their secretion that complete extraction does not take place. On the other hand, plasma concentrations much lower than 1 mgm. per cent do not permit accurate determinations by the usual laboratory methods. In consequence, the useful range of plasma concentration varies only 5-fold. With penicillin, however, because the biological method used for assay is sensitive to as little as 1 part in 80,000,000 (0.00125 mgm. per cent), and because complete renal clearance is observed up to a minimum level of 1 mgm. per cent in man (10 µg. per ml.), and in rabbits of at least 4 mgm. per cent, there is as least a 1,000-fold range of plasma concentration within which the renal clearance of penicillin can be used as a measure of renal function in man.

2. The low renal clearance of penicillin K in man, approximately ½ to ⅕ that of penicillins F, G, or X, would at first sight imply that penicillin K is excreted more slowly than the other species. This should be reflected in a more sustained blood level. Instead, previous work in this and other laboratories (2 to 4) has shown that penicillin K disappears from the blood more rapidly than do the other penicillins. Moreover, the total urinary excretion in man has been shown to average only 30 per cent of the amount injected, as compared with recoveries for G and X of 80 to 100 per cent. The contradictions involved in a low renal clearance, a rapidly falling blood level, and a low urinary recovery may be more apparent than real. The low urinary recovery of penicillin K, and its rapid disappearance from the blood are probably referable to the fact that it is bound and inactivated by both the plasma (14, 20) and tissues (21, 22, 23) to a greater extent than is e.g. penicillin G. That combination with plasma protein may be not only quantitatively more complete, but also less freely reversible, and thus prevent the complete removal of penicillin K from the blood by the renal secretory mechanism.

3. The fact that penicillins F, G, and X have a renal clearance approximating the total plasma flow through the kidney is reflected in the rapidly falling blood levels observed after their intravenous or intramuscular injection in aqueous solution.

Attempts to modify the rate of excretion by reducing the rate of urine flow, as by restricting salt and water intake, or by administering pitressin, are physiologically unsound. As is true of other substances with maximal tubular secretion, the renal clearance of penicillin has been shown to be unaffected even by wide variations in the rate of urine flow. Such measures could modify the rate of secretion only by affecting the blood flow to the kidney.

A second suggested method of delaying the excretion of penicillin is to block its excretion by the administration of other substances excreted by the same tubular mechanism. Diodrast, para-aminohippuric acid and benzoic acid (5 to 10, 12) have all been reported as effective in this respect. The difficulty lies in the fact that these blocking substances are as rapidly excreted as the penicillin itself. To maintain an effective concentration of such blocking agents may prove no less laborious, and with some of these agents, no less costly, than to repeat the injections of penicillin or to increase the dosage.

The most effective method yet suggested of prolonging the time for which penicillins F, G, and X remain in the blood at effective concentrations is to delay its absorption from an intramuscular depot. This has been accomplished by injecting the drug as a suspension in peanut oil and beeswax (15). The absorption then proceeds at a slower rate than the excretion, and the time for which the penicillin remains in the blood in demonstrable and effectively bactericidal concentrations is significantly prolonged.

4. It is clear from the data here reported that the therapeutic efficacy of penicillin would be greatly enhanced were it possible by appropriate chemical modification to decrease its renal clearance. An antibiotic with the same bactericidal activity as

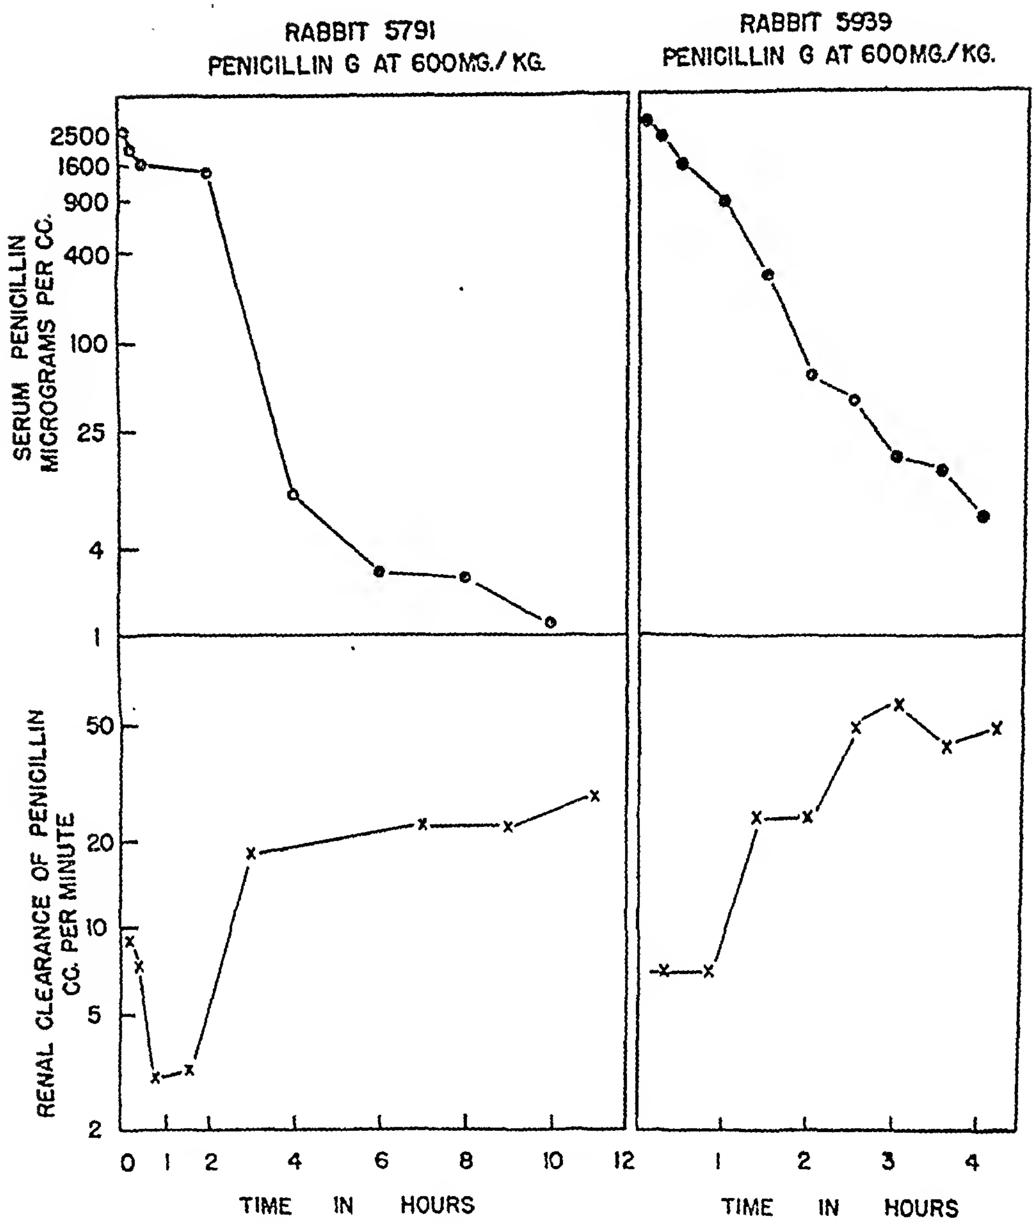

FIG. 4. THE SATURATION OF THE RENAL SECRETORY MECHANISM FOR PENICILLIN G BY A SINGLE MASSIVE INTRAVENOUS DOSE OF 600 MGM. PER KGM.

penicillin *in vitro,* but with a renal clearance in man of *e.g.,* 150 instead of 600 ml. per minute, might well be many times more active, since both the serum concentration of penicillin and the time for which an effective level was maintained would thereby be increased. The present experiments with F, G, and X indicate that the groupings present in these 3 species have no demonstrable effect on the rate of tubular secretion; and the apparently lower renal clearance of K is more than counteracted by some of its other pharmacological properties. It is nevertheless possible that derivatives of penicillin produced either by direct chemical modification or by the addition of appropriate precursors to the culture medium may have a significantly lower renal clearance than the 4 natural penicillins here studied, and a correspondingly enhanced therapeutic activity.

SUMMARY

1. The renal clearance of penicillins F, G, and X in man was found to approximate the total renal plasma flow and was approximately 4 to 5 times greater than the renal clearance of inulin or sodium thiosulfate. The penicillin clearance was independent of the absolute blood level over the entire

range 0.05 to 10 μg. per ml. and was similarly independent of the rate of urine flow.

2. The possibility is suggested that penicillin can be used in lieu of para-aminohippuric acid or diodrast as a test of renal plasma flow and renal function.

3. The renal clearance of penicillin K in man varied from ¼ to ½ that of F, G, or X. Possible explanations for this anomalous result are discussed in the text.

4. The tubular excretory mechanism was completely saturated in 2 rabbits receiving 600 mgm. per kgm. of penicillin G. In these the initial blood levels were 2,667 and 3,200 μg.; and the initial renal clearances of 3 and 7 ml. per minute corresponded to the glomerular filtration rate. As the serum concentration fell to less than the saturation level for the tubular mechanism, the renal clearances rose to normal levels of 18 to 28 and 23 to 57 ml. per minute.

5. Although no differences were found between the renal clearance of penicillins F, G, or X, the possibility is suggested that penicillin derivatives may be produced with significantly lower clearances than those of the natural penicillins so far identified, and with correspondingly enhanced therapeutic activity *in vivo*.

THE BLOOD LEVELS AND RENAL CLEARANCE IN RABBITS AND MAN OF AN ANTIBIOTIC DERIVED FROM B. SUBTILIS (BACITRACIN)

By HARRY EAGLE, ELLIOT V. NEWMAN, ROGER GREIF, T. M. BURKHOLDER, AND S. C. GOODMAN[1]

WITH THE TECHNICAL ASSISTANCE OF ARLYNE D. MUSSELMAN

(From The Laboratory of Experimental Therapeutics of the U. S. Public Health Service and The Johns Hopkins School of Hygiene, The Johns Hopkins Medical School, and the U. S. Marine Hospital, Baltimore, Maryland)

(Received for publication April 16, 1947)

The renal clearances of penicillins F, G, and X have been shown to approximate the total renal plasma flow (1, 2), varying between 529 and 865 ml. per minute in man, and 23 to 111 ml. per minute in rabbits (2). In consequence of that rapid excretion, the serum concentration of penicillin G decreases after its intramuscular injection in aqueous solution, at an average rate of 2 to 3 per cent of the residual penicillin per minute, and 70 to 80 per cent per hour; and it disappears from the blood even more rapidly after intravenous injection (3, 8). A therapeutic agent equal to penicillin in bactericidal activity, but with a slower rate of absorption or excretion, would provide effective levels for longer periods of time, and might be correspondingly more effective than penicillin similarly injected.

The antibiotic agent discovered by Johnson, Anker and Meleney (4) in culture filtrates of a strain of B. subtilis (Tracy), and termed by them bacitracin, possesses some of these properties. As will be here shown, it is excreted by both rabbits and man at a rate which corresponds approximately to the rate of glomerular filtration, rather than to the total renal plasma flow. In consequence, the blood levels observed after its intravenous or intramuscular injection fall off more slowly than do those of penicillin, and a given dosage provides effective levels for longer periods. The implications of these findings with respect to the therapeutic efficacy of this agent are discussed in the text.

METHODS AND MATERIALS

Bacitracin. Three different lots of bacitracin were used in these studies. The courtesy of Dr. Frank L. Meleney in facilitating their procurement is gratefully acknowledged. The 3 lots, designated in the tables as A, B–100, and PB–1, had relative gravimetric activities *in vitro* against the C–203 strain of Streptococcus pyogenes of 100, 165, and 330, respectively. Their activity in terms of the unit as defined by Meleney and his co-workers (4) was 18, 30, and 60 units per mgm., respectively. Lot PB–1 was concentrated in this laboratory from a commercial lot, B–103.

Blood specimens in rabbits were obtained by cardiac puncture, and urine specimens by bladder catheterization and irrigation.

Method of assay. A modified Rammelkamp-Rantz-Kirby method (5, 6), in which inhibition of hemolysis by the C–203 strain of Streptococcus pyogenes served as the endpoint, was used to assay the levels of the antibiotic in the blood and urine. The endpoint was not as sharp as with penicillin, and somewhat coarser interpolations were used than had proved feasible with the latter drug (2, 7). The unknown sample, in appropriate dilution as determined by a preliminary spot-assay, was distributed in amounts of 0.8, 0.64, 0.48, 0.4, 0.32, 0.24, 0.2 . . . ml., and the volumes brought up to 0.8 ml. with broth. To all the tubes were then added 0.5 ml. of 4 per cent rabbit (or human) blood broth, inoculated with 1/2,500 part of a fresh 6- to 8-hour culture of the organism in blood broth. Difficulties introduced by the occasional contaminated specimen were overcome by removing the assays from the incubator after 6 to 8 hours, when the streptococci had multiplied sufficiently to initiate hemolysis, but before they had been overgrown by the contaminant. The tubes were then allowed to stand at room temperature overnight, and the results read the next morning.

The threshold concentration for inhibition under the conditions of this assay averaged on the order of 0.01 "units" per ml., or 0.3 µg. of the impure preparation B-100. The threshold concentration of penicillin G under the same conditions was 0.015 µg. per ml.

EXPERIMENTAL

Blood levels of bacitracin in rabbits and man. Nine human subjects were injected intramuscularly with bacitracin in aqueous solution at dosages

[1] Supported in part by the Life Insurance Medical Research Fund.

varying from 14 to 150 units per kgm., representing 0.8 to 5 mgm. per kgm. of the preparations used. Rabbits were injected both intravenously and intramuscularly at dosages varying from 10.8 to 1,080 units per kgm. (0.6 to 60 mgm. per kgm.). The blood levels at varying intervals thereafter are graphically summarized in Figures 1 and 2, in which the bacitracin dosages and blood levels are expressed both as units and milligrams in order to permit comparison with the average curves given by penicillin G similarly injected.

In individual rabbits, the serum concentrations at any given time were linearly related to the dosage injected; and the average curves of Figure 1 reflect the constancy of that relationship. In man, the relationship between dosage and blood level was evident, but less regular (Table I).

There was a striking difference between the rate at which bacitracin and penicillin G disappeared from the blood. In rabbits injected intravenously, bacitracin disappeared from the blood at an average rate of 50 per cent of the residual activity per hour. With penicillin G, the hourly rate of fall has previously been found to be 70 to 80 per cent after

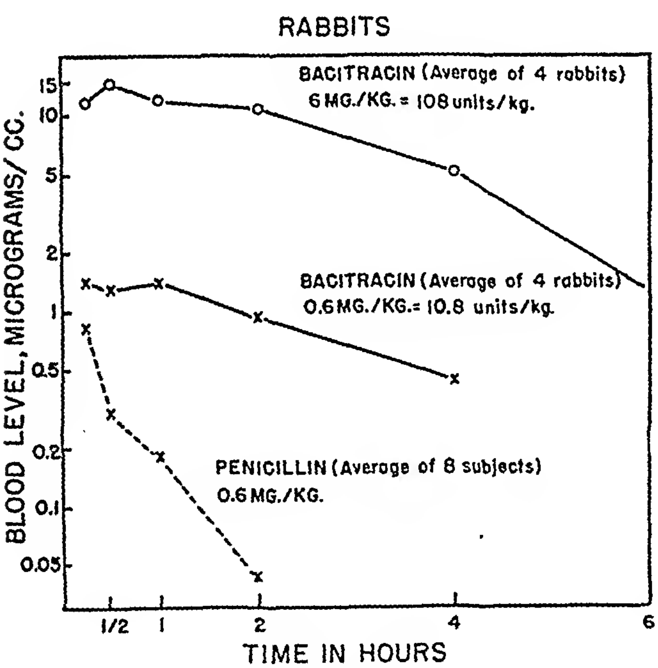

FIG. 1. THE AVERAGE BLOOD LEVEL OF BACITRACIN IN RABBITS AFTER ITS INTRAMUSCULAR INJECTION AT 6 MGM. PER KGM. AND 0.6 MGM. PER KGM. OF THE CRUDE PREPARATION A, CORRESPONDING TO 108 AND 10.8 MELENEY-JOHNSON UNITS PER KGM.

The blood levels are expressed in micrograms to permit comparison with the penicillin curve; the activity in units would be 0.018 times the levels shown in the figure.

TABLE I

Blood levels of bacitracin after its intramuscular injection in man

Subject	Dosage		Time in hours: ¼	½	1	2	4	6	8	24

intramuscular injection, and even greater after intravenous injection. The qualitative difference between penicillin and bacitracin is apparent on comparing the appropriate curves in Figures 1 and 2. In rabbits, one hour after the injection of penicillin G and (crude) bacitracin in equal gravimetric dosage, the serum levels of bacitracin were 8 to 20 times greater than those of penicillin; and 2 hours after the injection, the difference was 20- to 100-fold. In man also (Figure 2 and Table I), the blood levels 2 hours after the injection of bacitracin

TABLE II

The varying periods for which bacitracin and penicillin, similarly injected, remained in the circulating blood

	Dosage	Average number of hours indicated drug remained in serum at minimum level of 1 μg. per ml.: Penicillin	Bacitracin*
	mgm. per kgm.		
Man (intramuscular)	3	2.1	6.8
	1.5	1.2	2.5, 4.6
Rabbit (intravenous)	60	1.5	9–10
	6	0.9	5.7
	0.6	0.25	1.6

The penicillin blood levels in man are average of 8 subjects (9). The penicillin levels in rabbit are from single animals only. Bacitracin levels are from the experiments of Table I and Figures 1 and 2.

* 1 μg. per ml. of crude preparations here used = 0.03 Meleney-Johnson unit.

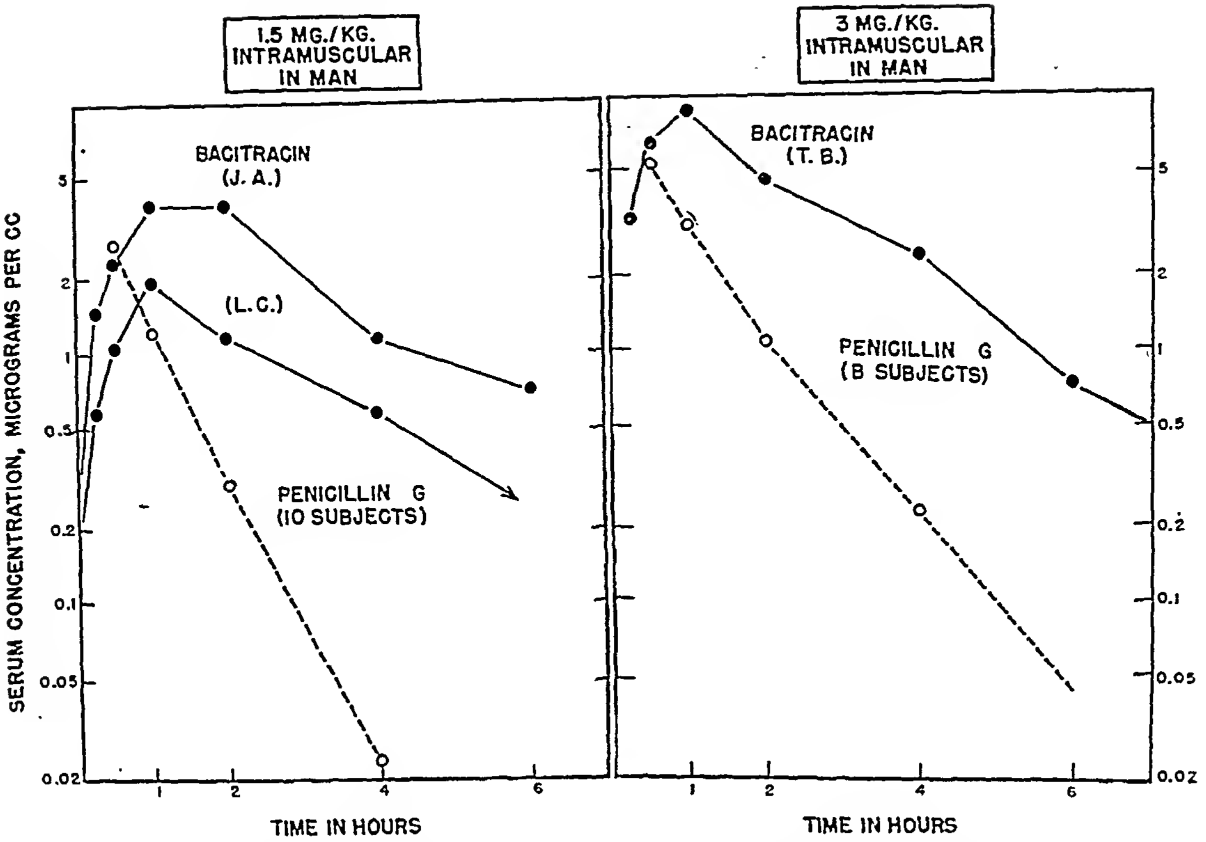

FIG. 2. THE AVERAGE BLOOD LEVELS AFFORDED BY BACITRACIN IN MAN AFTER ITS INTRAMUSCULAR INJECTION AT 1.5 MGM. PER KGM. AND 3 MGM. PER KGM. OF THE CRUDE PREPARATION B–100, CORRESPONDING TO 45 AND 90 MELENEY-JOHNSON UNITS PER KGM.

The blood levels are expressed in micrograms to permit comparison with the penicillin curve; the activity in units would be 0.030 times the levels shown in the figure.

at *e.g.*, 3 mgm. per kgm. (90 units per kgm.), were 4 times greater than the average observed with penicillin G; and the difference became progressively more pronounced thereafter.

A more important comparision between the 2 antibiotics is the length of time for which effective bactericidal levels were maintained. The pertinent data are summarized in Table II. In 2 subjects (J. A. and L. C.), injected intramuscularly with crude bacitracin B-100 at 1.5 mgm. per kgm. = 45 units per kgm., a level of 1 μg. = 0.03 unit per ml. was maintained for 2.5 and 4.6 hours (Figure 2). In 8 subjects similarly injected with penicillin G, that level was maintained for an average period of 1.2 hours (8). In subject T. B., injected with bacitracin at 3 mgm. per kgm. = 90 units per kgm., the 1-μg. level was maintained for 6.8 hours, as compared to an average of 2.1 hours in 8 patients receiving the same amount of penicillin G (8). In rabbits also, whether injected at 0.6 or 6 mgm. per kgm., a serum concentration of active material corresponding to 1 μg. per ml. was maintained 6 to 7 times longer with bacitracin than with penicillin.

Urine excretion of bacitracin. The pharmacologic basis for the marked difference in the blood levels afforded by penicillin and bacitracin is their widely different rate of urinary excretion. In 8 human subjects (Table III and Figure 3), the cumulative excretion of bacitracin in 1, 2, 4, and 6 hours averaged 17, 34, 66 and 87 per cent.[2]

[2] In 5 of the subjects listed in Table I, the total urinary excretion after 6 to 8 hours varied between 78 and 119 per cent of the amount injected, reflecting essentially com-

* Anomalous high results in parentheses not included in calculation of mean excretion.

The corresponding values for penicillin G have been previously reported to be 60, 72, 78, and 86 per cent (8). In the first hour, penicillin G was therefore excreted 3 times faster than bacitracin (Figure 4); after 2 hours, however, when most of the penicillin had already appeared in the urine, and its rate of excretion in the following 2 hours had fallen to 3 per cent per hour, the rate of urine excretion of bacitracin was still 16 per cent per hour, 5 times that of penicillin. The shapes of the blood curves mirror the differences in the rate of excretion of the 2 antibiotics.

In rabbits also (Table IV, and Figures 3 and 4) from 7.5 to 26 per cent (averaging 17 per cent) had appeared in the urine in the first hour, as compared with 58 per cent for penicillin G (3); but after 2 hours, bacitracin was being excreted at an hourly rate of 14 per cent, or 1.7 times greater than penicillin similarly injected. Beyond that time period, only insignificant amounts of penicillin were recovered in the urine, while bacitracin was still being excreted in appreciable quantity.

The renal clearance of bacitracin. Nine experiments to determine the renal clearance of bacitracin in man are summarized in Table V, and one experiment is graphically summarized in Figure 5. The results varied considerably from subject to subject, and even in successive time periods in the same subject. To some extent, the latter variation may have reflected incomplete voiding, since only 2 of the patients were catheterized. The average clearances in the 9 subjects varied between 105 and 283 ml. per minute, averaging 159. The corresponding average values for penicillins F, G, and X in man have been found to be 725, 560, and 710 ml. per minute (2). The renal clearance of bacitracin in man is therefore approximately ½ to ⅙ that of penicillin, explaining the more prolonged blood levels and the more sustained but initially lower rate of urinary excretion of the former.

plete excretion. In 1 subject (J. M.), however, the cumulative total of 164 per cent exceeded the experimental error of the method of assay. An even greater anomalous excretion was observed in patient J. P. In both cases, the anomalous result was due to an abnormally high excretion during the 2- to 4-hour period, as yet unexplained.

The ratio of the bacitracin clearance to the total renal plasma flow (calculated) in these 8 subjects, given in column 5 of Table V, varied between 0.15 and 0.39, averaging 0.23.

The ratio of the bacitracin clearance to the (calculated) glomerular filtration rate, given in Column 6 of Table V, varied between 0.8 and 2.04, averaging 1.23. As is indicated in the foregoing section, a significant error in clearance was introduced in 7 of the 9 subjects by the fact that the urine specimens were probably inaccurately voided. Particularly in these patients, the ratio of the renal clearance of bacitracin to the glomerular filtration rate simultaneously determined by the clearance of thiosulfate (9) was of greater significance than the absolute values of either, since an error in urine collection would not affect the ratio of the 2 clearances. This ratio of bacitracin clearance to thiosulfate clearance varied between 0.52 and 1.83, averaging 1.1.

Eight experiments to determine the renal clearance of bacitracin in rabbits are summarized in Table VI, and one experiment is shown in Figure 6. In these 8 rabbits the renal clearance of bacitracin varied between 2.0 and 7.1 ml. per minute, averaging 4.1. This is less than the glomerular filtration rate in the rabbit (10), and is to be compared with an average renal clearance in that species for penicillins F, G, and X of 34, 61, and 36 ml. per minute, with a range of 18 to 100 (2). The

certain strains of B. subtilis (bacitracin) remain in the circulating blood for significantly longer periods and at higher levels than does penicillin similarly injected. This reflects the fact that the renal clearance of bacitracin was of the same order of magnitude as the glomerular filtration rate, as compared to a renal clearance for penicillins F, G, and X, approximating the total renal plasma flow.

The mechanism whereby bacitracin is excreted by the kidney is not clear from the present data.

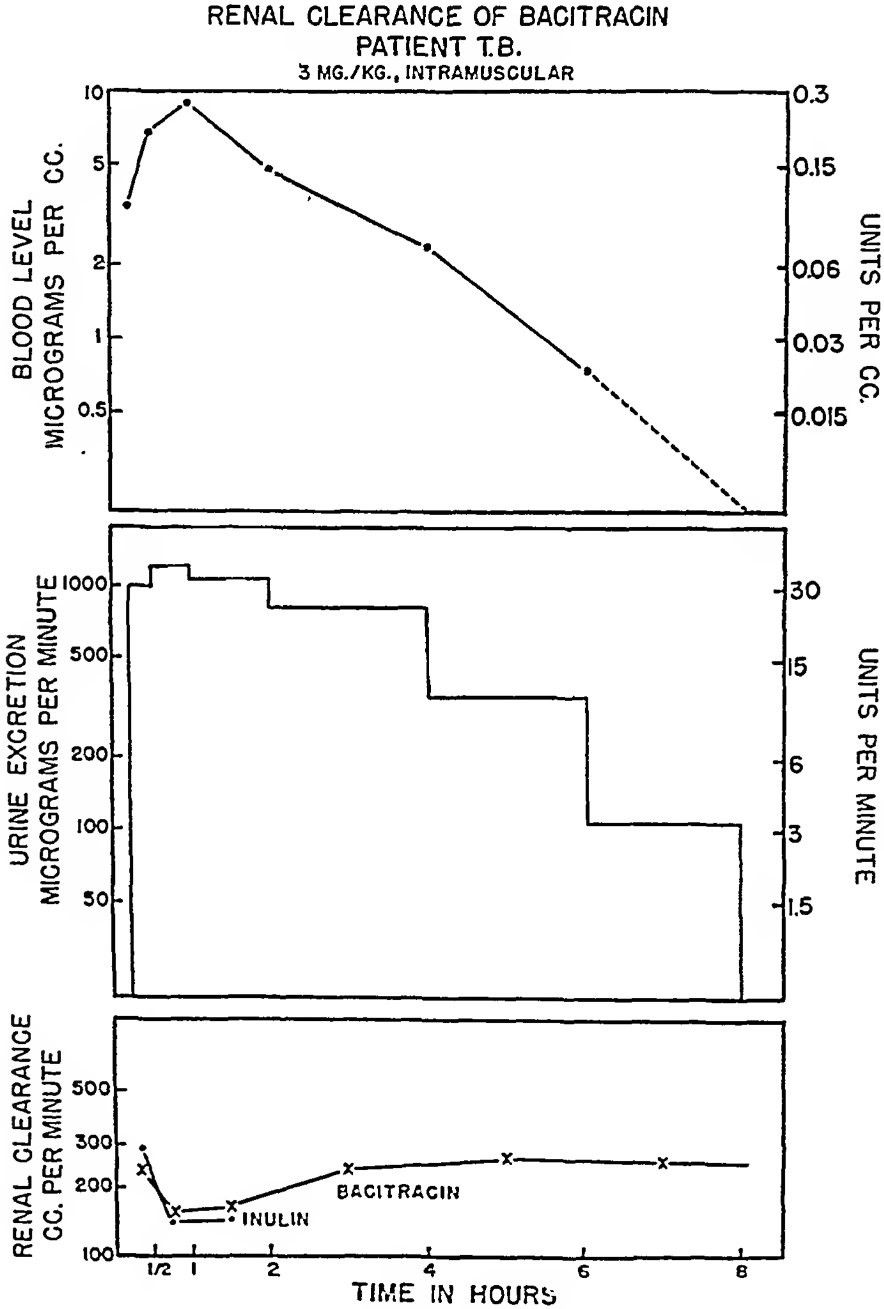

FIG. 5. ILLUSTRATING THE LOW RENAL CLEARANCES OF BACITRACIN IN MAN

Subject T. B. was injected with Preparation B-100 at 3 mgm. per kgm. = 90 Meleney-Johnson units per kgm.

* The lot A injected contained 18 units per mgm. To translate these data to units, figures in these columns should be multiplied by 0.018.

It is possible that bacitracin is excreted only by glomerular filtration, and that the large differences obtained in the ratio of *bacitracin clearance: thiosulfate clearance*, which varied from 0.5 to 1.8, averaging 1, were due to technical factors in the collection of urine and in the assay of activity (page 919). It is, however, also possible that there is a certain amount of tubular secretion, and that nephrotoxic products known to be present in the crude bacitracin here used (11) exerted a variable inhibitory effect on the renal excretion. The degree to which bacitracin is bound by serum protein is now under study.

In any event, it is evident that the active material in the crude preparations of bacitracin here used was cleared by the kidney at a rate approximating that of glomerular filtration, while penicillin is cleared at a rate approximating the total renal plasma flow.

Against the C–203 strain of streptococcus here used, the most potent preparation of bacitracin so far available (PB–1) was gravimetrically only 1/12 as active as penicillin G *in vitro*. Unless the active material in this preparation constituted only a small fraction of its solid content, even the more favorable pharmacologic properties of bacitracin might not counterbalance its relatively low bactericidal activity against this particular strain. However, for organisms against which bacitracin has an activity *in vitro* comparable with that of penicillin, its slower excretion and more sustained blood levels might permit cure to be effected with smaller doses, or with injections administered at less frequent intervals, than is the case with penicillin.

SUMMARY

1. Three different lots of "bacitracin," antibiotic concentrates derived from culture filtrates of B. subtilis (Tracy), have been studied with respect to blood levels, urinary excretion, and renal clearance in rabbits and man.

2. The serum concentration after the intravenous or intramuscular injection of bacitracin varied linearly with dosage over a wide range. These serum concentrations fell off far more slowly, and were consistently higher, than was the case with penicillin G, similarly administered.

Two to 4 hours after injection, the serum levels of bacitracin were 10 to 50 times higher than those of penicillin similarly injected; and concentrations in excess of a given level were maintained 4 to 8 times longer.

3. Corresponding to the sustained blood levels, the rate of urine excretion of bacitracin remained at a fairly constant level for a period of 2 to 4 hours after its intramuscular injection.

(*a*) In man, the cumulative urinary excretion of bacitracin, 1, 2, 4, and 6 hours after its intramuscular injection, averaged 17, 36, 66, and 87 per cent of the amount injected. The hourly excretion in the first hour was one-third that of penicillin G; but after 2 hours, bacitracin was being excreted at a rate 5 times that of penicillin G.

(*b*) In rabbits, the cumulative totals of bacitracin excreted in 1, 2, and 4 hours averaged 17, 34, and 62 per cent of the amount injected. Initially, bacitracin was excreted at less than 1/3 the

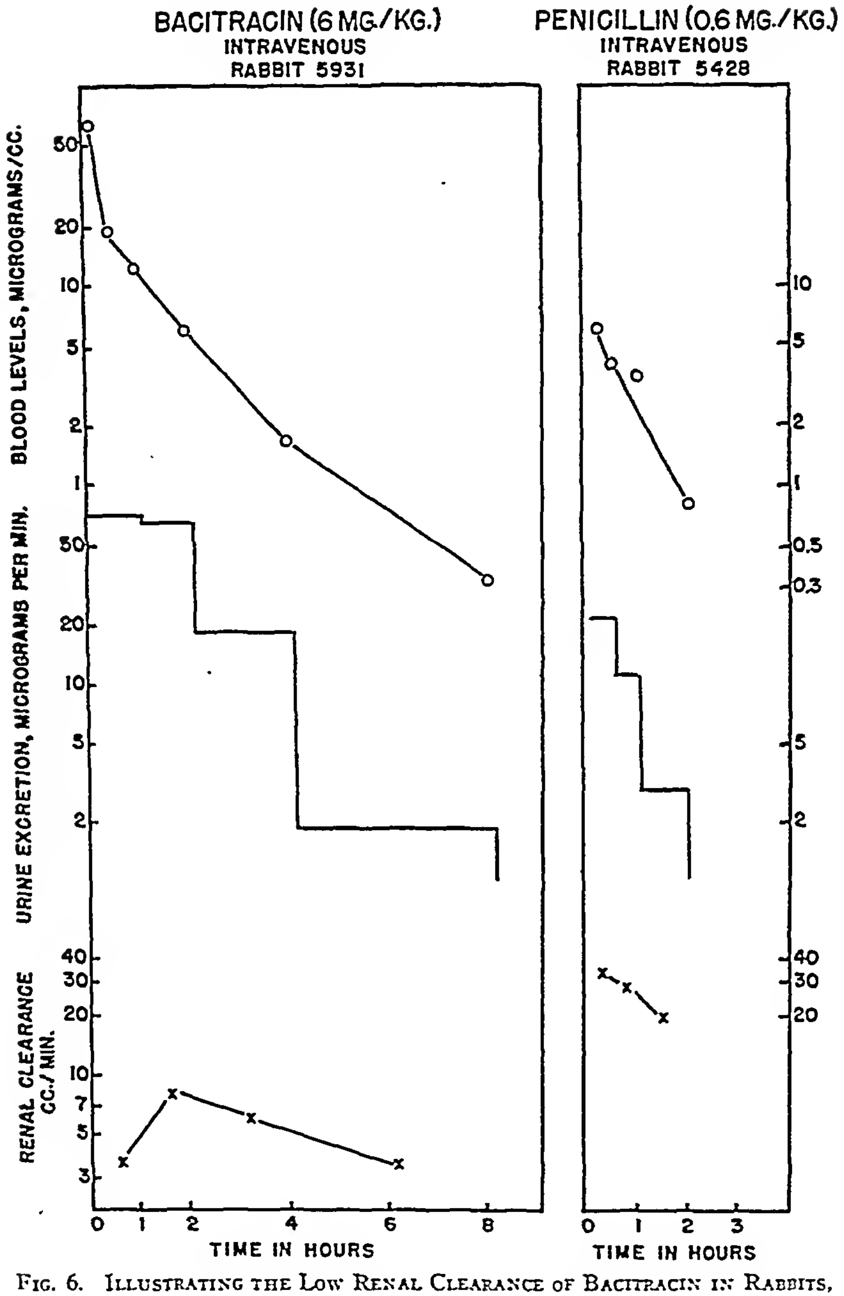

Fig. 6. Illustrating the Low Renal Clearance of Bacitracin in Rabbits, Compared to that of Penicillin

The dosages and corrections are expressed in the figure as mgm. per kgm. in order to permit comparison with penicillin. To obtain the serum concentrations and urine excretions in units, the microgram values should be multiplied by 0.018.

rate of penicillin; but after 2 hours, the rate of excretion was 1.7 times that of penicillin G.

4. The prolonged blood levels of bacitracin as compared with penicillin G, and its slower urinary excretion, are explained by its low renal clearance, which approximated the glomerular filtration rate.

(*a*) The renal clearance of bacitracin in 9 human subjects varied between 105 and 283 ml. per minute, averaging 159.

(*b*) In 8 rabbits, the renal clearance of bacitracin varied from 2 to 7 ml. per minute, averaging 4.1.

(*c*) In both man and rabbits, the renal clearance of penicillins F, G, and X for rabbits has previously been shown to approximate the total renal plasma flow.

CHEMICAL, CLINICAL, AND IMMUNOLOGICAL STUDIES ON THE PRODUCTS OF HUMAN PLASMA FRACTIONATION. XXXV. THE PERSISTENCE OF FIBRIN FILM IN TISSUE AND ITS MODIFICATION BY HEAT TREATMENT[1,2]

By PETER R. MORRISON and MARCUS SINGER

(From the Departments of Physical Chemistry and Anatomy, Harvard Medical School, Boston)

(Received for publication February 7, 1947)

The fractionation of human plasma into its component proteins (1) has made possible the preparation of several new plastic materials (2, 3). These materials, fibrin film and fibrinogen plastic, are formed from native homologous proteins and have found application in surgery because of their favorable mechanical properties and their faculty of being absorbed in the body with almost no irritative reaction. The rate of absorption and the persistence time, however, depend on the modifying treatment to which they have been exposed. In its application as a dural substitute (4), thus far its most extensive clinical use, heat-sterilized fibrin film persists for periods of several months. Observations on unheated fibrin film, on the other hand, have shown much more rapid absorption. For certain uses, such as in peripheral nerve suture (5) or in tendon repair, neither of these extremes seemed desirable; the heat-sterilized film evoked too great tissue reaction, while the untreated film disappeared too rapidly to be effective.

The present study was undertaken to obtain exact information on the rate of absorption of fibrin films which had been exposed to varying degrees of heat treatment and to find, if possible, conditions which would allow fixing the persistence time to meet a given surgical need. Some quantitative measurements on the extent of gross tissue reaction to the implant are also reported. Observation on the histological sequence involved in the absorption of heat-sterilized films (6) and plastics[3] have already been made by Bailey, and a preliminary report of some of these findings has already been presented (7). Although primarily concerned with the absorption of fibrin films, some observations on the absorption of implanted fibrinogen plastic, and the tissue responses to its presence, are also reported.

Measurements were also made to determine the resistance of variously heated fibrin films to tryptic digestion. Proteolytic digestion has previously been used (8, 9) as a measure of the absorbability of surgical gut. Although the 2 processes are qualitatively similar, important quantitative differences may obtain. The absorption of fibrin film *in vivo* is compared to its tryptic digestion *in vitro*.

MATERIALS AND METHODS

Fibrin film was prepared from human fibrinogen and thrombin (10). Some films were made aseptically from solutions which had been previously sterilized by filtration; in others, unsterile materials were used and the films were subsequently sterilized by heat treatment. Fibrinogen plastic containing 67 per cent of glycerol as plasticizer was prepared by heating at 100° C. under pressure for 15 minutes. The types of material used, according to thickness and extent of heat treatment, were as follows:

A. Aseptically prepared fibrin films of 4, 7, and 11 mgm. fibrin per sq. cm.
   1. Unmodified.
   2. Heated in glycerol at 100° C. for periods of ½, 1, 3, and 10 minutes.
B. Heat-sterilized fibrin films[4] of 17 mgm. fibrin per sq. cm.

---

[1] This work has been carried out under contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University.

[2] This paper is Number 58 in the series "Studies on the Plasma Proteins" from the Harvard Medical School, Boston, Massachusetts, on products developed by the Department of Physical Chemistry from blood collected by the American Red Cross.

[3] Bailey, Ford, and Hawn. A report to the Proctor Fund, Harvard University, September 1, 1942. This study of the histological response to a series of implanted fibrinogen plastics was begun early in 1941.

[4] Fibrin film was at first sterilized in this manner but it was subsequently found possible to sterilize it by direct

1. Autoclaved under glycerol for 15 minutes at 120° C.
2. Heated in glycerol for 1 minute at 155° C.

C. Fibrinogen plastic of 13 mgm. dry weight per sq. cm., sterilized by autoclaving under glycerol for 15 minutes at 120° C.

Squares (1 cm. by 1 cm.) of these materials were implanted in rabbits both subdermally over the femorococcygeal muscle and intermuscularly between that muscle and the adductor group. The implants were made in normal and burned[5] tissues; however, results proved identical in both cases. Furthermore, it was observed that absorption proceeded similarly irrespective of whether implantation was subdermal or intermuscular. Consequently, the observations on these 2 situations are not treated separately, but have been combined in the discussion of results.

The implants were anchored at each corner with a loop of silk thread. They were removed at intervals and the residual fibrin was determined gravimetrically by soaking in distilled water, drying at 110° C., and weighing to 0.1 to 0.2 mgm. There was a variability of 0.2 to 0.5 mgm. in the initial weight of individual pieces and the initial weight was taken as the average of a series of 6 squares. In the late stages of absorption the difficulty in locating and removing the remaining fragments of fibrin introduced an additional error.

In measuring tryptic digestion a 1 per cent solution of a commercial trypsin in phosphate buffer of pH 7.0 and ionic strength of 0.15 was clarified by centrifugation and filtration. It was allowed to act at 38° C. for various lengths of time, and the residual fibrin was determined as

exposure to steam (3, 11) and material for clinical use is now prepared in this manner. In use as a dural substitute the persistence time and tissue reaction to the 2 types are similar (4).

[5] In one series implants were introduced into areas which had been injured by burning in order to clarify the observation that fibrin films used therapeutically on burns often disintegrated much more rapidly than in other situations. Note reference (12).

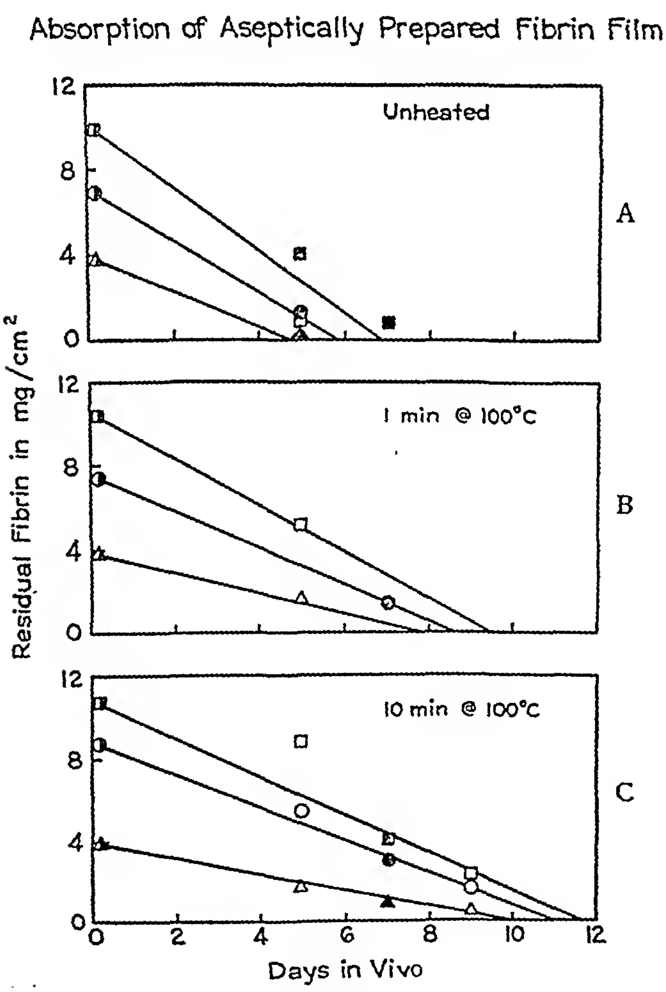

Fig. 1. The Absorption of Unheated and Moderately Heated Fibrin Films

above. This trypsin (Cenco) required twice as long as standard trypsin (U.S.P.) to digest heat-sterilized fibrin film. Measurements of tensile strength were made using a simple spring balance. Pieces of film 1 by 6 cm. and of a single weight, 16 mgm. per cm^2., were used in these experiments.

RESULTS

The experimental results are summarized in Figures 1 and 2 and show the progressive absorption of the fibrin following implantation. The unmodified films are absorbed most rapidly and the heat-sterilized films most slowly; the moderately heated films lie between these extremes. In presenting the data on unmodified and moderately heated films the course of absorption has been represented by a straight line whose slope gives the absorption rate and whose intercept is the persistence time. This follows the convention of Jenkins and Hrdina (13) in their studies on the absorption of surgical gut. It should be noted, however, that histological examination has revealed small fragments of fibrin after considerably longer periods than the persistence time as indicated by this method (5). The course of absorption of the heat-sterilized materials cannot be represented by a straight line since the absorption rate clearly falls off with time.

Unmodified film. Complete absorption of all the unmodified films (4, 7, and 11 mgm. per cm.^{2}) occurs in less than 9 days (Figure 1A). The absorption rates vary from 0.85 to 1.45 mgm. per day with increasing thickness of film. Even at the earliest time of examination (5 days) the film was very weak and could not be removed in a single piece.

Heat-sterilized film. The absorption curves shown by fibrin film heated for 15 minutes at 120° C. and for 1 minute at 155° C. (Figures 2A and B) are very similar. They have initial slopes (or absorption rates) of 0.24 to 0.35 mgm. per day but level off to 0.12 to 0.14 mgm. per day after 40 days in the animal. In the single animal examined after a longer period (81 days) considerable amounts of film still remained. In contrast to unmodified film, heat-sterilized film retained more of its tensile strength and could usually be removed in a single piece.

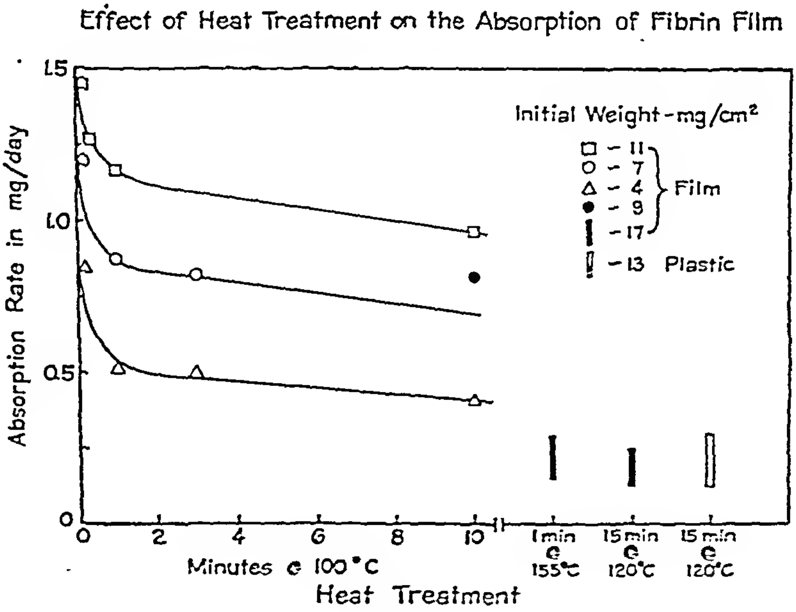

FIG. 3. THE EFFECT OF HEAT TREATMENT ON THE ABSORPTION OF FIBRIN FILM

Ordinate, rate of absorption in mgm. of fibrin per day (*i.e.*, the slopes of the curves in Figures 1 and 2); abscissa, degree of heat treatment. In the strongly heated materials whose absorption rate changed with time the range of values has been shown by the height of the symbol.

Moderately heated film. The course of absorption of films subjected to moderate heat treatment (Figures 1B and 1C) was intermediate to those of the unmodified and the heat-sterilized films. Although persisting for longer times, films heated at 100° C. for ⅓, 1, or 3 minutes resembled the unheated films in their fragmentation and rapid loss of tensile strength. On the other hand, those heated for 10 minutes behaved more like the heat-sterilized films and retained their original form during most of the absorption period. The effect of heat treatment on the absorption rates of these films has been summarized in Figure 3 and it may be seen that the 3- and 10-minute films have quite comparable absorption rates, roughly ½ that of the unmodified film, despite this marked difference in mechanical properties.

Tissue reaction to the implant. In the unmodified and moderately heated films, with their shorter persistence times, gross encapsulation by fibrous connective tissue could not be detected. In contrast, the absorption of heat-sterilized films, with their extended persistence times, always was accompanied by the development of a firm fibrous capsule. Although undoubtedly preceded by a histological sequence of events (5, 6), this capsule was grossly evident as a well-organized structure only after 10 days following implantation. It was observed to increase in thickness during the following 20 days. The capsule was easily separated from the surrounding loose connective tissue and completely enveloped the film. The film, in turn, lay free within the capsule and could usually be removed in a single piece. Internally the capsule was characterized by a shiny smooth surface having the appearance of a serous lining. Since it could be so easily separated from the surrounding tissue and the enclosed film, quantitive estimates of the response of the host to the foreign body could be obtained. The dry weight of the capsule was measured in a manner similar to that used for the film.

Figure 4 pictures the progressive growth of the capsule. The curve is characterized by a rapid increase during the 10- to 25-day period followed by a leveling off at about 10 mgm. during the succeeding 30 days. This value may be more fully appreciated when it is compared to the dry weight of the connective tissue sheet normally occurring at the implantation site which is of the order of 1 mgm. per cm². A single pair of measurements after 81 days suggests that there is a reduction in

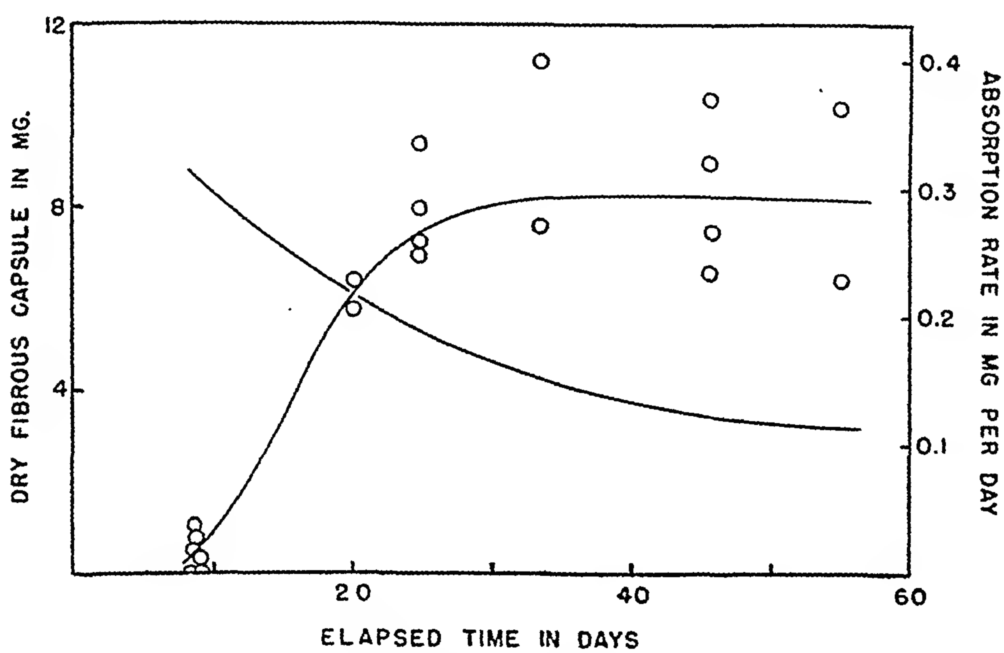

FIG. 4. THE ENCAPSULATION OF IMPLANTED HEAT-STERILIZED FIBRIN FILM AS A FUNCTION OF TIME

Points represent the dry weight of the capsule surrounding a 1 cm. by 1 cm. piece of film. The descending curve which shows the falling off in the rate of absorption with time derives from the slopes of the average curves in Figure 2.

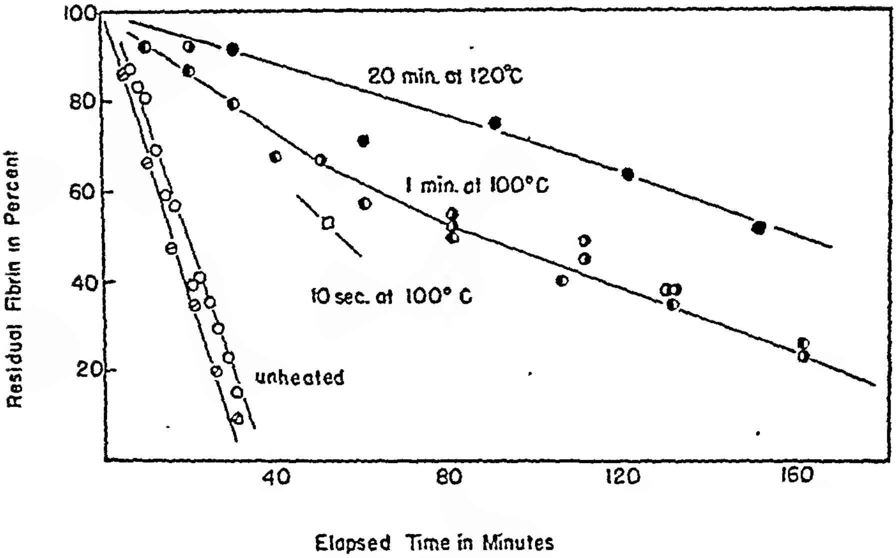

FIG. 5. THE COURSE OF TRYPTIC DIGESTION IN VARIOUSLY HEATED FIBRIN FILMS

Symbols represent different heat treatments as indicated. Temperature, 38° C.; pH, 6.9; ionic strength, 0.15; fibrin film, 12 mgm. per sq. cm., plasticizer not removed before heating.

size of the capsule as absorption of the fibrin nears completion. In these 2 instances the weights were 2.6 and 6.4 mgm. or about ½ the average value between 30 and 50 days.

Fibrinogen plastic. The course of absorption of heat-sterilized fibrinogen plastic is entirely comparable to that of heat-sterilized fibrin film. This is shown in Figure 2C where the progressive falling off of the absorption rate is clearly seen. The plastic also became surrounded by a thick fibrous capsule with a dry weight of about 10 mgm., but it retained less strength than the film, particularly in the latter stages of absorption where it fragmented badly. After 81 days only traces of the plastic could be detected.

Tryptic digestion of fibrin film. Results on the digestion by trypsin of variously heated fibrin films are summarized in Figure 5. The data are well represented by straight lines with the exception of the film heated for 1 minute at 100° C. which disappears more rapidly during the first few minutes. Under these conditions the unmodified film shows a half digestion time of 16 to 18 minutes. A very brief exposure to heat (10 sec. at 100° C.) increases this half time 3-fold, to 54 minutes. Intense heat treatment, sufficient for sterilization, extends the half digestion time only by another factor of 3, to 100 minutes.

During digestion the breaking strength of the film progressively decreases. As is shown in Figure 6 this loss in strength is in general proportional to the loss in fibrin. This is in contrast

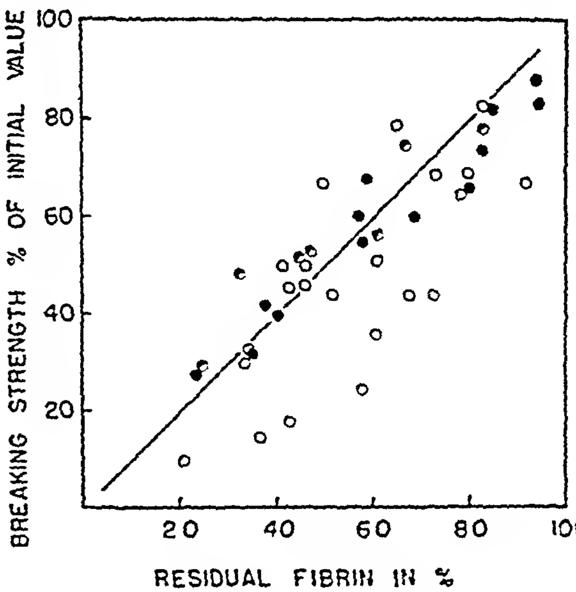

FIG. 6. THE BREAKING STRENGTH OF FIBRIN FILM UNDERGOING TRYPTIC DIGESTION AS A FUNCTION OF THE AMOUNT OF RESIDUAL FIBRIN

Symbols represent different series of measurements all performed with unheated film of initial weight of 16 mgm. per sq. cm.

to observations on the loss of tensile strength *in vivo*. The considerable scatter of the points reflects the dependence of this measurement on flaws in the film. The percentage of fibrin in the wet film becomes lower during digestion; thus the wet weight is reduced more slowly than the dry weight. This emphasizes the importance of using the latter as the measure of the proteolysis.

DISCUSSION

The wide range of absorption rates shown by the various types of film is seen in Figure 3. The effect of heating is to increase progressively the resistance of the film. However, at 100° C., the larger portion of this effect is obtained within the first minute and further heating, even for 10 times this period, makes the film only slightly more resistant. However, this additional treatment does increase the strength of the residual film. At the higher temperature of 120° C. the absorption rate is reduced to ⅕ that of the unmodified film.

Upon comparing films of different initial weight though of similar treatment (see Figure 1), one observes that the greater the thickness the greater the absorption rate. Indeed, the absorption rate in *mgm. per day* is roughly proportional to the initial weight. However, this means that the persistence time and the absorption rate in *per cent per day* should be nearly independent of the initial weight. Reference to Figure 1 shows the former to be true since, with a 3-fold difference in initial weights, the persistence times vary by a factor of only 1.2 to 1.3. This proportionality between the initial weight and the absorption rate suggests that proteolysis is occurring throughout the film rather than only at the surface. In the latter situation we would have expected different weights of film to show proportional persistence times and the same absorption rate in mgm. per day.

In this study only one thickness of heat-sterilized film was used so that similar deductions cannot be made regarding this material. However, in film sterilized by direct exposure to steam (11), tryptic digestion is more rapid in the thinner pieces. This would indicate that the enzyme is acting at the surface and that in this material the heat-imparted resistance could be accounted for, at least in part, by exclusion of the enzyme from the film interior.

In heat-sterilized film the absorption rate falls off steadily with time and the range of the changing values has been represented in Figure 3 by a vertical line. In Figure 4 this decrease in the rate of absorption is compared to the increasing encapsulation and it may be seen that there is a fairly good inverse correspondence between these 2 variables. This would suggest that this progressive decrease in the rate of absorption as these films remain in the body may be due merely to the formation of the fibrous capsule and not to any characteristic of the absorptive process.

The absorption of a protein structure in the body and its digestion *in vitro* both represent enzymatic proteolysis, and the 2 processes are therefore qualitatively similar. However, such enzymes may be quite specific and are very sensitive to the conditions under which they act (14). Extrapolation from an enzyme in one situation to a different enzyme in another situation should be made cautiously. In studies of the peptic digestion of collagen sutures Jenkins and Hrdina (9, 13) found, in general, a satisfactory correlation between the loss of strength *in vitro* and *in vivo*, but they noted that discrepancies sometimes occurred in which a suture, satisfactory by *in vitro* standards, disappeared too rapidly in the body.

TABLE I

Treatment	Time for half proteolysis			
	In vitro		*In vivo*	
	min.	heated / unheated	days	heated / unheated
Unmodified	19		3.5	
10 sec. at 100° C.	54	2.9		
1 min. at 100° C.	84	4.4	4.6	1.32
10 min. at 100° C.			5.8	1.65
15 min. at 120° C.	156	8.2	48	13.7
1 min. at 155° C.			38	10.8

A comparison of the effect of heat treatment on the digestion of fibrin film *in vivo* and *in vitro* reveals a similar picture; heat treatment increases the persistence in both situations but the quantitative relations are quite different. The half persistence times as measured by the 2 methods are summarized in Table 1, and it is seen that slight and moderate heat treatment prolongs the tryptic digestion time much more than the persistence in

the body. On the other hand, in the heat-sterilized films the change is of the same order of magnitude.

The changes in the physical and chemical properties of fibrin film which accompany heat treatment have been carefully studied (11). The heated film has a higher water-equilibrated fibrin content, a lower opacity, a higher tensile strength, a lower swelling index in acid and alkali and a lower permeability. All of these physical changes may be attributed to the formation of additional permanent cross links in the fibrin network to yield a denser, more rigid structure. The decreased permeability which results may be of particular importance in increasing the resistance of the heated film to proteolytic enzymes both *in vitro* and *in vivo*. Thus, although the heat-sterilized film is completely impermeable to hemoglobin, for example, this protein passes freely through the unmodified film. If the action of the enzyme were thus restricted to the outer surface of the film, it would result in a much slower rate of proteolysis. Of course, the increased cross linking *per se* may also increase the resistance to enzymes. The chemical changes induced by the heat treatment, which are most strikingly shown in the change in affinity for acid and basic dyes, are undoubtedly associated with the physical changes and may be also involved in the increased persistence.

SUMMARY

The course of absorption of variously heated fibrin films, after implantation in rabbits, has been studied. A quantitative measure of absorption was obtained by measuring the actual weight of residual fibrin after different lengths of implantation. A measure of the tissue reaction to the implant was obtained by measuring similarly the weight of the surrounding fibrous capsule.

Persistence times ranged from less than 5 days for unmodified fibrin film to more than 80 days for heat-sterilized films. Intermediate persistence times were obtained by milder heat treatment. A heavy encapsulation of heat sterilized film occurred between 10 and 30 days following implantation.

The resistance of these variously heated films to tryptic digestion was measured and the responses *in vivo* and *in vitro* compared. The effect of heat treatment showed qualitative similarity but important quantitative differences were noted.

STUDIES ON EXPERIMENTAL PHOSGENE POISONING. III. OXYGEN THERAPY IN PHOSGENE-POISONED DOGS AND RATS[1]

By H. D. BRUNER, ROBERT D. BOCHE, CHARLES C. CHAPPLE, MARY H. GIBBON, and MILES D. McCARTHY

(From the Harrison Department of Surgical Research, Schools of Medicine, University of Pennsylvania, Philadelphia)

(Received for publication February 11, 1947)

Clinical opinion of the value of inhalational oxygen therapy in "lung irritant" casualties in the first World War was uniformly high (1 to 4). The use of oxygen in subsequent accidental poisonings has confirmed that evaluation (5 to 12) and led to extension of the original views to *pure* phosgene poisoning. The relief usually afforded the patient appears to have been impressive. Objective improvement consisted of disappearance of the cyanosis and clearing of the sensorium; the tachycardia was sometimes relieved, but the dyspnea generally was not (2). Therapy with 100 per cent oxygen has been reported to reduce cough and relieve the sensation of a constricted chest (8, 9). For these reasons, oxygen therapy is the chief measure prescribed for phosgene poisoning in official manuals and treatises on this subject. Further substantiation is necessary for other claimed benefits of oxygen therapy, such as inhibiting the development of severe edema, shortening the duration of illness, and diminishing dilatation of the right side of the heart (1, 8, 13, 14).

While it is generally agreed that oxygen therapy is clinically indicated in this type of pulmonary edema, no data have been found which permit statistical confirmation of the ultimate benefits of such therapy. A close examination of the literature brought out the following: (*a*) The clinical prognosis must have been the basis for claims of its life-saving value, but experience with poisoned animals has shown the fallibility of prognosis. (*b*) The average mortality attributable to phosgene in the A. E. F. of World War I was very low, less than 2.5 per cent of gas casualties (15). This low mortality rate automatically emphasized symptomatic relief rather than survival as the criterion of value. (*c*) At the time when the original observations were made, oxygen was administered by methods the best of which (Haldane's reservoir mask) provided concentrations of less than 60 per cent; the nasal catheter and funnel-over-the-face techniques were commonly used and the regimen varied from a few breaths at intervals to continuous use for symptomatic relief of cyanosis (1 to 3). (*d*) The true value of oxygen therapy in phosgene casualties is difficult to assess because it was but one of several drugs or procedures employed. (*e*) In accidental poisonings, deaths have been recorded despite apparently effective methods of oxygen administration (10, 11).

The previously reported data on oxygen therapy of experimentally poisoned animals contradict the clinical evaluation. Underhill (16) found that survival of poisoned dogs was not significantly improved by residence in 50 per cent oxygen for the first 72 hours after gassing, although symptomatically the dogs seemed better and the arterial and venous oxygen saturations were temporarily raised. Meek and Eyster (17) noted that the majority of an unspecified number of dogs lived 48 to 72 hours in 40 to 60 per cent oxygen, instead of the average of 16 hours in air. Dumoulin and Charlier (18) reported that 50 per cent oxygen did not increase the survival of phosgene-poisoned rats, while continuous stay in 90 per cent oxygen resulted in a still higher ultimate mortality. Soulie (19) confirmed these results and emphasized the similarity of survival rates during the first 24 hours of treatment, during which oxygen poisoning is unlikely.

Additional information was therefore necessary as to whether oxygen therapy improved the survival rate in phosgene poisoning and, if so, what were the optimum conditions of administration. Because omission of therapy in accidental poison-

[1] The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the University of Pennsylvania.

ing might lead to loss of life, the problem was necessarily studied in animals, although it was recognized that the pathologic physiology and resistance to anoxia in the dog and rat might differ from that of man. The main experiments were patterned after Underhill's (16), using an L(CT) 60 to 80 of phosgene. This mortality was chosen as being most favorable for demonstrating a beneficial effect from oxygen therapy. Additional experiments with low oxygen tensions were carried out to test the possibility discussed by Drinker (20) that anoxia might contribute to the development of pulmonary edema, or further it in the sense of a vicious circle.

MATERIALS AND METHODS

The dogs were healthy adult mongrels, weighing 6 to 12 kgm., used after an isolation period had shown them to be free of respiratory infection. The rats were young adults, obtained directly from the Wistar Institute. The dogs in fours or sixes were exposed to a mixture of air and pure phosgene in a 850-liter gassing chamber, operated dynamically at a flow of 800 liters per minute. The mean concentration of phosgene and standard deviation were 0.275 ± 0.0045 mgm. per liter by analysis, and the duration of exposure was 30 minutes. The rats were similarly gassed in groups of 20 or 40, but for the shorter time required to give the desired mortality. Selection of gassed animals for oxygen therapy was by lottery.

Oxygen therapy was administered to the dogs by keeping them in a closed chamber of 964 liters capacity, the atmosphere of which circulated at the rate of 935 liters per minute. During circulation the atmosphere passed over a cooling radiator at 0° C., and trays of soda-lime and $CaCl_2$ in that order. By frequent sampling or automatic regulation the atmosphere was controlled to the following levels: (*a*) Humidity was less than 40 per cent, average 32 to 34 per cent. (*b*) CO_2 was less than 0.5 per cent, average about 0.2 per cent by Haldane analyzer. (*c*) Temperature was room temperature $\pm 5°$ F. (*d*) The oxygen concentration, determined by the Scholander-Roughton method or the Pauling meter, was put up by flushing the chamber with oxygen to the desired level, which then was maintained by a Pitot type injector system. Inflow of oxygen or oxygen-air was in large excess of the requirements of the animals. Three concentrations of oxygen were employed, 95 per cent, 80 per cent, and 40 per cent.[2]

Six or 8 gassed dogs, depending on size, were placed in the chamber and kept there until death, or for 72 hours. Oxygen therapy was not begun until all the animals of an experiment had been gassed and hence with different animals there was an interval of 20 minutes to 2½ hours between the end of gassing and beginning of oxygen therapy. At the end of 72 hours in oxygen the survivors were brought immediately into room air. By means of sleeved ports which permitted access into the chamber without loss of oxygen concentration, hematocrit determinations, heart rate, respiratory rate, and other clinical observations were made routinely. The animals were supplied with water, Purina checkers, and a protein digest in water at all time. Dead animals were removed from the chamber for immediate autopsy. In 2 experiments gassed rats were placed in barricaded cages in the oxygen chamber with the dogs given 95 per cent oxygen therapy.

Experiments on rats in low oxygen mixtures were carried out using either a 67-liter chamber, or the large chamber; both were operated dynamically by means of a continuous inflow of mixtures of air, nitrogen, and carbon dioxide at rates of 2 to 5 liters per minute. The rats were placed in these chambers at once after gassing and kept there for varying periods. They were unrestricted and had access to food and water. The controls remained in similar cages in room air in most experiments, but in 2 experiments the factor of air movement over the rats was controlled by placing the gassed controls in another similar chamber and passing air through it.

Oxygen toxicity control studies

In view of the probability that oxygen poisoning might be superimposed on phosgene poisoning when 80 per cent and 95 per cent oxygen were used, a series of experiments was designed to assess the effect of oxygen alone.

Three of 21 normal dogs died after 47 to 48 hours in 95 per cent oxygen, while 4 more died after 52, 59, 63, and 89 hours in this atmosphere. One animal survived 116 hours and when sacrificed after 1 hour in room air showed only slight pulmonary edema and congestion, although markedly dyspneic. This dog contrasts with another which died an acute anoxic death upon being removed from the oxygen chamber after 48 hours. Eleven of the 21 dogs were sacrificed at the end of 48 hours in oxygen; these animals showed edema of the larynx, some pulmonary congestion, and minimal pulmonary edema; and the lung-to-body weight ratios were slightly beyond the upper limits of normal. One dog lived indefinitely following 48 hours residence in 95 per cent oxygen.

Eight dogs were confined in 80 per cent oxygen for 72 hours and none died. Four, sacrificed at the end of that period, showed mild pulmonary congestion and slight pulmonary edema, and the lung-to-body weight ratios again were at the upper limits of normal. The remaining 4 dogs survived without apparent difficulty.

Adult rats appeared to show somewhat greater susceptibility to oxygen poisoning: 18 of 20 rats died after 36 to 65 hours in 95 per cent oxygen; 1 died on removal from the chamber and only 1 survived 72 hours residence.

These data emphasize the high degree of individual susceptibility to 95 per cent oxygen, and are in agree-

[2] A large series of phosgene-poisoned dogs treated with 60 per cent oxygen was studied by another group elsewhere and will be reported separately.

ment with the findings of others (19, 21). The general physiologic characteristics of oxygen poisoning noted in recent reviews by Bean (22) and Stadie (23) were observed in these experiments.

The lungs of oxygen-poisoned animals resemble liver in appearance and consistency, and drip fluid on section; the histologic picture resembles that of phosgene poisoning rather closely (24). Inflating such lungs brings out the emphysema, and grossly they then resemble phosgene-poisoned lungs rather than liver. In most instances the degree of lung damage was poorly correlated with clinical appearance and respiratory distress.

No control experiments were carried out with 40 per cent oxygen, as the series with 80 per cent oxygen, although small, showed no lethal effects. This latter series also served as a control for conditions of residence in the chamber.

RESULTS

The survival curves of the 3 series of experiments on dogs are shown in Figures 1, 2, and 3; the number of dogs in the control and experimental groups are shown in each figure. Attention is directed to the deaths occurring shortly after removal from the atmospheres of 95 and 80 per cent oxygen. These animals died with signs of acute anoxia in room air, whereas in the oxygen-enriched atmospheres they had not been cyanotic, despite dyspneic breathing. A detailed statistical analysis of the data makes the following statements probable:

1. According to Fisher's test for homogeneity (25) the 3 control series are comparable one with another and form a homogeneous set of data; therefore, they may be grouped together. This is true regardless of the time at which survival numbers are taken, *i.e.*, the percent survivals at 1, 2, 3, and 10 days are essentially the same in the 3 control groups. The number of delayed deaths in the controls for the 95 per cent series was somewhat unusual, but this does not alter the statistical homogeneity.

2. Comparison of the 95 per cent oxygen series with the *grouped* controls failed to show a very significant increase in survival at 24 hours ($P = 0.057$, Fisher's exact method) but did show a significant improvement at 2 days ($P = 0.03$) and 3 days ($P = 0.02$). The ultimate survival, based on that of the tenth day, was *significantly decreased* ($P = 0.02$) by treatment with 95 per cent oxygen when administered as described above.

3. Comparison of the 80 per cent oxygen series with the *grouped* controls showed that survival was not improved on a 1-, 2-, or 3-day basis, and that the ultimate, or 10-day, survival was significantly decreased ($P = 0.03$).

4. Comparison of the 40 per cent oxygen series with the *grouped* controls shows that this concen-

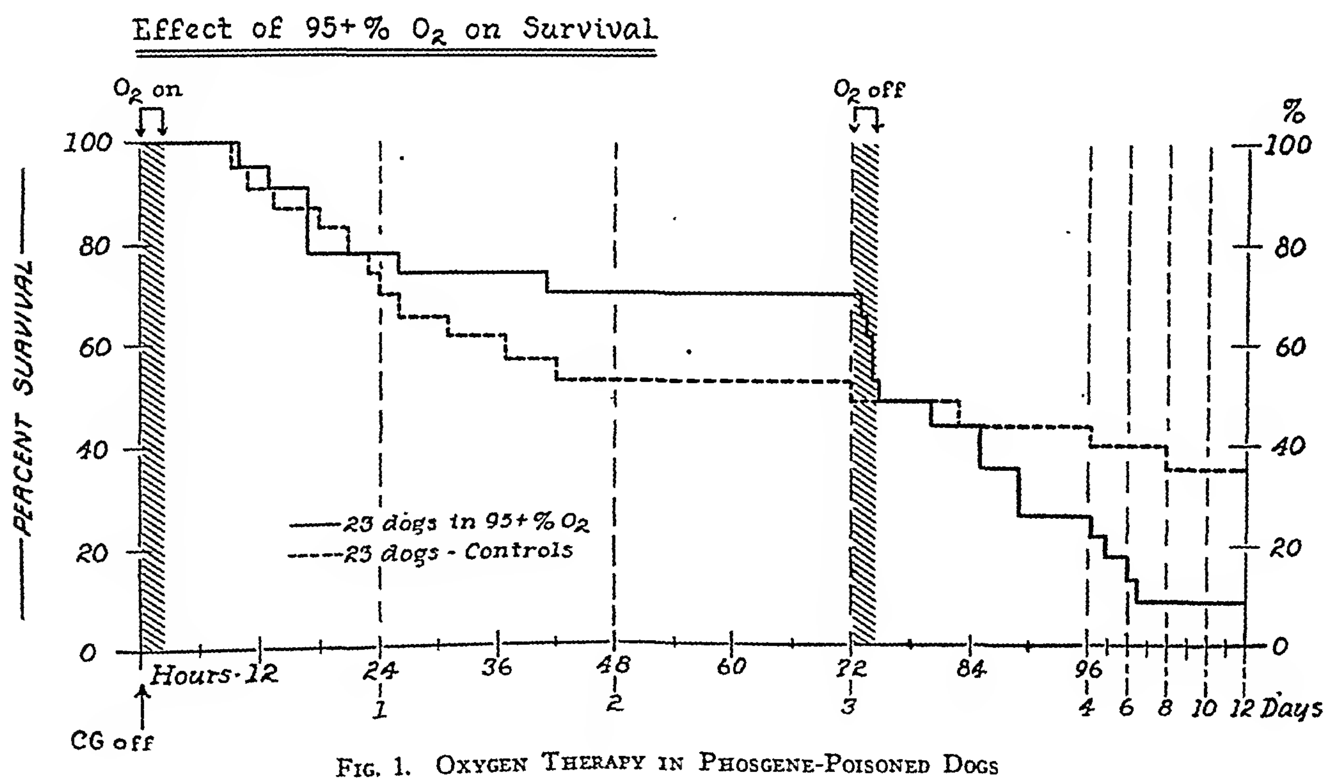

FIG. 1. OXYGEN THERAPY IN PHOSGENE-POISONED DOGS

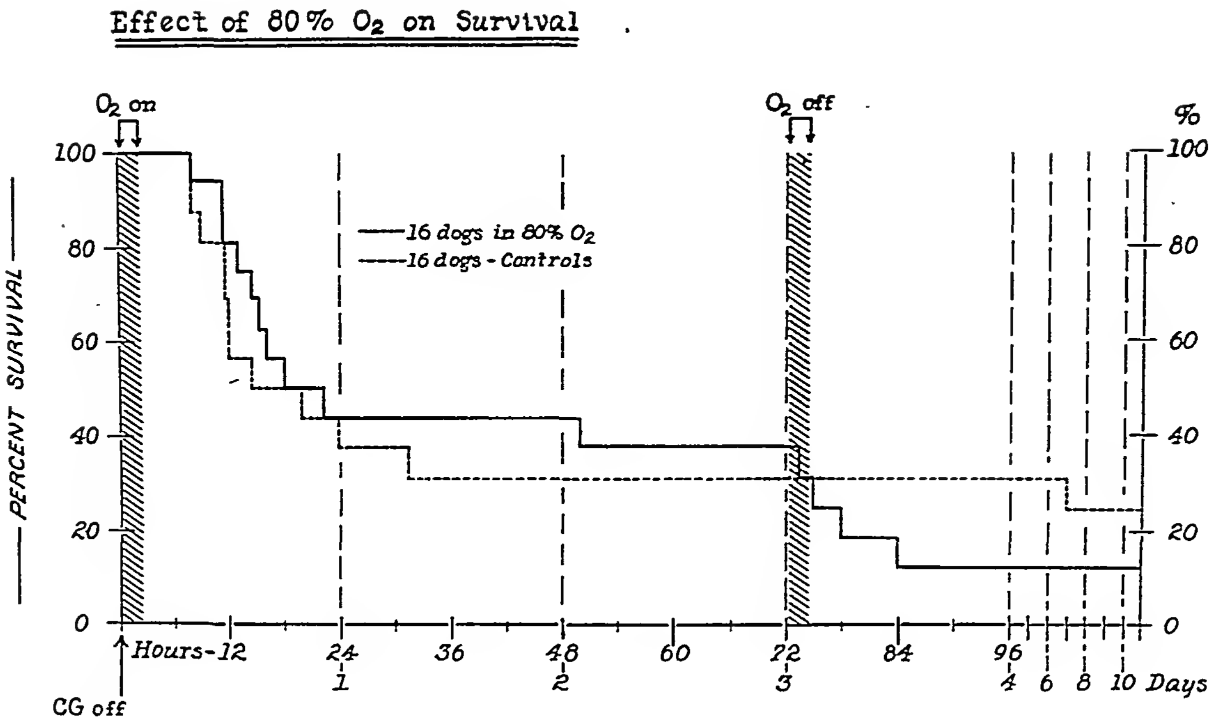

FIG. 2. OXYGEN THERAPY IN PHOSGENE-POISONED DOGS

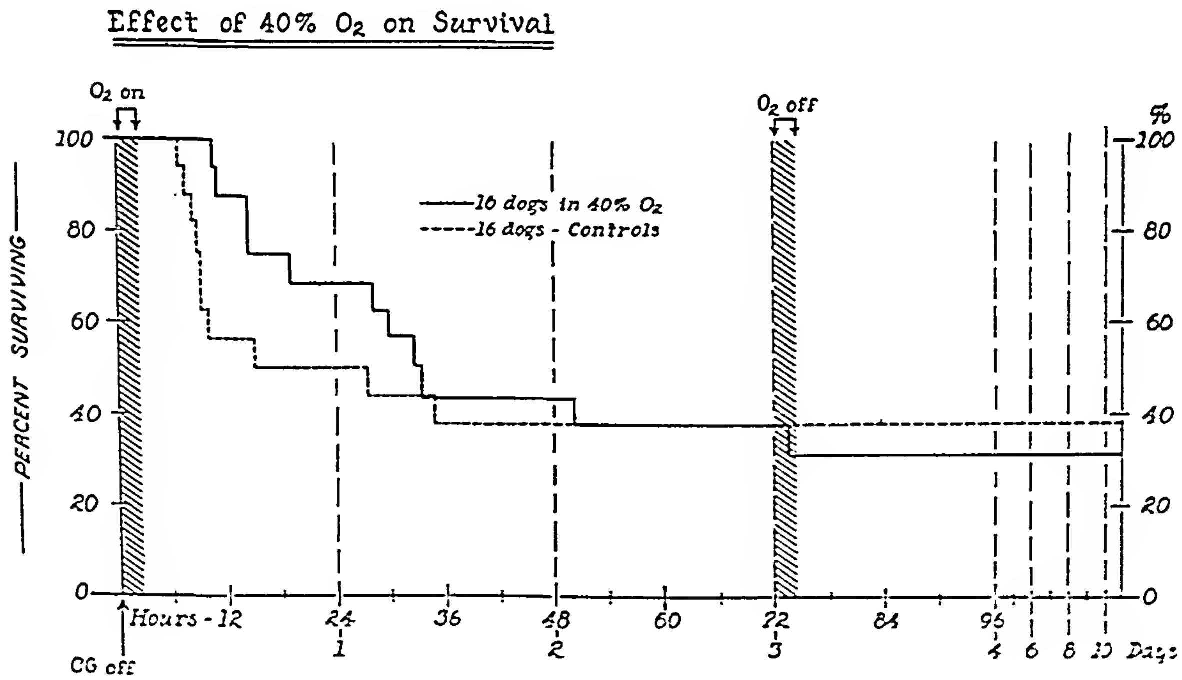

FIG. 3. OXYGEN THERAPY IN PHOSGENE-POISONED DOGS

tration of oxygen did not significantly influence either immediate or ultimate survival.

While the numbers of animals in each of the treated groups are comparatively small, the statistical analysis is supported by its agreement with the interpretations gained by inspection of the survival curves.

Judged by the responsiveness of the animals, their appetite, and the rate, depth, and ease of breathing, those treated with 40 per cent oxygen appeared to be in better clinical condition throughout than the controls, even up to the immediate premortem phase. In 80 per cent and 95 per cent oxygen this improvement was noted only during the first 36 to 48 hours; thereafter, the survivors appeared worse clinically than the controls living in room air. The surviving controls by this time gave clinical evidence of having passed the critical period.

No relation was found between the length of survival and the interval between gassing and beginning oxygen therapy. No effect of oxygen therapy was found on the rate of development of pulmonary edema as judged by the rate of hemoconcentration. The degree of edema at death (within 80 hours) was essentially the same for both groups, the treated animals having an average lung-to-body weight ratio of 4.1 and the control group an average of 4.2. The heart rate tended throughout to be slower in the oxygen-treated animals than in the controls. Bradycardia was found in normal animals residing in oxygen concentrations of 80 per cent or above.

At autopsy, gassed animals that had died in the 95 per cent oxygen, or within 1 or 2 hours after removal into room air, showed the liver-like lung of oxygen poisoning, but forced inflation of the lung restored the typical picture of phosgene poisoning. In the 80 per cent oxygen series, a few emphysematous blebs were present at death, while in the 40 per cent oxygen series the lungs were like those of typical phosgene poisoning; the latter was also true of the dogs of the 80 per cent and 95 per cent series which died 4 hours or longer after being returned to air.

The survival of 20 phosgene-poisoned rats was similarly unimproved by 95 per cent oxygen treatment. Their autopsy findings were like those described for dogs.

It was impossible to determine from either gross or histologic examination of the lungs and other tissues how oxygen therapy had influenced the course of phosgene poisoning, or whether oxygen poisoning had been superimposed on the phosgene poisoning. The pulmonary damage by the 2 agents is so similar as to defeat pathological methods of differentiation (24).

Five phosgene-poisoned rats were kept for 48 hours in 100 per cent oxygen maintained at ½ atmosphere, a condition which was proved not to produce oxygen poisoning in normal animals. The lungs of these rats were solid and liver-like; hence, the anatomic appearance of the lung after high oxygen therapy may be attributed to the absence of an inert gas and not to high oxygen tensions *per se*. This form of oxygen therapy also failed to lower the mortality rate.

Data on the mortality following residence in low oxygen tensions for 1 and 4 hours after gassing are shown in Table I. It is evident that this procedure did not increase the mortality of phosgene-poisoned rats, and comparison by the χ^2

TABLE I

Survival of phosgene-poisoned rats following residence in low oxygen atmospheres during the early phases of poisoning*

Dose of phosgene	Procedure	No. of rats	Hours in low oxygen	Average oxygen level	Rats surviving at: 24 hours	Rats surviving at: 72 hours
mgm.-min. per liter				*per cent*	*per cent*	*per cent*
2.32	Treated	5	1	10.6	60	60

* CO_2 was 0.25 per cent or less; humidity and temperature equal to room air.

** Controls kept in similar 67-liter chamber with room air circulating.

test of the summed survivals of the rats treated for 4 hours, with their summed controls gives a P value of slightly less than 0.03, *i.e.,* a probably significant reduction of mortality. This, however, is not fully representative of the remaining 13 experiments, using 300 rats, in which oxygen percentage was varied between 10 and 18 per cent, CO_2 between 0.25 and 5 per cent, humidity between 35 and 100 per cent, and duration of treatment between 1 and 4 hours, beginning at once after gassing. In these latter experiments the data were ambiguous in the sense that consistent, repeatable results could not be obtained; some experiments gave decidedly favorable survival rates in the treated groups, whereas others gave equally unfavorable survival rates. In short, it appears that treatment with low oxygen tensions in this way was not deleterious; whether it was beneficial is uncertain. Variations in factors other than oxygen percentage appeared not to influence the results.

The rats in the low oxygen tensions experienced anoxia, as judged by the respiratory efforts, the color of their ears and retina, and their behavior; when they were removed from the chamber after 4 hours they had palpable rales. No animals remained in the low oxygen atmospheres longer than 4 hours, a time at which edema generally was about half maximal. The lung-to-body weight ratios of many of the rats which died a few hours after being returned to room air were low compared with the controls.

DISCUSSION

The data show that while continuous 95 per cent oxygen therapy delayed death after gassing, it failed to improve ultimate survival. In fact, 95 per cent oxygen therapy as administered to gassed dogs had an adverse effect on ultimate survival, due presumably to superimposed oxygen toxicity. This finding is not peculiar to the dog, according to the reports of Dumoulin and Charlier (18) and Soulie (19). It therefore assumes clinical importance, first because high concentrations of oxygen, administered for long periods, were required to banish cyanosis in phosgene casualties of World War I (1), and, second, modern techniques of oxygen therapy are capable of providing oxygen tensions which might lead to oxygen poisoning. Thus it would be unwise to administer oxygen tensions in excess of those necessary to saturate the hemoglobin. It is not reasonable to assume that unavoidable interruptions are a factor of safety in the so-called 100 per cent oxygen therapy by mask (26).

Although the data suggest that oxygen poisoning was superimposed on the phosgene poisoning, it is not possible to be certain of this at present. No differentiation could be made by either the histologic or physiologic methods used (24). Apparently, both induce similar if not identical pulmonary reactions and produce death by the same process, but oxygen at inhaled tensions of 600 to 760 mm. Hg requires a longer time factor. The wide variations in susceptibility to oxygen poisoning provide another important but unassessable consideration. A possible interpretation is that high tension oxygen therapy, by delaying death, permits accumulation of edema fluid in amounts greater than that which would have induced fatal anoxia in air; this extra fluid may then nullify therapy. The essential question must remain open for the present: Will high oxygen tensions administered to a lung damaged by phosgene give rise to processes which ultimately are just as lethal as the primary damage?

The data above suggest that oxygen therapy does little to prevent or break up the compound vicious cycle associated with the 2 forms of anoxia identified in phosgene poisoning: (*a*) an anoxic anoxia, dependent on the pulmonary edema, and (*b*) a stagnant anoxia arising from the shock-like hemodynamics connected with reduced blood volume and increased blood viscosity. Oxygen therapy alone may relieve the anoxic anoxia and improve cardiac action without materially improving the general capillary circulation. Yet attempts to improve the circulation by infusions during oxygen therapy have not been successful (27).

It does not follow that every case of phosgene poisoning presents this gloomy outlook. It is reasonable to anticipate that an unknown but probably small proportion of cases would die during the phase of maximal edema if not supported by oxygen therapy. This possibility should not be disregarded in the clinical management of the single case, statistics notwithstanding. On the other hand, the above data justify use of the alternate case method in assessing clinically the value of

oxygen therapy in the event of a mass exposure. The effects of sublethal anoxia on other tissues such as the kidney (28, 29), whose function is required during the subsequent restorative processes, indicate the use of oxygen. If it minimizes these later extra-pulmonary derangements, it is worthwhile.

While recognizing the mutual conflicts in the foregoing discussion, we nevertheless believe both points of view justified. However, it must be emphasized that a lessened ultimate mortality should be considered the only definitive criterion of benefit.

Drinker (20) recently proposed that anoxia of the pulmonary capillaries may cause, or exaggerate, edema initiated by other agents. This hypothesis might apply to phosgene poisoning, for blood oxygen analyses of gassed dogs show an anoxic and a stagnant anoxia present shortly after gassing (30) (Table II). This is also true of dogs poisoned by lower doses of phosgene (16). Generally, there is a partial recovery of normal saturation which is again reversed about the time edema becomes clinically detectable. It was noted that the more severe the immediate anoxemia, the sooner the animals died. Barcroft (31) reported similar changes in phosgene-poisoned goats.

TABLE II

Average and range of oxygen saturations of arterial and venous blood of dogs poisoned by an L(CT) 99 of phosgene

Oxygen saturation	Before gassing (8 exps.)	15 to 20 minutes after gassing (8 exps.)	2 to 5 hours after gassing (5 exps.)
		per cent	
Arterial oxygen saturation	96	82	80
	(94–99)	(58–93)	(68–90)
Venous oxygen saturation	62	21	26
	(37–91)	(11–84)	(16–47)

On the other hand, this hypothesis is unlikely to apply in phosgene poisoning for the following reasons: (*a*) Some gassed animals developed edema with typical findings without showing the early anoxemia (16, 27). (*b*) The dogs that died in the high oxygen atmospheres with 24 hours after exposure to phosgene showed full pulmonary edema. Oxygen toxicity does not occur within this time. (*c*) Exposure of phosgene-poisoned rats to low oxygen tensions during the period of development of edema did not increase the mortality over that of controls in air. (*d*) The bronchiolar obstruction of phosgene poisoning might cause anoxia of distal alveoli (24), the severity of which would depend on the oxygen tension of the pulmonary artery blood. These tensions have been found in many instances higher than the oxygen tensions used by Drinker and associates (20, 32) to increase lymphatic drainage from the lung, which is not in itself proof of pulmonary edema. The peribronchial tissues, which are supplied with arterial blood, are the first areas of the lung to show edema (24), and anatomically the lymphatics are more closely related to these tissues than to the alveolar areas (33). (*e*) Animals (34) and men (35) have been subjected to very low oxygen tensions without evidence of pulmonary edema, and the generally accepted view that anoxia of a capillary leads to increased permeability has recently been brought up for re-examination (36). Thus it seems unlikely that alveolar anoxia significantly influences the production of edema in phosgene poisoning.

The contradiction between clinical and experimental findings may be due to the fact that oxygen therapy in phosgene poisoning in man has never been subjected to as strict a test as that described above.

SUMMARY

1. Clinical opinion has assigned oxygen therapy a critical role in the treatment of phosgene poisoning, but this evaluation has not been confirmed in experimental studies previously reported.

2. One-hundred-ten dogs were exposed to an L(CT) 70 dose of phosgene. Half were then placed in a chamber operated dynamically, in oxygen atmospheres of 95 per cent, 80 per cent and 40 per cent, until death or for 72 hours. No improvement in ultimate survival was observed. Although death was delayed while the animals were in 95 per cent oxygen, ultimate survival was significantly decreased.

3. To assess the factor of oxygen poisoning in the above results, ungassed dogs were exposed to similar oxygen concentrations. Because the pulmonary damage from continuous exposure to high oxygen tensions was so similar to that of phos-

gene poisoning, it was uncertain whether the increased mortality in the 95 per cent series was due to superimposed oxygen poisoning.

4. Because of the possibility that the edema might have been related to pulmonary anoxia, gassed rats were kept in low oxygen atmospheres (10 to 18 per cent) for the first 1 to 4 hours after gassing. This treatment did not modify the course of the poisoning, nor did it decrease survival. In some experiments survival was significantly improved.

5. The experimental findings are discussed in relation to their clinical application.

THE EFFECTS OF CONTINUOUS PRESSURE BREATHING ON KIDNEY FUNCTION [1]

By D. R. DRURY, J. P. HENRY, and JOSEPH GOODMAN

(From the Departments of Physiology and Aviation Medicine, The University of Southern California, Los Angeles, California)

(Received for publication February 18, 1947)

Continuous pressure breathing is a technique developed to increase the alveolar oxygen tension by breathing oxygen at higher than ambient pressure. In other words the pressure within the alveoli of the lungs is higher than that outside the chest wall. It is found that as much as 16 mm. Hg of such extra pressure can be tolerated for periods of 30 to 60 minutes by the average healthy man. However, as the extra pressure is increased above this figure, evidence of a deleterious effect upon the circulation becomes increasingly apparent. At pressures of 25 to 40 mm. Hg circulatory collapse and fainting become frequent. Often in cases in which this does not ensue there may develop sensations of impending collapse with pallor and sweating, necessitating termination of the test. Although the blood pressure remains above the control level the pulse is small and difficult to feel and the cardiac output is diminished (1). When using these higher pressures not only is much blood pooled in the veins of the arms and legs but also there is a progressive hemoconcentration due to the passage of fluid from the blood stream into the tissue spaces under the influence of the raised intravascular pressure (2). A considerable fraction of the total blood volume is thus more or less sequestrated from the general circulation under these conditions and when collapse ensues it is in large part due to decreased effective blood volume. The actual total volume of blood thus isolated cannot be readily assessed and there is need of a reliable but simple test which could be used to assay the impairment of circulation induced by pressure breathing.

With this aim in view we studied the blood pressure changes occurring during continuous pressure breathing. This was determined in the usual manner on the arm. Such an approach proved unsatisfactory since a fall in the pressure was usually only observed when the subject was on the verge of syncope. Otherwise the blood pressure was the same as the control value or, as was usual, it was somewhat elevated. We then decided to investigate the value of a determination of the changes in kidney function produced by pressure breathing.

METHOD

The specific function of the kidney studied was its capacity to excrete urea. This information is obtained by determining the rate of urea excretion during any period and dividing this by the blood urea concentration at the time, thus obtaining a value essentially the same as the kidney clearance. Urea was chosen because of the accuracy with which it can be determined and the constancy of its clearance in a given individual under standard conditions. In addition it has been shown to be responsive to physiological changes in the circulatory system which take place in such conditions as severe exercise (3) and hemorrhage (4). The test was carried out as follows: The subject went without breakfast in the morning and drank a liter of water on rising and 500 ml. per hour thereafter until the completion of the test. Within 2 hours a good diuresis usually developed and the determination of function was then started. The subject emptied his bladder and noted the exact time. Thirty minutes later a blood sample was taken and 30 minutes after that, the first urine collection was made. Immediately after completion of this 1-hour control period the subject pressure-breathed for 30 minutes.

Either compressed air or pure oxygen was used and applied by an Army A-13 pressure-breathing mask. Pressures were measured at the mask and determined by observing a manometer connected to a tube introduced into the mask. In order to ensure a full application of the pressure the subjects were instructed not to restrict the passage of gas to the lungs by closure of the glottis. No counter-pressure was applied to the body. A blood sample was taken midway through the pressure-breathing period and the urine collected at the end. Observations were continued during the post-pressure-breathing period for 2 or 3 consecutive hourly periods. Thus each test involved a series of 4 or 5 periods which together occupied a whole morning.

Four subjects were studied with repeated tests. On any given test the breathing pressure remained constant throughout the pressure-breathing period. Duplicate run-

TABLE I

Representative table showing the decrease in kidney function during a 30-minute period of breathing at 40 mm. Hg super added pressure

The equation below illustrates the method of calculating the reduction in kidney function produced by the pressure breathing and the figures so obtained are those depicted in Figures 1, 2, 3, and 4. In addition the table illustrates the lag in return of function after pressure breathing is stopped.

June 10, 1946
Subject: E. K.
Pressure: 40 mm. Hg

Period	Time	Urine urea	Blood urea	Urea clearance	Kidney function (control)
.	*min.*	*mgm. per hr.*	*mgm. per 100 ml.*	*ml. per hr.*	*per cent*
1	68	906	19.8	4580	100.0
2 P.B. Period	32	426	18.3	2330	50.9
3	31	106	18.6	570	12.4
4	47	847	18.9	4480	97.8

$$\frac{\text{Urea clearance Per. 2}}{\text{Urea clearance Per. 1}} = \frac{23.3}{45.8} = 50.9 \text{ per cent.}$$

were carried out on all subjects using 10, 20, 30, and 40 mm. Hg mask pressure.

The urea in the blood and urine was determined by the urease technique of Addis (5). The rate of excretion of urea was calculated on a per hour basis for each period (pre-pressure-breathing, pressure-breathing and the two post-pressure-breathing periods). This hourly rate was divided by the urea concentration of mgm. per cent found in the blood taken at the middle of the period. (Determinations of the blood urea showed no significant change throughout the morning of a given test.) The quotient so obtained was taken as the measure of kidney function during any particular period. The value for the kidney function during the pre-pressure-breathing period of a given test was taken as 100 per cent and the kidney functions found during the succeeding periods were calculated on this basis.

RESULTS

It is apparent from Table I that the pressure breathing has caused a decrease in kidney function not only during the period of active pressure breathing (Period 2) but also during the post-pressure-breathing period (Period 3). In Figure 1 are shown the results of a series of such tests on the same subject, each circle representing the reduction in kidney function during the pressure-breathing period of one test. Figures 2, 3, and 4 represent similar series of tests for 3 other subjects. It will be seen that at 40 mm. Hg pressure the function was reduced to between 20 to 50 per cent of normal.

A pressure of 10 mm. Hg shows practically no effect; but, beginning with 20 mm. Hg there is a definite functional depression which becomes greater with successively higher pressures. In many experiments the function remains depressed for an hour or more after the resumption of normal breathing. Figure 5 illustrates this point. The continuation of the depression of urine volume and urea clearance during the first post-pressure-breathing period is marked. It may be noted that when the urine volume decreases to levels of 0.1 ml. per min., as it did in the post-pressure-breathing

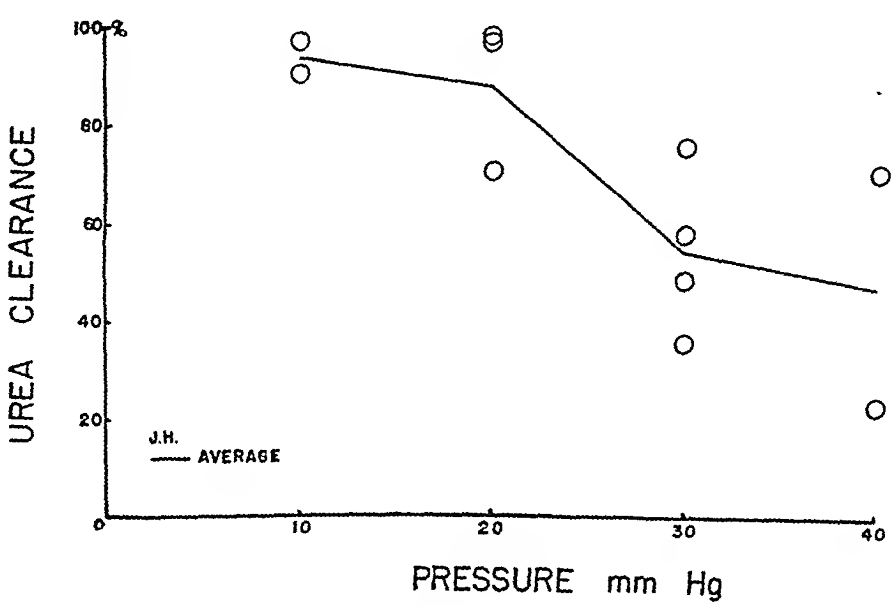

FIG. 1

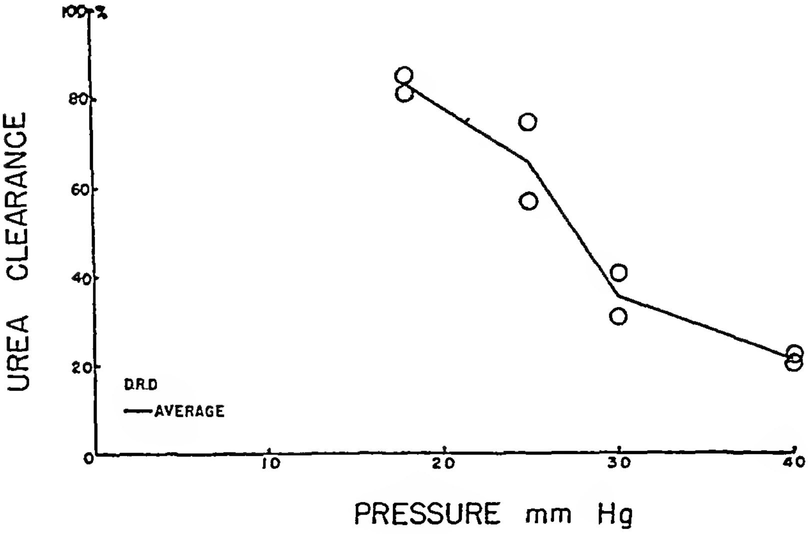

FIG. 2

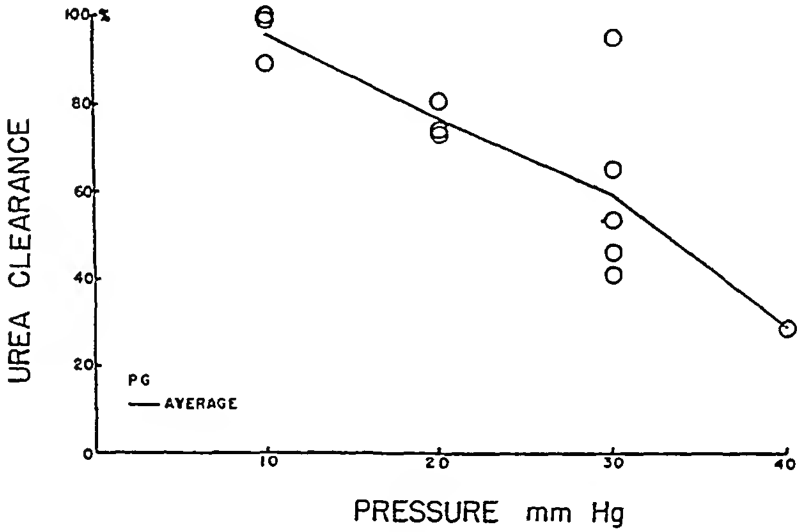

FIG. 3

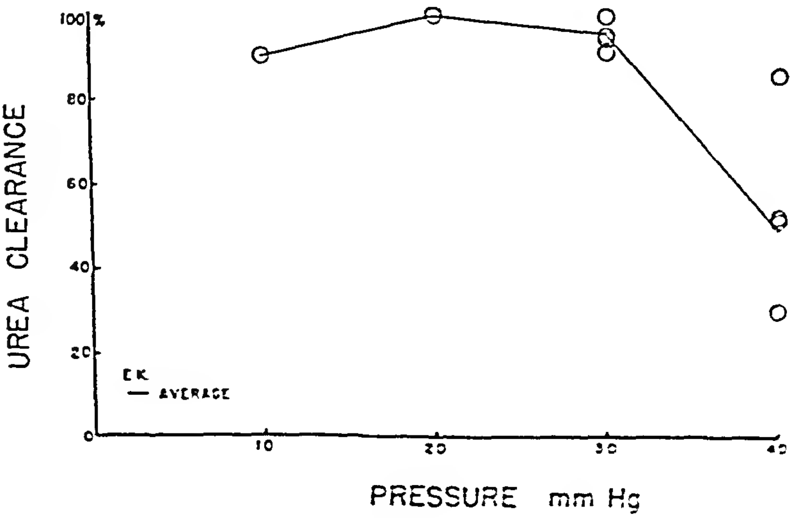

FIG. 4

period represented in this case, the urea clearance determination becomes less accurate (6). Figure 6 illustrates a case in which the function during the post-pressure-breathing period is markedly diminished below that during the pressure-breathing period. However it must be remembered that the charts give only the average of function during each period. It is not possible to determine the

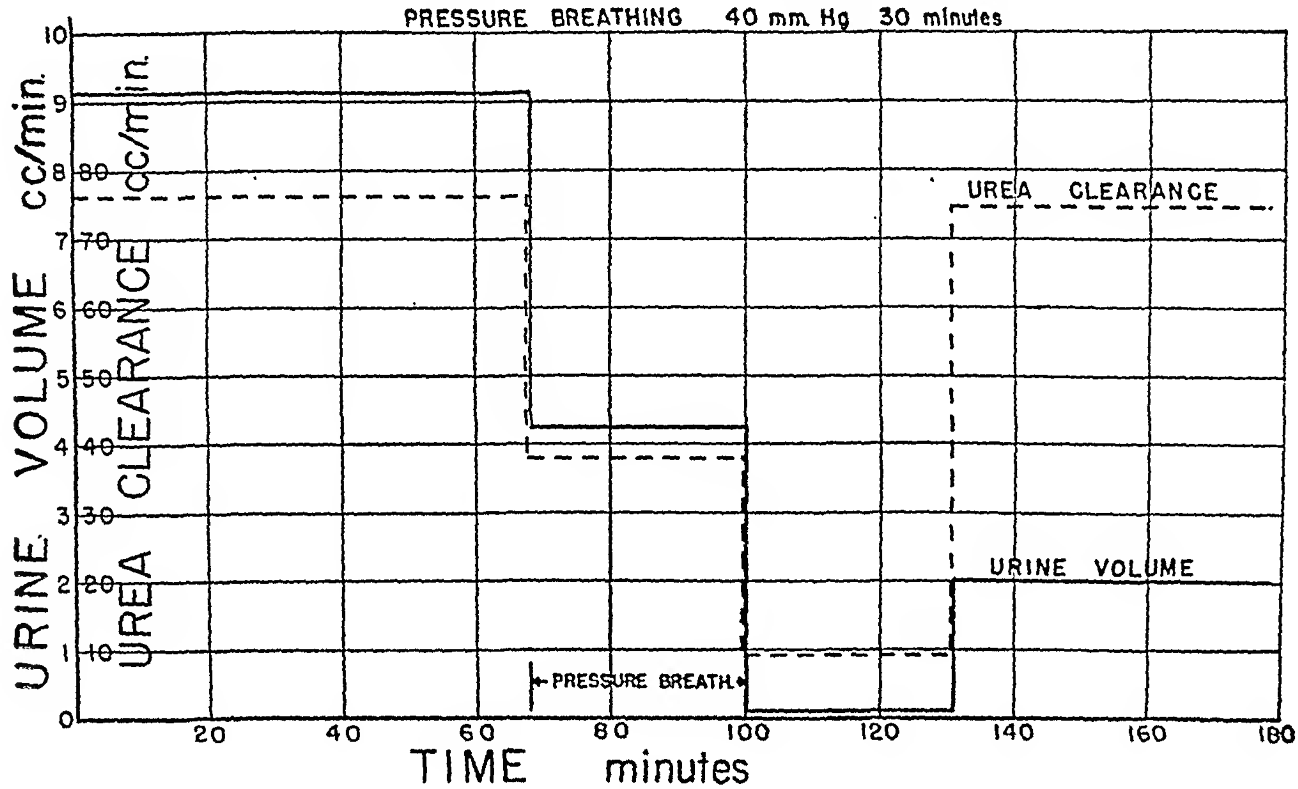

Fig. 5

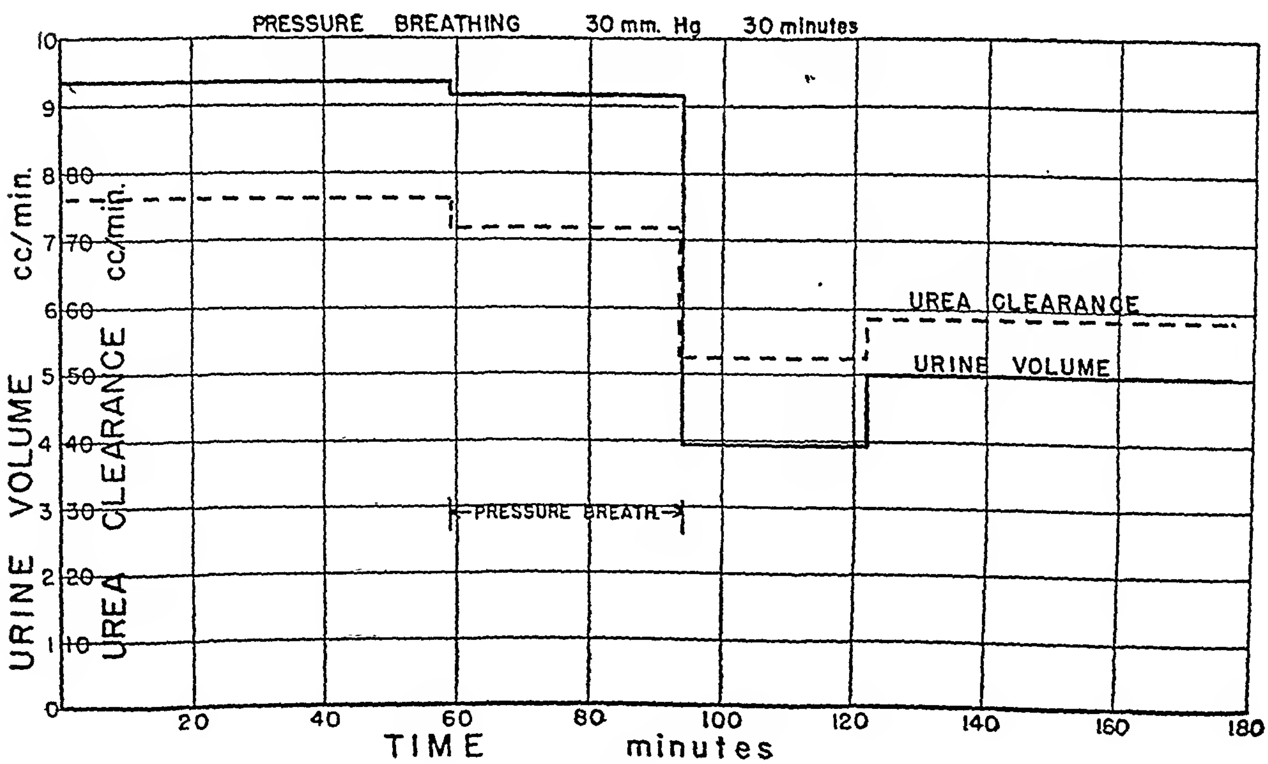

Fig. 6

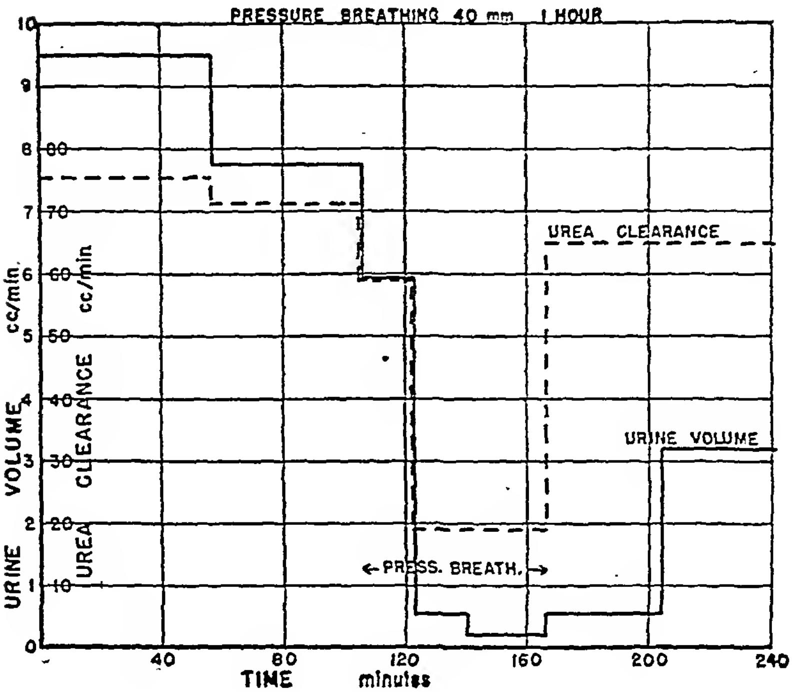

Fig. 7

function for each minute. Therefore, for the case shown in Figure 6, it does not follow that the function during the last minute of the pressure-breathing period was actually lower than that of the first minute of the after period.

This prolonged depression in function following the pressure breathing suggested that there is a certain "inertia" of function prolonging response beyond the causal period. The question arose whether there was a corresponding delay in the decrease in function at the onset of the pressure-breathing period. To test this, an experiment was carried out in which the subject continued pressure-breathing for 1 hour (Figure 7). This period was subdivided into 3 periods in each of which a separate function determination was carried out. It is apparent that marked depression does not occur immediately and that during the first 15 to 20 minutes the function remains relatively high.

DISCUSSION

Reference may be made to some of the work that has been published in recent years indicating that the kidney circulation is early reduced in conditions that embarrass the general circulation (7 to 9). The results of these workers in addition to that of others support the view that a measurement of kidney function can be used to determine the degree of circulatory stress. Our findings are definitely in line with this. Care must be taken in every particular case to evaluate the action of additional factors, such as kidney disease and specific renal toxins, which can affect kidney function. Pain also has been shown to diminish renal function (10). The exact mechanism of its action on the kidney has not yet been decided. There was some degree of discomfort in breathing at the higher pressures and this action may have contributed to the reduction in kidney function seen here.

Pressure breathing may be considered a useful experimental method by which definite circulatory stress can be produced rapidly and with relative safety. We feel that the degree of depression of kidney function that we obtained is proportional to the magnitude of the circulatory stress produced. Used in this way the procedure has been of some value to us in determining the efficacy of supportive measures which may be used to combat the deleterious effect of pressure breathing on the circulation.

Our results indicate that pressure breathing of moderate magnitude can be tolerated by normal healthy individuals for appreciable times, *i.e.*, ½ to 1 hour. The higher pressures cannot be tolerated

so long. We believe that pressure breathing might be used as a test of circulatory fitness. It would seem probable that individuals with reduced circulatory reserve such as is found in persons employed in sedentary occupations would be affected by those lower pressures which do not have very much effect on physically active people in good circulatory condition. The degree of effect on the circulation could, we believe, be readily estimated by determining the effect on kidney function. Not only does such a test give an opportunity for quantitative measurements but it can be carried out without producing the alarming and uncomfortable symptoms associated with circulatory collapse.

In conditions in which the amount of actively circulating blood is reduced by loss of fluid or pooling in inactive areas the vasomotor system will cut down on blood flow through regions that can tolerate this temporarily. The circulation through the kidney behaves somewhat like that through the skin in this respect and kidney blood flow can be reduced to $1/10$ to $1/20$ of normal resting volumes when strain is imposed on the circulatory system (11). The kidney circulation can in fact serve as an important reserve for the general vascular system. Not only is a certain volume of blood made directly available by the reduction in kidney volume following renal vaso-constriction but in addition it may be noted that normally $1/4$ of the blood in the great veins, heart, lungs and aorta is concerned with the renal circulation and that when blood flow through the kidney is reduced this blood can then be utilized to serve the vital areas of the body.

The question might be raised as to the "wisdom of the body" in sacrificing kidney function in conditions putting a strain on the circulatory system. If this strain is not prolonged beyond a few hours then cutting down of the blood flow through the kidney would seem to be a proper mechanism to help tide the circulatory system over a temporary embarrassment. The concomitant temporary reduction in kidney function would not be harmful. Thus, a normal individual can remain for at least a day without kidney function without showing otherwise any serious disturbance. Upon the resumption of activity this organ can quickly make up for the period of inactivity. We might speak of the body going into a "renal debt" in order to help the circulatory system carry on during a period of temporary stress. Naturally there should not be complete cessation of renal blood flow for any appreciable duration since this may lead to irreparable kidney damage if lasting more than 1 hour (12).

However, such a mechanism is not without its dangers. If the circulation cannot be established within a reasonable time the continued impairment of kidney function would lead to serious consequences. This can be the case in prolonged traumatic shock and infectious diseases causing peripheral circulatory failure (7). It is probable that continued dehydration can also be dangerous for this reason. Finally if renal function had already been inadequate for a prolonged period before the imposition of circulatory stress then a further reduction in renal blood flow even for a few hours could be a serious matter.

The lag in the return of kidney function to normal after cessation of pressure breathing is of interest. It represents to some extent the time required for the circulatory system to return to normal. However, this period is normally very brief since the blood pooled in the limbs is immediately available for active circulation on the cessation of pressure breathing. Some of the delay is due to the time (10 to 20 minutes), needed for return to the blood of fluid that had escaped into the extravascular compartment. In addition, time is needed for the kidney tissue to reestablish itself after proper blood flow has been started again. Thus Selkurt (13) has shown that after clamping the renal arteries for 20 minutes the return of kidney function to normal was delayed at least 2 to 3 hours after release of the artery, whereas direct measurement of blood flow showed a much more rapid restitution.

An additional important mechanism, however, which may account for much of the prolonged lag lies in the possibility of hormonal activity. The urine volume changes during the test suggest that an antidiuretic (presumably posterior pituitary) action may enter into the picture. Since pituitrin depresses urea clearance in addition to the urine volume, posterior pituitary activity may also play a significant part in the lag in return of kidney function to normal after cessation of pressure breathing (3). That this hormone is involved is suggested by the report of Brun *et al* (14) who studied kidney function during the circulatory collapse pro-

duced by prolonged maintenance of the upright position on the tilt table. They found that the inulin and diodrast clearances were reduced during the period of collapse and for periods of a quarter of an hour or more thereafter. The subjects drank large amounts of water so that they were well hydrated and were excreting large volumes of urine prior to the collapse. Following collapse the urine volume was markedly diminished and remained low for periods of 1 hour or more. They present evidence to support the view that this reduction in urine volume is due to increased secretion of an antidiuretic hormone. Our results are similar with respect to changes in urine volume. It should be noted that the urine volumes in our cases were depressed for a considerable period after the pressure breathing and that the urea concentration in the urine was increased at this time, although the clearance was depressed. Our findings differ from those of the above mentioned workers to the extent that we did not have symptomatic circulatory collapse and that the blood pressure was well maintained, whereas their subjects showed very low blood pressures during the period of reduced kidney function.

SUMMARY

1. Four subjects submitted to 30-minute periods of continuous pressure breathing at 10, 20, 30 and 40 mm. Hg above ambient pressure showed a progressive reduction of kidney function which, with the higher pressures, reached approximately 20 to 50 per cent of normal values.

2. This depression in function persisted for 1 to 2 hours after the cessation of the pressure-breathing period. The possible mechanism of this continued depression is discussed.

3. These results support the view that estimations of kidney function may be used as a measure of the circulatory stress induced by a reduction of effective blood volume.

4. It is suggested that pressure breathing should be investigated as a test of circulatory fitness by employing estimations of disturbance of kidney function as an index of the extent of its effect upon the circulatory system.

LIVER BLOOD FLOW IN PREGNANCY—HEPATIC VEIN CATHETERIZATION [1]

By EQUINN W. MUNNELL and HOWARD C. TAYLOR, JR.

(From the Department of Obstetrics and Gynecology, New York University College of Medicine and the Obstetrical and Gynecological Service [Third Division] Bellevue Hospital)

(Received for publication February 27, 1947)

Numerous liver function tests have been devised and most investigators agree that some disturbance in liver function occurs during the toxemias of pregnancy. These changes are of relatively small magnitude and the clinical use of these tests in pregnancy is not widespread. The technique of venous catheterization with resultant sampling of blood directly leaving the liver offers further opportunities for study of liver function.

METHODS

A method of estimating hepatic blood flow in man based on the "Fick" principle has been described by Bradley and coworkers (1). In their article they point out that "The 'Fick' principle may be applied to any organ provided three facts are known: (*1*) the concentration of some substance, *X*, in the blood entering the organ, (*2*) the concentration of *X* in the mixed venous blood leaving the organ, and (*3*) the total amount of *X* removed from the blood by the organ each minute. Given these data, the blood flow through the organ per minute may be calculated by dividing the total removal rate of *X* by the amount of *X* removed from each milliliter of blood as it traverses the organ."

The removal rate of *X* by the liver cannot be measured directly, but an indirect method is available if *X* can be given at such a rate that its blood level remains constant. Under these conditions, the infusion rate equals the hepatic removal rate, provided that the extraction of *X* depends entirely upon hepatic activity. Bromsulfalein (BSP) was used as the test substance since it apparently satisfied these conditions.

The calculation of hepatic blood flow then can be determined by the following formula:

$$EHBF = \frac{R}{0.01\,(P - H)} \times \frac{1}{1 - \text{Hematocrit}}$$

Where $EHBF$ = estimated hepatic blood flow,
R = removal rate or the infusion rate in mgm. per minute,
P = peripheral venous concentration of BSP in mgm. per minute,
H = hepatic venous concentration of BSP in mgm. per minute.

Hematocrit was from anticoagulated blood drawn from the hepatic vein in most cases. Four hematocrits were always taken and the average of the 4 used in the calculations. Occasionally peripheral vein blood would be used for hematocrit determination because of temporary difficulty in obtaining enough hepatic vein blood through the catheter: in Tables I, II, and III these peripheral vein hematocrits are starred (*).

If the concentration of BSP in the peripheral blood is changing, hepatic blood flow may also be estimated if the plasma volume is determined. In this case, R (the removal rate of BSP by the liver) $= I$ (the infusion rate mgm. per minute) plus or minus $\Delta P \times V$ where $\Delta P =$ the rate of change in concentration of BSP in the peripheral blood in mgm. per ml. per minute and $V =$ plasma volume in ml. Plus or minus depends on whether the concentration of BSP in the peripheral blood is rising or falling. If the peripheral concentration is rising, $R = I - (\Delta P \times V)$ since less dye is being removed than is administered. If the peripheral concentration is falling, $R = I + (\Delta P \times V)$ for the converse reason.

Samples of hepatic vein blood are obtained with more or less ease by catheterization of the right hepatic vein with a 100-cm. No. 8 ureteral catheter with a slightly curved through-and-through tip with one eye. The catheter, through which an isotonic saline infusion is running, is inserted in the median basilic vein under local anesthesia. With the patient in the supine position on a fluoroscope table, the catheter is then passed into the subclavian vein, the superior vena cava, the right atrium, the inferior vena cava, and the right hepatic vein. The patient experiences no discomfort during this procedure. The most difficult part of the procedure is to get the tip of the catheter past the right atrium and into the inferior vena cava rather than down into the right auricle and ventricle. In advanced pregnancies this was more difficult than in the non-pregnant cases presumably because of increased angulation of the vena cava at this point due to elevation and deviation of the heart to the left by the upward displacement of the diaphragm and liver. Apprehensive patients with small peripheral veins were occasional failures

[1] This study was carried out with the aid of a grant from the Commonwealth Fund.

* Indicates peripheral vein hematocrit. All others from hepatic vein. (See page 952.)

when peripheral venous spasm rendered the catheter immovable except for withdrawal. Not leaving the catheter in the body for longer than 90 minutes was preferred after 2 patients developed peripheral phlebitis when the catheter had been left in the veins for longer than 2 hours; the phlebitis disappeared rapidly under simple treatment.

The BSP infusion was allowed to run into the same arm through which the catheter was inserted and samples of peripheral blood were withdrawn from the opposite arm. The concentration of BSP in the peripheral blood was considered equavalent to afferent blood to the liver since the liver presumably is the exclusive site of removal of the dye.

In pregnancy it would be necessary to take into account the action of the fetal liver in removing BSP were it not for the fact that bromsulfalein does not cross the placenta. Two patients in the second stage of labor were given bromsulfalein intravenously in quantity sufficient to keep the peripheral concentration high for a period of 20 to 30 minutes prior to delivery of the baby. Immediately after delivery, samples of the blood from the umbilical cord showed no BSP present whereas the mother's peripheral blood concentration was still very high.

For a complete discussion of the method of determining the BSP concentration, of the validity of the method, and of the calculation of the *EHBF*, the reader is referred to Bradley *et al* (1). Our method of BSP determination was essentially the same as theirs. However, we did work with higher blood levels of BSP (*i.e.*, 1.0 mgm. per cent or over for the hepatic blood levels, since these are always lower than the peripheral) because below this level we found an increasing percentage of error in the plasma BSP recoveries. If the plasma concentration was 1.0 mgm. per cent or over, the percentage error was only 2½ to 5 per cent. Since the best plasma recoveries usually showed a 5 per cent loss, all plasma levels were corrected for this loss by dividing by .95.

Whereas in non-pregnant patients the estimated plasma volume could be determined from the surface area by reference to the tables of Gibson and Evans (2), in pregnant patients this could not be done. Hence, in the pregnant patients, it was necessary to measure the plasma volume accurately, using the dye T-1824 or Evans blue. This determination was done immediately following completion of the bromsulfalein part of the experiment according to the technique of Price and Longmire (3) with the following modification. Approximately 5 ml. of Evans blue were loaded in a 5-ml. syringe equipped with a guard to keep the plunger steady and weighed together with the needle. The dye was injected into an infusion tubing just above the hub of the infusion's needle and extreme precautions taken to lose none of the dye by using the smallest possible hypodermic needle (gauge No. 26) for injection with a clamp just behind the site of injection to prevent diffusion of the dye backwards into the infusion tubing. Immediately following injection, the infusion

was allowed to run very rapidly for 3 minutes to insure complete flushing of the dye from the infusion tubing. The needle and syringe together with the residual dye on the walls of the syringe were then weighed again and the difference from the original weight represented the amount of T–1824 injected. Samples were taken according to the method of Gibson and Evelyn (4) at 15-minute intervals and the concentration of the dye in the plasma determined in the Coleman spectrophotometer. A constant (K) for the lot of dye used and for the machine was determined from a calibration curve.

RESULTS

A series of non-pregnant women was first examined in order to provide a standard for comparison. This series is presented in Table I; the *EHBF* varied from 1,177 to 1,900 ml. per minute per 1.73 M². of body surface with an average of 1,548 ml. These results are practically the same as those of Bradley and coworkers. It will be noticed that the average ΔP in this series is high. We found it difficult to maintain a constant blood level of the bromsulfalein. Therefore, all our results were dependent on the added determination of plasma volume, and these values were obtained from the tables of Gibson and Evans. The last column in these tables represents the *EHBF* percentage of total blood volume. In these non-pregnant women, it averaged 35 per cent with a range of from 28.2 per cent to 42.8 per cent.

Fifteen normal pregnancies of various periods of gestation were studied and the equivalent hepatic blood flows determined. These data are presented in Table II. The range of *EHBF* was from 1,075 to 2,465 ml. per minute per 1.73 M². of body surface area with an average of 1,554 ml.

* Table III shows a few toxemic pregnant patients examined with interesting but inconclusive results since there are so few cases.

Patient L. P. with very mild pre-eclampsia had a normal *EHBF*. Patient E. Z. had essential hypertension and a normal *EHBF*. Patient A. G., examined when 3 months pregnant, had chronic nephritis but went on to term successfully; her *EHBF* was normal.

J. M. had severe pre-eclampsia for which Caesarean section was performed; her *EHBF* was somewhat elevated both before delivery and to a less extent post-operatively. It is interesting also to note the high *EHBF* percentage of total blood volume in her case. The same elevations of *EHBF* and *EHBF* per cent of blood volume were found in patient A. B. who had hypertension with superimposed pre-eclampsia, developing premature separation of the placenta and delivering a 6 lb. 11 oz. stillbirth.

Patient M. F. had a very high *EHBF* per minute, so high, in fact, it represented 88 per cent of the total blood volume. Two previous pregnancies had been complicated by eclampsia and pre-eclampsia. She was examined at 10 weeks in this, the third, pregnancy at which time her temperature, pulse, blood pressure and urine were normal. The remainder of her pregnancy was perfectly uneventful, with normal labor occurring at term.

While most inconclusive because of the paucity of examined cases, these results suggest some abnormality of liver blood flow in the severe toxemias of pregnancy. Further study in this direction is expected, and certainly necessary before any definite conclusions can be made as to the effect of toxemias on liver blood flow.

** Indicates peripheral vein hematocrit. All others from hepatic vein. (See page 952.)

which is practically identical with the non-pregnant average *EHBF*. Subject R. D. in this series was examined when she was pregnant 4 months. She had had 2 previous normal pregnancies. Although her *EHBF* was high, 2,465, she went on to term with this pregnancy without developing any signs of toxemia.

As would be expected from the fact that the equivalent hepatic blood flow does not change in normal pregnancy, the *EHBF* percentage of total blood volume was somewhat decreased, particularly late in pregnancy when the blood volume is increased. The *EHBF* percentage of total blood volume in this series averaged 28.5 per cent with a range of 17.1 to 44.2 per cent. A physiological increase in blood volume is a known fact in pregnancy. Liver blood flow remains unchanged, however, presumably because of shunting of the excess blood volume through the placenta.

CONCLUSION

Liver blood flow in normal pregnancy does not differ from liver blood flow in non-pregnant patients with normal livers. The average *EHBF* per minute per 1.73 M.² was 1,554 ml. in normal pregnancy and 1,548 ml. in non-pregnant women. The decreased *EHBF* per cent of total blood volume in pregnancy is an obvious corollary to the fact that liver blood flow remains unchanged in the presence of an increased blood volume of pregnancy.

The authors wish to thank Dr. Stanley E. Bradley for his assistance in establishing this study. We are also indebted to Anna Rosenthal, Edith Oblatt, Marion Heaton, and Margaret Hood for technical assistance.

EXPERIMENTAL TRANSMISSION OF MINOR RESPIRATORY ILLNESS TO HUMAN VOLUNTEERS BY FILTER-PASSING AGENTS. I. DEMONSTRATION OF TWO TYPES OF ILLNESS CHARACTERIZED BY LONG AND SHORT INCUBATION PERIODS AND DIFFERENT CLINICAL FEATURES[1]

By THE COMMISSION ON ACUTE RESPIRATORY DISEASES[2]

(From the Respiratory Diseases Commission Laboratory, Regional Hospital, Fort Bragg, N. C.)[3]

(Received for publication March 3, 1947)

INTRODUCTION

Investigations of respiratory disease in military populations, and to a less extent in civilian life, have consistently demonstrated that a large majority of the respiratory illnesses are of unknown etiology (1 to 10). Clinical and epidemiological studies have indicated points of similarity and of difference in selected groups of such cases (1, 6, 11, 12), but in the absence of laboratory confirmation, it has been almost impossible to segregate distinct entities. In the Army, for example, studies in the field, in dispensaries, and in the hospital (13, 14) have shown variations in the clinical picture from mild, "coryzal" types of infection, resembling the "common cold," to severe, "grippe-like" illnesses, either with or without pulmonary infiltration. Similarly, epidemiological observations have revealed waves of mild respiratory infections, chiefly resembling the "common cold," in the summer and fall (13) and epidemics of more severe disease, apparently associated with an increased incidence of primary atypical pneumonia, in the winter and spring (2, 13, 15). Laboratory studies have failed to reveal causative agents in these cases, although human volunteer experiments have suggested a relationship between minor respiratory illness and primary atypical pneumonia (16 to 18).

A more direct attempt (*a*) to segregate "entities" from this group of unclassified respiratory illnesses and (*b*) to clarify the relation between minor respiratory illnesses and primary atypical pneumonia has been made by a series of experiments in human volunteers. Four donor subjects were selected whose illnesses appeared clinically to represent different types of respiratory disease:

(*1*) A relatively severe febrile illness, with sore throat, hoarseness and cough, in a recruit; referred to here as "acute respiratory disease" (ARD),

(*2*) A coryzal illness, with fever and constitutional symptoms, in a laboratory officer, referred to here as "severe common cold" (S-CC),

(*3*) A mild coryzal illness, without fever, in a medical officer, referred to here as "common cold" (CC), and

(*4*) A severe febrile illness, with marked constitutional symptoms and rales in the lungs, in a recruit, referred to here as "bronchitis resembling atypical pneumonia" (Br-AP).

Filtered washings from the respiratory tracts of these 4 donors, inoculated into 4 groups of volunteers, induced 2 types of minor respiratory ill-

[1] This investigation was supported through the Commission on Acute Respiratory Diseases, Board for the Investigation and Control of Influenza and Other Epidemic Diseases in the Army, Preventive Medicine Service, Office of the Surgeon General, United States Army, and by grants from the Commonwealth Fund, the W. K. Kellogg Foundation, the John and Mary R. Markle Foundation, and the International Health Division of the Rockefeller Foundation, to the Board for the Investigation and Control of Influenza and Other Epidemic Diseases, for the Commission on Acute Respiratory Diseases.

[2] Members and professional associates of the Commission on Acute Respiratory Diseases were: John H. Dingle, Lt. Col., M.C., A.U.S., Director; Theodore J. Abernethy, Lt. Col., M.C., A.U.S.; George F. Badger, Major, M.C., A.U.S.; Joseph W. Beard, M.D.; Norman L. Cressy, Major, M.C., A.U.S.; A. E. Feller, M. D.; Irving Gordon, M.D.; Alexander D. Langmuir, Major, M.C., A.U.S.; Charles H. Rammelkamp, Jr., M.D.; Elias Strauss, Major, M.C., A.U.S.

[3] Now located in the Department of Preventive Medicine, School of Medicine, Western Reserve University, Cleveland, Ohio.

ness as indicated by clinical characteristics and incubation periods. The results are reported in the present paper.

Further differentiation of these 2 types of minor respiratory illness was achieved on the basis of active immunity by reinoculation of the volunteers with homologous and heterologous washings from the donors. Finally, it was determined that primary atypical pneumonia could still be induced in individuals convalescent from both types of disease. These findings are presented in the second paper.

Terminology

Inadequate knowledge of causation of the respiratory illnesses dealt with in this paper results unavoidably in cumbersome nomenclature. The terms and abbreviations employed here are used in an attempt to name the individual illnesses which were selected for study because they might represent entities and to relate those illnesses, insofar as possible, to cases observed in previous investigations.

Undifferentiated acute respiratory disease (ARD). This term is applied to an acute febrile respiratory disease of short duration characterized by constitutional reactions or local respiratory symptoms, or both, of sufficient severity to require hospitalization,[4] and by epidemic occurrence among recruits in the winter months (2, 14, 15). The etiology is unknown. The diagnosis is made by exclusion, based on: (*1*) the absence of clinical or serological evidence of streptococcal infection or specific contagious disease; (*2*) absence of pulmonary consolidation, as determined by roentgenogram; and (*3*) absence of serological evidence of influenza A or B.

Severe common cold (S–CC). This name indicates a respiratory illness characterized by coryza, constitutional symptoms and fever. With respect to the particular donor used in the present experiments, the term was applied retrospectively at the end of the study because of the difficulty in classifying his illness clinically as an instance of "acute respiratory disease" or of "common cold."

Common cold (CC). This term refers to a respiratory infection characterized principally by coryza, minimal constitutional symptoms and little or no fever.

Bronchitis resembling atypical pneumonia (Br–AP). This term is used to describe a febrile respiratory disease in which the character of onset, physical findings, including rales in the lungs, and clinical course of illness are similar to those observed in primary atypical pneumonia; roentgenographic evidence of pulmonary consolidation, however, is lacking (1).

Minor respiratory illness (MRI). This phrase is employed as a general term to indicate those respiratory illnesses, occurring among the recipients in these and previous experiments (16 to 18), which were characterized by variable clinical patterns and absence of roentgenographic evidence of pulmonary consolidation. The term has also been used in previous publications (13, 15) to designate a mild, usually afebrile respiratory infection which was observed among recruits on duty and in dispensaries, but which did not require hospitalization.

METHODS AND MATERIALS

The experiments were performed in the same hotel utilized for previous studies. In general, the selection of volunteers, isolation precautions, clinical and laboratory examinations and inoculation procedures were the same as those employed the year before in the third experiment of the series (18). Each volunteer was isolated in an individual room during the entire experimental period in order to prevent chance exposure to respiratory diseases through outside contact. A control period of isolation of not less than 2 weeks preceded the inoculation of each individual. The techniques of a contagious hospital were instituted; gowns and face masks were worn at all times by the attending staff.

Subjects. Thirty-seven volunteers comprised the first study group. These men were observed during a 7-week period from May 17 to July 5, 1945. At the completion of this study 16 of the original group volunteered to remain in isolation for an additional 7 weeks; the remaining 23 men were released from observation and 25 replacements secured. The second half of the study was conducted during the 7-week period from July 11 to August 31, 1945; 41 volunteers comprised the experimental group. None of the volunteers had participated in previous investigations performed in 1943 or 1944.

Laboratory Studies. Complete blood counts using capillary blood were done at the beginning of the isolation period. Total and differential leukocyte counts were obtained subsequently at 3- or 4-day intervals. The erythrocyte sedimentation rate was determined weekly by the Rourke-Ernstene method (19).

Venous blood was taken at weekly intervals for the following tests: cold hemagglutination (20), antistrep-

[4] In the Army the usual criterion for hospitalization was a temperature of 100° F. or higher.

tolysin (21), heterophile antibody (22) and agglutinin-inhibition tests for influenza viruses A and B (23). From 4 to 6 specimens were obtained from each individual during any given study period. Specimens from each subject were always tested at the same time at the conclusion of the experiment.

Bacteriological study of the throat flora was made on each volunteer and on each member of the attending staff every second day. Swab cultures of the pharynx and tonsils or tonsillar fossae were taken before breakfast, placed immediately in 5 ml. of sterile broth and subsequently plated on blood agar according to a standard technique (24). Every 4th day an additional throat swab was obtained and placed in media selective for the cultivation of *Beta*-hemolytic streptococci (25). The presence or absence and relative frequency of the following organisms were recorded: *Beta*-hemolytic streptococcus, *Staphylococcus aureus*, pneumococcus, *Hemophilus influenzae*, *H. hemolyticus*, Friedländer's bacillus, and gram-negative cocci. The usual mouse technique was employed for the detection of pneumococci. Anaerobic cultures were not performed.

Inocula. The inocula consisted of nasal and pharyngeal washings obtained from each of the 4 donor subjects during the acute stage of illness and from each of nine well persons in a control group. The inocula were prepared in the following manner: Several specimens of nasal and pharyngeal washings in sterile broth were collected from each donor, frozen immediately and stored at $-70°$ C. A few days prior to inoculation, the individual specimens from each donor were thawed rapidly in a 37° C. waterbath and pooled. After manual shaking or homogenization in a Waring blendor, the material was centrifugalized at 4,500 r.p.m. for 10 minutes in an angle centrifuge, and the sediment discarded. Approximately half of the supernate was filtered through Corning "UF" fritted glass filters and half through single-pad Seitz filters. All procedures were carried out in the cold. Specimens from each filter were placed in separate Pyrex Erlenmyer flasks, a portion was reserved for bacteriological study and the balance of the filtrate refrozen and stored at $-70°$ C. until ready for use. Aerobic and anaerobic cultures of the several specimens of filtrate were made on blood-agar plates, and in blood broth and thioglycolate medium. All filtrates proved to be sterile, so that none had to be discarded. On the day of inoculation the specimens were thawed rapidly, kept iced and used in proportion of approximately 1 part Corning filtrate to 1 part Seitz filtrate.

Inoculation procedures. Five groups of men, A, B, C, D and E, were given inoculations of various types of filtrate on different days (Table I). The inoculations were given out-of-doors and sterile precautions were used throughout.

Each volunteer received a total inoculum of 10 ml. administered in 3 equal doses during the morning and afternoon of a single day. Approximately 2.5 ml. was given by nebulizer and 7.5 ml. by atomizer. The material was sprayed into the nose and throat in synchronization with deep inspiration; a tank of nitrogen served as a source of pressure. Comparable techniques were maintained, not only in the separate inoculations of a given day, but also in those given on different days.

Treatment. The treatment of patients was symptomatic. Antipyretic or antibacterial drugs were not used. Nasal instillation of sympathomimetic drugs was avoided. Codeine sulphate and phenobarbital were administered to control headache, cough or restlessness. Barbiturates were used freely as sedatives.

RESULTS

Inoculation of autogenous filtrates (control)

Separate autogenous filtrates were prepared, using pharyngeal and nasal washings collected from each of 9 individuals after 9 and 11 days in isolation, respectively. Such inocula were employed in order (*1*) to assess the mechanical effects of the spraying procedures, (*2*) to demonstrate the possible existence of a latent agent, and (*3*) to avoid the selection, as "control" donors, of apparently normal individuals who might be actually harboring an agent. After a total period of 14 days of isolation, each volunteer was inoculated with his own filtrate (Group A, Table II).

TABLE I

Types of illness in donors of the inocula administered to the volunteers in the various groups

Group	Number of men	Date of inoculation	Types of illness in donors*	Code designation
A	9	5/31/45	None	Control
B	14	6/8/45	"Acute respiratory disease"	ARD
C	14	6/11/45	"Severe common cold"	S-CC
D	10	7/27/45	"Common cold"	CC
E	10	7/26/45	"Bronchitis resembling atypical pneumonia"	Br-AP

* See text for definitions of the illnesses.

TABLE II

Summary of results in 48 volunteers inoculated with filtrates from cases of respiratory disease and in 9 controls inoculated with autogenous filtrates

Group	Type of inoculum*	Days of isolation prior to inoculation	Number of men	Results: MRI	Results: No illness
A	Control	14	9	0	9
B	ARD	22	14	12	2
C	S-CC	25	14	9	5
D	CC	17	10	6	4
E	Br-AP	16	10	4	6

MRI = Minor respiratory illness.
* See Table I and text for explanation of code designations.

Of the 9 volunteers given autogenous filtrates all remained well for a period of 30 days following inoculation (Table II). In no instance were symptoms or physical signs indicative of respiratory disease observed.

Inoculation of ARD filtrate

On June 8, after a control period of 22 days, 14 volunteers received ARD filtrate (Group B, Table II). The donor of this filtrate had suffered a moderately severe respiratory illness comparable to the "undifferentiated acute respiratory disease" of recruits (2, 14, 15). Pertinent data regarding the illness are given below and shown graphically in Figure 1.

The patient (NE) was an 18-year-old soldier with 5 weeks of Army service. He was well until the evening of May 7, at which time he became feverish, drowsy and developed a sore throat. The following morning these symptoms were still present and he was admitted to the hospital. The temperature on admission was 102.8° F., the pulse rate, 124, and the respiratory rate, 24. He appeared moderately ill. Physical examination revealed palpable non-tender cervical lymph nodes, slight nasal discharge (which was no more than normal for the patient), and mild injection of the soft palate, pharynx and tonsils. The tonsils were not conspicuously enlarged; exudate was not present. The lungs were clear. Roentgenograms of the chest taken in posterior-anterior and oblique positions showed no consolidation. Sinus films showed polypoid thickening of both antra, but no evidence of acute infection.

The febrile period was of 2 days' duration. Sore throat and later, hoarseness and cough, were the most prominent symptoms noted. By the 6th day all symptoms had disappeared. Convalescence was uneventful.

The total leukocyte count was normal. Bacteriological studies performed during the first 3 days from throat swabs, and from throat and nasal washings showed *H. influenzae* and *H. hemolyticus*. Serological tests were made on 4 samples of serum obtained at weekly intervals from admission; these tests included cold hemagglutination, heterophile agglutination, antistreptolysin "O" titers and antibody determinations for influenza viruses A and B. None of these tests revealed findings of diagnostic significance.

Of the 14 volunteers inoculated with ARD filtrate, 12 developed minor respiratory illness and 2 remained well (Table II). None of the group developed primary atypical pneumonia.

In 9 individuals, symptoms were first observed on the 5th or 6th day after inoculation. In the remaining 3 cases, onset of illness occurred on the 3rd, 8th and 9th days, respectively.

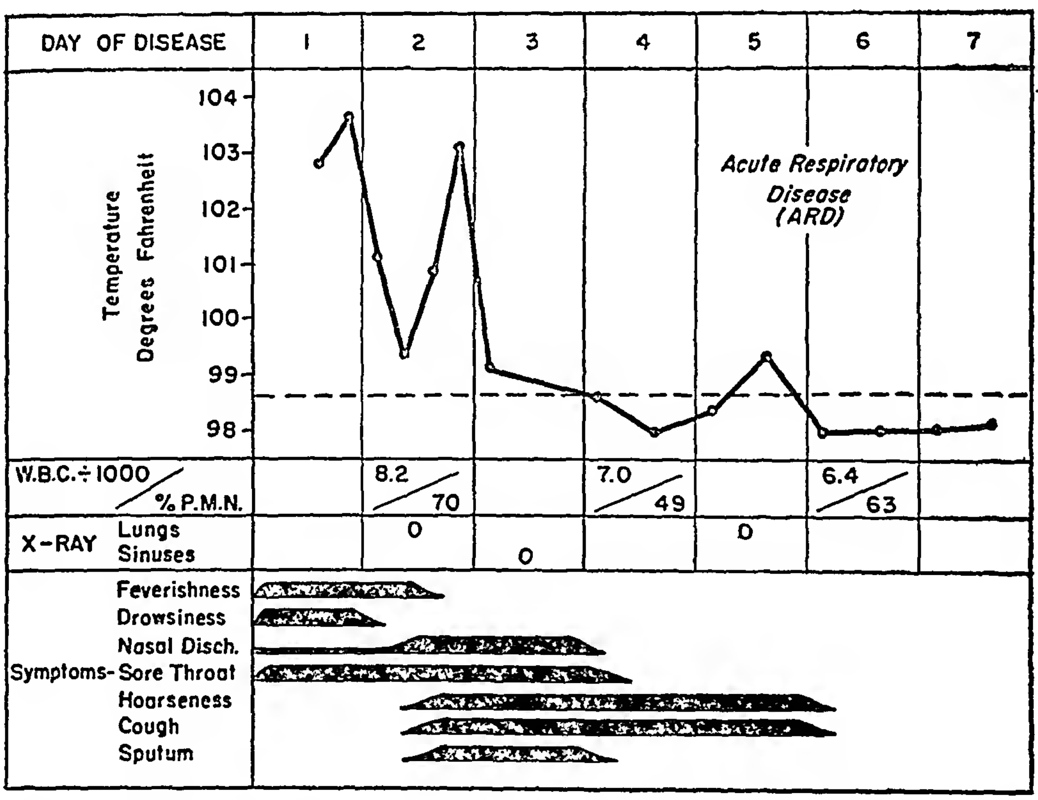

FIG. 1. CLINICAL CHART OF DONOR WHOSE ILLNESS WAS TERMED ACUTE RESPIRATORY DISEASE (ARD)

The clinical pattern observed in these cases was variable. In general the illnesses were mild in nature, with minimal constitutional symptoms, and varying degrees of symptoms and signs referable to upper respiratory tract. In 7 patients the duration of illness was no more than 4 days; in 5 patients it lasted between 6 and 12 days. Fever was not a conspicuous feature in any of the subjects; none had as brisk a febrile response to illness as did the donor.

The onset of illness was usually characterized by the development of dry or sore throat during the course of 24 or 48 hours. Generally, there were accompanying signs of mild inflammation of the soft palate or pharynx (injection or lymphoid hyperplasia). Nasal symptoms (sneezing, obstruction and discharge) were frequent during the first 48 hours from onset, but were of minimal intensity and not associated with obvious signs of nasal obstruction or coryza. Hoarseness and cough were observed at some time by approximately half of the patients, but were not conspicuous features of the early course of illness.

The following case reports illustrate the characteristics of the illnesses following inoculation of ARD material.

Case No. RP3-331. Five days after inoculation this patient first observed sore throat which was unaccompanied by constitutional or other local symptoms. During the next 24 hours there was minimal nasal obstruction and discharge as well as soreness of the throat. Physical examination revealed only prominent pharyngeal lymphoid follicles. On the 3rd day of illness he complained of headache; there was improvement in nasal symptoms, but no lessening of throat symptoms. The cervical lymph nodes were tender, but not conspicuously enlarged. Nasal obstruction was of moderate degree. There was gradual improvement in symptoms and signs, and all evidences of illness disappeared by the 7th day. The maximum temperature was 99.8° F. on the day after onset of symptoms, or 6 days after inoculation.

The total and differential leukocyte counts showed no alteration following inoculation. There was no elevation of the erythrocyte sedimentation rate at any time. Serological procedures showed no diagnostic increase in antibodies to influenza viruses A or B, heterophile agglutinins, or cold hemagglutinins. *Beta*-hemolytic streptococcus, group C, was isolated from throat cultures before and after inoculation, but no diagnostic rise of antistreptolysins was demonstrated in the patient's serum during convalescence.

Case No. RP3-321. This 26-year-old subject gave a history of infrequent mild respiratory infections of short duration occurring once a year, and consisting of sore throat, nasal congestion and coryza. He had had no respiratory illness in the previous 8 months. Beginning 6 days after inoculation he observed gradual onset of dryness of the throat, which was later followed by soreness of the throat, dry cough and malaise. On the 2nd day of illness he complained of feverishness, loss of appetite, aching of the eye-balls, sneezing and "stuffiness" of the nose. Physical examination revealed tender cervical lymph nodes and minimal injection of the nasal and pharyngeal mucosa. On the 3rd day there was improvement in constitutional symptoms but little change in throat or nasal symptoms; in addition the cough became productive of mucoid sputum. From the 4th to 8th day of illness he noted substernal discomfort during coughing. The nasal symptoms persisted until the 10th day. Cough decreased in amount and intensity, finally disappearing on the 12th day, 18 days after inoculation. Pulmonary infiltration was not demonstrated by auscultation or by roentgenography. Roentgenograms of the paranasal sinuses showed no evidence of acute or chronic infection. Recovery was uneventful. Bacteriological examinations showed no change in flora of the throat; serological examinations were non-contributory.

Inoculation of S–CC filtrate

Fourteen volunteers were inoculated with S–CC filtrate after a control isolation period of 25 days (Group C, Table II). The donor of this inoculum had experienced a moderately severe febrile respiratory illness in which nasal symptoms, coryza and cough were associated with constitutional symptoms. The clinical course of illness in this donor is given below and in Figure 2.

OL, a 35-year-old laboratory officer, had been well for at least a month when on the morning of April 23 he observed coryza, cough and substernal soreness. He reported for duty but felt unwell because of malaise, fever, coryza and continued cough which was productive intermittently of greenish-yellow sputum. In the afternoon, the malaise became worse. By evening he felt "grippy" and observed a dull frontal headache. The oral temperature was 100.2° F. The following morning there were dryness of eyes, mouth, throat and lips and diminution of nasal symptoms. Physical examination revealed a temperature of 99.4° F., mild hypertrophy of the pharyngeal lymph follicles, edema and injection of the nasal mucosa without discharge. The lungs were clear. Roentgenograms of the lungs and paranasal sinuses showed no acute or chronic pathological changes. Trans-illumination of the sinuses was normal; a consultant found no evidence of allergic rhinitis. The temperature rose to 101.2° F. on the evening of April 24, the 2nd day.

On the morning of the 3rd day the most prominent symptoms were malaise, feverishness, headache, anorexia, obstruction of the nares and cough. Physical examination revealed profuse serous nasal discharge. By the 4th day he was considerably improved; coughing was less fre-

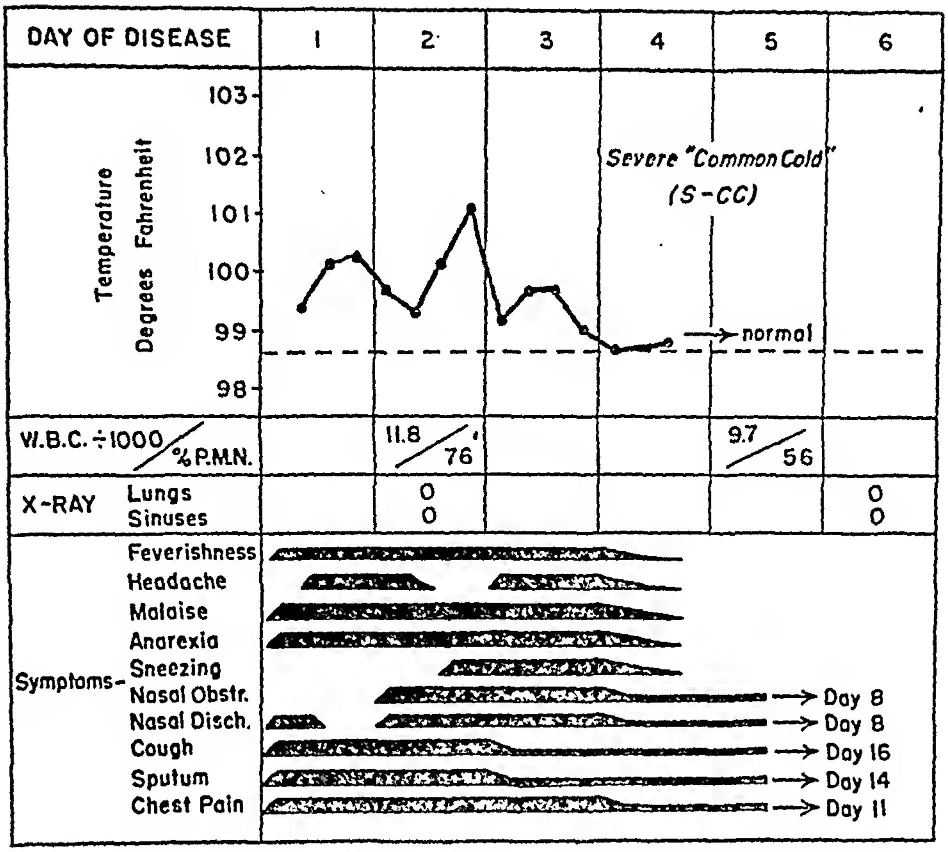

Fig. 2. Clinical Chart of Donor Whose Illness was Termed Severe "Common Cold" (S–CC)

quent and there was gradual decrease in nasal symptoms and signs. Roentgenograms of the chest and sinuses on the 6th day showed no pathological changes. Convalescence was prolonged.

The total leukocyte count on the 2nd day was 11,800; on the 5th day the count had decreased to 9,700. Polymorphonuclear leucocytes constituted 76 and 56 per cent, respectively, of the differential formulae. Cultures of the throat and sputum revealed pneumococcus, type 11. *H. hemolyticus* was isolated from throat washings. Samples of acute and convalescent sera showed no increase in antibody titer to sheep cells, streptolysin "O," group "O" human erythrocytes, or influenza viruses A and B.

Of the 14 subjects given S–CC inoculum, nine became ill with mild to moderately severe respiratory infection (Table II). None of this group developed roentgenographic evidence of primary atypical pneumonia.

In contrast with the finding in the ARD group, all patients developed illness within 24 to 48 hours after inoculation of S–CC filtrate. The clinical pattern was featured by sneezing, nasal obstruction and objective evidence of coryza. Because of the prominence of nasal symptoms and signs there was usually little difficulty encountered at the bedside in distinguishing this type of illness from that which followed the ARD inoculum. The duration of illness, furthermore, was more prolonged. Symptoms were present for from 4 to 7 days in 4 patients, from 9 to 13 days in 5. The type and course of illness resulting from S–CC inoculum resembled that of naturally acquired cases of the "common cold." An example is presented in the following case report:

Case No. RP3–236. This 22-year- old volunteer had experienced rare head colds of 2 weeks' duration during the past few years. He suffered occasionally from frontal headaches and, during most of the preceding year, from slight nasal congestion and post-nasal discharge. His last previous respiratory infection occurred during the spring of 1945 with symptoms lasting for only 1 day. During the 25-day control period of isolation he was free of respiratory symptoms.

Inoculated on June 11, he first noted an abrupt onset of illness at 6 p.m. on June 12. The incubation period was calculated to be not less than 27 hours nor more than 33 hours. The initial symptoms were excessive sneezing, nasal discharge and increased post-nasal drip. Later that evening he noted generalized weakness, dull cranial discomfort and mild sore throat. The following day cough and feverishness were present, and physical examination disclosed only slight injection of the pharynx. The temperature rose to 100.2° F. on the afternoon of the 2nd day

of illness. On the 3rd day (June 14) the temperature returned to normal, headache persisted, but other constitutional symptoms were absent. Local symptoms, however, were prominent and consisted of sneezing, nasal obstruction and discharge, dry and sore throat, hoarseness and dry cough. Physical examination at this time revealed nasal obstruction, thin serous discharge from the nares and slight injection of the pharynx. The lungs were clear. The subsequent course of illness was characterized by improvement in nasal symptoms and signs and gradual diminution of cough which was no longer present after the 13th day. Roentgenograms of the chest showed no pulmonary infiltration at any time. Sinus films were clear before as well as 2 weeks after inoculation.

The leukocyte counts, differential formulae, and erythrocyte sedimentation rates were within normal limits. Serological tests on acute and convalescent sera showed no antibodies which were diagnostic of influenza, infectious mononucleosis, primary atypical pneumonia or streptococcal infection. Cultures of the throat showed *Beta-hemolytic* streptococcus, Group D, and pneumococcus, type 3, both of which were isolated repeatedly before as well as after inoculation.

Inoculation of CC filtrate

After an isolation period of 17 days, 10 volunteers were given CC filtrate obtained from a donor who had a mild afebrile respiratory illness characterized principally by coryza. This illness was considered to resemble the "common cold" (Group D, Table II). During convalescence from his infection the donor developed cold hemagglutinins in the serum in low titer. The course of illness in this patient is shown in the following case report and in Figure 3.

MI, a 29-year-old medical officer, first observed onset of respiratory disease on May 11, 1945. The first symptoms were dry throat and slight burning and irritation of the nose. Later in the day there was watering of the eyes. The following morning sneezing, nasal obstruction and coryza were prominent symptoms. The nasal discharge was copious and serous in character. Mild dysphonia also was present for a short period. Constitutional symptoms, except for fatigability, were absent. He carried on with his normal duties. Physical findings were confined to congestion and edema of the nasal mucosa. Roentgenograms of the chest and sinuses were interpreted as being normal.

The maximum temperature did not exceed 99° F. Nasal obstruction and discharge were the most prominent features of illness. The appearance of the nasal mucosa did not suggest an allergic rhinitis. Cough was present for 2 days but was non-productive. No rales were audible in the lungs at any time.

A single total leukocyte determination showed 10,500 cells with normal differential distribution. Cold hemag-

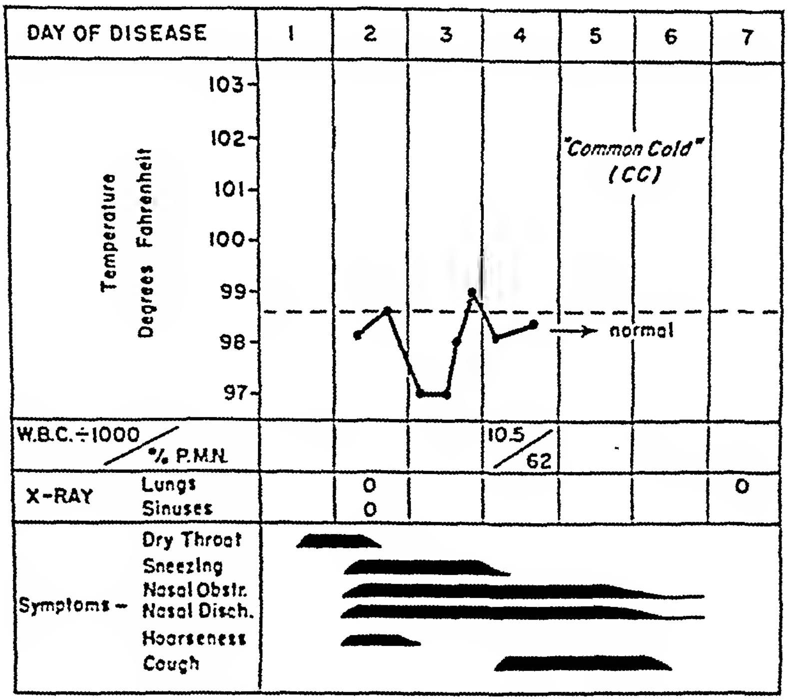

FIG. 3. CLINICAL CHART OF DONOR WHOSE ILLNESS WAS TERMED "COMMON COLD" (CC)

glutinin titers were as follows: 2nd day, < 8; 9th day, 32; 16th day, < 8; 23rd day, 8. Antistreptolysin, heterophile and influenza antibody studies showed no diagnostic increases in titer.

Six of the 10 subjects became ill following the inoculation of CC filtrate (Table II). The illnesses were not associated with fever, were mild in character and were featured by the presence of nasal symptoms and signs resembling those of the "common cold." None of the patients developed pulmonary infiltration or cold hemagglutinins.

Onsets of illness occurred approximately 24 hours after inoculation in 3 cases, on the 2nd day in 2 cases, and the 4th day in 1 case. Illness in these patients usually began abruptly with the development of sneezing, nasal obstruction, and coryza in association with constitutional symptoms of mild degree. In 2 patients, dry or sore throat and cough were also early symptoms. In 2 patients, hoarseness was noted. Constitutional symptoms of chilliness, feverishness, headache, malaise or weakness were observed by 5 of the 6 cases but were of short duration.

Abnormal physical signs in the respiratory tract, except for obvious nasal obstruction and discharge, were minimal. Injection of the soft palate was not encountered and signs of inflammation of the pharynx (injection or lymphoid hyperplasia) were present in 3 cases. Rales were not audible. The illness in one patient, representative of the group, is given in the following case report.

Case No. RP4–321. A 30-year-old male had had "influenza" in January 1944. He usually experienced 2 to 3 respiratory infections each winter lasting about 1 week and manifested by sore throat, nasal congestion and coryza. There had been no illness of this type in the previous 4 months. During the pre-inoculation period of isolation he was well.

On July 28, at 2 p.m., approximately 30 hours after the first inoculation, he noted abrupt onset of excessive sneezing, nasal obstruction and coryza. Later that day he observed myalgia and postorbital aching. Dry cough and hoarseness were intermittently present during the first 12 hours. The following day, in addition to the above symptoms, he observed headache, a dry, sore throat and substernal aching. Physical examination revealed moderate nasal obstruction and clear serous discharge.

On the 3rd day (June 30) the constitutional symptoms were no longer present, the nasal symptoms were unchanged, post-nasal "drip" was noted and the cough was productive of a slight amount of mucoid sputum. Prominent lymphoid follicles on the pharynx were observed for the first time on this date. The subsequent course was characterized by rapid subsidence of all symptoms and signs. The clinical course of illness lasted 5 days. There were no signs of pulmonary infiltration. Recovery was uneventful.

The total and differential leukocyte counts and erythrocyte sedimentation rate showed no significant change from normal following inoculation. Cold hemagglutinins were not present in significant titer, all specimens showing titers of < 8. Bacteriological study of the throat flora showed no significant change as a result of inoculation or of illness.

Inoculation of Br-AP filtrate

After a control isolation period of 16 days, a group of 10 volunteers was given filtrate Br-AP (Group E, Table II). The illness in this donor was more severe than that experienced by any of the other donors. The symptoms, physical signs, clinical course and serological findings were consistent with the diagnosis of primary atypical pneumonia. Roentgenographic evidence of pulmonary infiltration, however, was lacking. The course of illness is given in the following case history and shown graphically in Figure 4.

BA, a 35-year-old soldier with 1 month of Army service, was admitted to the hospital on April 30, 1945. On the afternoon of admission there was an abrupt onset of chilliness, feverishness, generalized aching, weakness and dry cough. Later, headache was noted. The temperature was 100.8° F., the pulse, 80, and respirations, 20 per minute. Physical examination the next day revealed a moderately ill patient whose soft palate and pharynx were injected. The lungs at this time were clear to percussion and auscultation and roentgenograms of the chest and sinuses were normal. During the 2nd day of disease the temperature rose to a maximum of 103.5° F., the constitutional symptoms continued, cough persisted and was productive of a small amount of thick yellow sputum. On the 3rd day, the patient was still moderately ill, the temperature reaching a maximum of 104° F. Fine rales were audible for the first time at the base of the left lung. A roentgenogram of the chest on the 4th day was clear. Rales continued to be heard at the left base, and subsequently, at the right base, until the 6th day. The temperature fell by lysis, reaching normal on the 6th day. Cough and sputum continued until the 10th day.

The total leukocyte and differential counts were normal. Throat cultures showed *Hemophilus influenzae* and *H. hemolyticus*. From throat washings and sputa, the following organisms were isolated: pneumococcus, types 10, 14 and 29; *H. influenzae* and *H. hemolyticus*. Cold hemagglutinins were present in the convalescent sera during the 3rd week in a titer of 16; blood taken during the acute illness showed a titer of < 8. Heterophile antibody tests, antistreptolysin determinations and agglutinin-inhibition tests for influenza viruses A and B showed no diagnostic increases in titers.

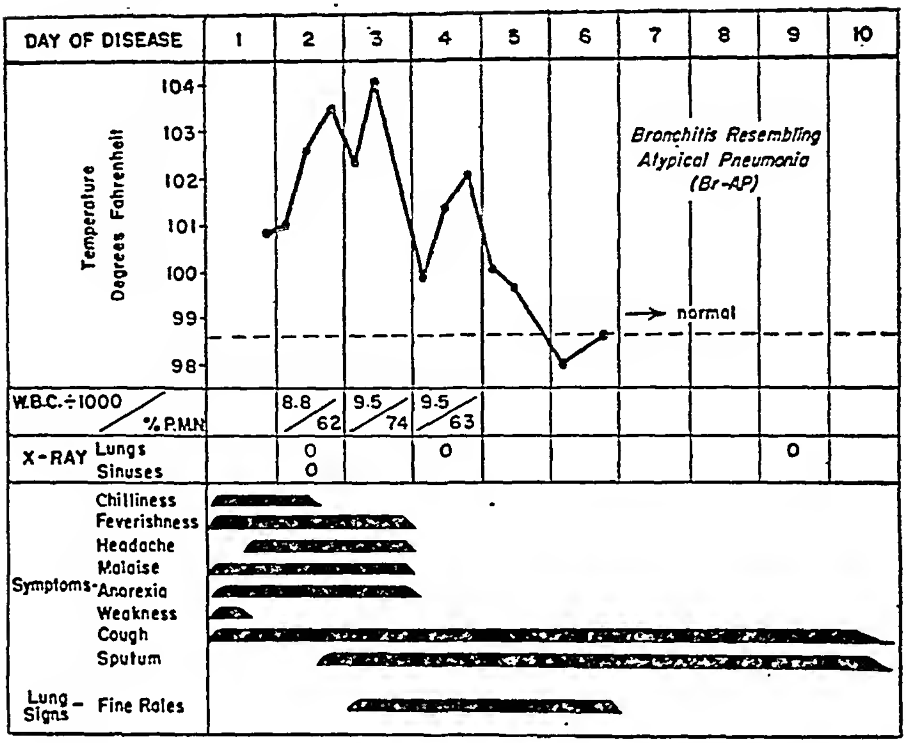

FIG. 4. CLINICAL CHART OF DONOR WHOSE ILLNESS WAS TERMED BRONCHITIS RESEMBLING ATYPICAL PNEUMONIA (Br–AP)

Of the 10 volunteers receiving Br–AP filtrate, 4 developed minor respiratory illnesses (Table II). Onsets of disease in these patients were observed 2, 3, 3 and 7 days, respectively, after inoculation. The illnesses were mild; fever was not observed in any of the patients. Auscultatory or roentgenographic evidence of pulmonary infiltration was not detected in any of those with illness.

Constitutional symptoms of feverishness, headache and malaise were present in only 1 patient. Two patients experienced sore throat as the initial symptom; the remaining 2, nasal symptoms. Hoarseness was noted in 2 cases. Cough was not observed in any of the 4 who became ill.

Physical findings were minimal and consisted of tender cervical lymph nodes (1 case), nasal injection and obstruction (2 cases), pharyngeal injection (1 case) and pharyngeal lymphoid hyperplasia (2 cases).

No characteristic clinical pattern was evident in these cases. None of the illnesses was as severe as that of the donor of the inoculum.

CLINICAL CORRELATIONS

Comparison of the types of illness observed in each of the experimental groups revealed many clinical features which were common to all groups. Nevertheless, certain features such as nasal symptoms and signs, were more prominent in some groups than others. For purposes of increasing the material available for analysis, 6 cases of illness from the second half of the study are included (26). Four of these illnesses were induced by reinoculation of 5 men of the control group with filtrate S–CC, and the other 2 illnesses followed the inoculation of 5 men with filtrate ARD (see Figure 1 in the following paper [26]). Thus, clinical correlations were made from the following material: 14 cases, filtrate ARD; 13 cases, filtrate S–CC; 6 cases, filtrate CC; and 4 cases, filtrate Br–AP.

Incubation period. The sharp difference in incubation periods observed in the groups inoculated with filtrate ARD and S–CC is readily seen in Figure 5. Although the number of cases in the CC

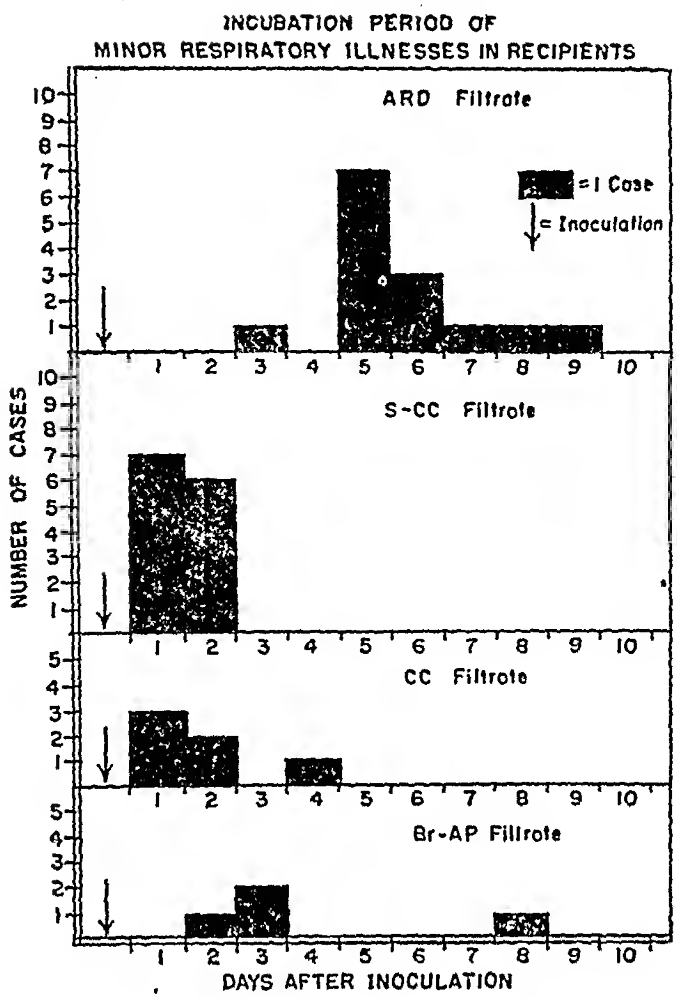

Fig. 5. Incubation Period of Minor Respiratory Illnesses in Recipients of the 4 Inocula

See Table I and text for explanation of code designations ARD, S-CC, CC, and Br-AP.

TABLE III

Total frequency of symptoms in 37 cases of experimentally induced minor respiratory illness

Symptom		Frequency of symptoms in various groups*			
		ARD (14 cases)	S-CC (13 cases)	CC (6 cases)	Br-AP (4 cases)
Constitutional:	Chilliness	0	0	1	0
	Feverishness	1	4	3	1
	Headache	7	8	4	1
	Malaise	4	3	4	1
	Anorexia	3	1	0	0
	Weakness	2	3	1	0
Local:	Sneezing	4	8	5	1
	Nasal obstruction	10	11	6	2
	Nasal discharge	8	12	6	2
	Dry throat	6	8	5	0
	Sore throat	10	7	2	3
	Hoarseness	5	8	2	2
	Cough	6	9	3	0
	Sputum	5	4	1	0
	Chest pain	3	4	2	0

* See Table I and text for explanation of code designations.

group is small, 5 of the 6 cases had onsets on the 1st or 2nd day after inoculation. In this respect and in other features which will be pointed out below, the CC and S-CC groups were similar. The incubation period in the Br-AP group was not clearly defined because of the small number of illnesses.

Symptomatology. The total frequency of symptoms is shown in Table III. Only slight differences are apparent for each symptom among the various diagnostic groups. With respect to daily frequency and time of appearance of nasal and throat symptoms, however, further analysis revealed certain differences between the ARD and S-CC groups (Figure 6). Nasal symptoms (sneezing, obstruction and discharge) tended to develop earlier, that is, within the first 48 hours from onset and were present in greater day-by-day

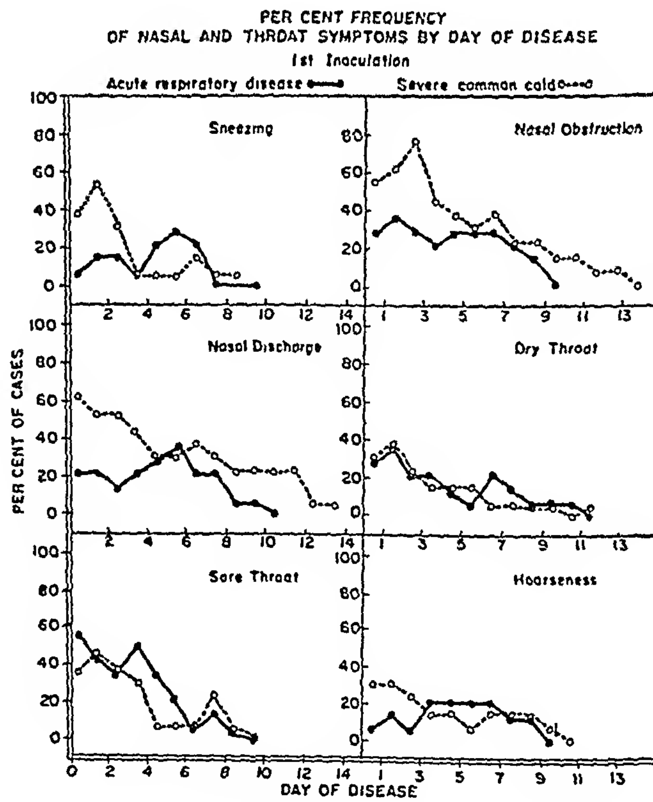

Fig. 6. Daily Frequency and Time of Appearance of Nasal and Throat Symptoms in Minor Respiratory Diseases Experimentally Induced by ARD and S-CC Inocula

frequency, in the S–CC group than in the ARD group. These findings substantiated clinical impressions gained at the time the patients were ill. Throat symptoms (dry and sore throat), on the other hand, appeared in each group at approximately the same time and were present in the same daily frequency during the course of disease. The CC and Br–AP groups are omitted from consideration because of the small number of cases.

The number of nasal symptoms (sneezing, obstruction and discharge) observed during the first 48 hours also showed differences among the groups (Table IV). The presence of 2, or of all 3 nasal symptoms was encountered more often in those men in the S–CC and CC groups. Conversely, multiple nasal symptoms were experienced infrequently by those in the ARD group.

TABLE IV

Total number of nasal symptoms present within 48 hours after onset in various diagnostic groups

Number of nasal symptoms*	Group†		
	ARD	S-CC	CC
None	4	3	0
One	7	3	0
Two	3	1	2
Three	0	6	4
Total cases	14	13	6

* Sneezing, obstruction and discharge.
† See Table I and text for explanation of code designations.

The duration of throat complaints and nasal symptoms was approximately the same in the various groups. Obstruction and discharge tended to persist somewhat longer in the S–CC and CC groups.

The relation of nasal symptoms to nasal signs and throat symptoms to signs during the first 2 days of illness is shown in Table V. In general, better correlation was found between nasal symptoms and signs in groups S–CC and CC, in which coryza was a prominent feature, than occurred in group ARD. Conversely, more correlation was found between throat symptoms and signs in the ARD group, in which sore throat was a characteristic feature, than was shown in the other groups.

Physical signs. The total frequency of physical signs at any time during illness is shown in Table VI. It is apparent that nasal signs were frequent

TABLE V

The relation of nasal symptoms and signs and throat symptoms and signs during first 48 hours of illness in various diagnostic groups

Physical signs	Symptoms*

§ See Table I and text for explanation of code designations.

and that signs referable to the throat were minimal. The percentage frequency of nasal and throat signs of any degree by day of disease is shown in Figure 7 for groups ARD and S–CC. The other 2 groups are omitted from this analysis because of the small number of cases. Differences between the 2 groups were most marked in the case of nasal obstruction and discharge.

TABLE VI

Total frequency of physical signs in 37 cases of experimentally induced minor respiratory illness

Physical signs	Frequency of physical signs in various groups*

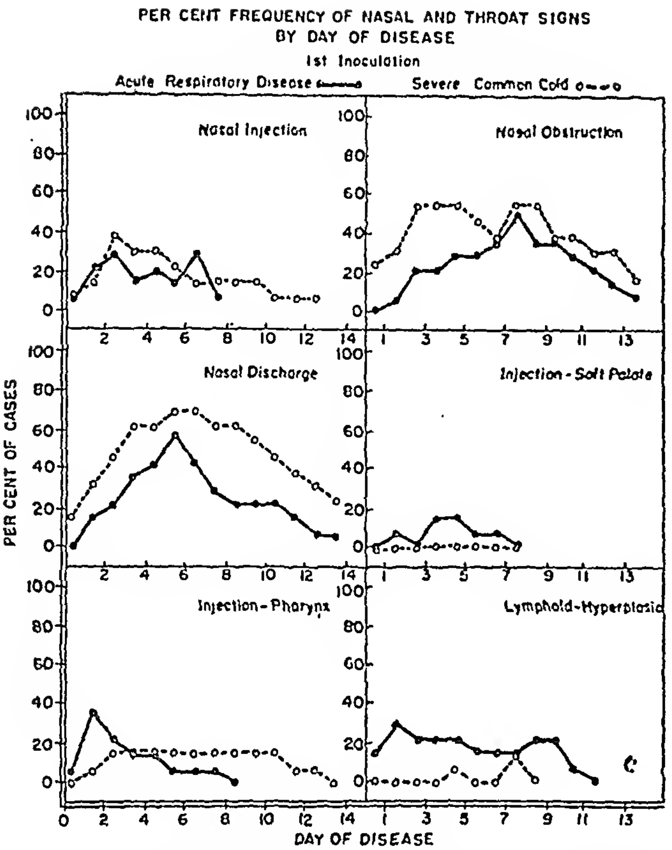

FIG. 7. DAILY FREQUENCY AND TIME OF APPEARANCE OF NASAL AND THROAT SIGNS IN MINOR RESPIRATORY DISEASES EXPERIMENTALLY INDUCED BY ARD AND S-CC INOCULA

Fever. Fever was not a conspicuous clinical feature of illness in the majority of the volunteers (Table VII). Only 2 individuals, both of whom received S-CC inoculum, developed temperatures of 100° F. or more. Maximum temperatures in the other groups did not exceed 99.8° F. The median febrile curves were essentially normal in the ARD and S-CC groups. Slightly higher temperatures, however, were found in the ARD group from the 5th to the 8th days, and in the S-CC group on the 2nd day. These periods corresponded with the time when symptoms were present in the two groups of cases.

TABLE VII

Febrile response in 37 cases of experimentally induced minor respiratory illness

Group	Total cases with illness*	Number of cases with			Maximum fever at any time (degrees F.)
		No fever 99° F.	Fever 99.2–99.8°	Fever 100° F.+	
ARD	14	5	7	0	99.8
S-CC	13	3	7	2	100.2
CC	6	4	1	0	99.4
Br-AP	4	1	3	0	99.8

* 4 cases (2 in the ARD, 1 in the S-CC group and 1 in the CC group), showing intermittent low grade fever (99 to 99.4° F.) before and after inoculation, are omitted from analysis. In each case the temperature curve was not altered as a result of inoculation.

TABLE VIII

Average total leukocyte count in 57 volunteers in relation to inoculation and in 31 patients with illness in relation to onset

Type of inoculum*	Number inoculated	Leukocyte count (thousands)		Number with illness	Leukocyte count (thousands)	
		Before Inoculation	After Inoculation		Before onset	After onset
Autogenous	9	7.3	7.1	0		
ARD	14	7.6	6.7	12	7.6	6.5

CC	10	7.0	7.5	6	6.9	7.4
Br-AP	10	8.0	7.6	4	8.7	8.0

* See Table I and text for explanation of code designations.

LABORATORY STUDIES

Hematology. Tabulation of the average total leukocyte count was made in each of the experimental groups according to inoculation and in relation to onset. A total of 381 individual leukocyte counts was made during the first study. As shown in Table VIII, the leukocyte counts in 3 of the 4 groups (ARD, S-CC and Br-AP) and in the control group fell to a slight extent; the average count in the remaining group (CC) increased. Similar differences were shown when the analyses were restricted to patients with illness. All of the average counts, however, were normal and within the limits of technical variation. Individual instances of leukocytosis or leukopenia were not encountered.

The relative percentage of polymorphonuclear neutrophils, lymphocytes, eosinophils and monocytes showed no significant change in any group either as a result of inoculation or after the development of illness.

The corrected erythrocyte sedimentation rate was normal (0.2 to 0.4) in every subject both before as well as after inoculation.

Serology. A diagnostic increase in titer (4-fold or greater) of cold hemagglutinins was not encountered following inoculation in any of the subjects. Similarly, no increase in titer of hetero-

phile antibodies, or of antibodies against streptolysin "O" and influenza viruses A and B was shown in representative samples of serum.

Bacteriology. The results of bacteriological study of the throat flora, performed at 2-day intervals, were analyzed for the purpose of detecting any change in flora for any given organism in relation to time of inoculation or resultant illness. The organisms which formed the basis of the analysis were the *Beta*-hemolytic streptococcus, pneumococcus, *H. influenzae* and *H. hemolyticus.*

During the period of May 18 to 31, 37 individuals comprising the control, ARD, and S–CC groups were in quarantine prior to inoculation. After May 31, when the control group received autogenous filtrates the other 2 groups were observed continuously and on June 8 and 11, respectively, they received initial inoculations. Thus, the interval, May 18 to 31, provided a suitable period in which the bacteriological results could be compared within each of the groups. The interval, June 2 to 8, was a period in which the bacteriological findings in the inoculated control group could be contrasted with those in the ARD group; similarly, comparisons were permitted between the control and S–CC groups during the period, June 2 to 10. The results are given in Table IX. Marked fluctuations occurred in the frequency with which each of the 4 organisms was isolated during the period of quarantine, May 18 to 31. No significant change in throat flora was observed in the control group as a result of having received autogenous filtrate.

The effect of inoculation on the pharyngeal flora of the ARD and S–CC groups is compared in Table X. The analysis was restricted to those individuals who experienced illness, and the results are contrasted with those obtained in the control group, the members of which had experienced no illness. It is apparent that before inoculation there was wide fluctuation in the percentage of individuals from whom any one of the organisms was isolated. Similar variations were evident after inoculation. Comparison of the results in the ARD and S–CC groups after inoculation with those of the control group showed slight differences; for example, in the case of the pneumococcus. However, these differences were of no greater order of

magnitude than were present during the control period.

DISCUSSION

The initial phase of this study was an attempt to demonstrate the transmission of "minor respiratory illnesses" (MRI) to human volunteers by the inoculation of filtered respiratory secretions obtained from 4 donor subjects whose illnesses appeared to differ in their clinical characteristics. Minor respiratory illnesses were induced by the inocula from all 4 of the donors and presumptive evidence was obtained for the existence of separate etiological "entities." Only 2 types of illness, however, could be distinguished. The first type, induced by the "acute respiratory disease" (ARD) filtrate, was characterized by prominence of pharyngeal involvement and an incubation period of 5 to 6 days. The second type, induced by both the "common cold" (CC) and "severe common cold" (S–CC) filtrates, was characterized chiefly by coryza and an incubation period of 24 to 48 hours. The illnesses induced by the inoculum from the fourth donor, whose infection was termed "bronchitis resembling atypical pneumonia" (Br–AP), were too few in number and variable in character to permit classification. The etiology and clinical nature of these induced minor respiratory illnesses will be discussed briefly in this paper. In the following paper, which presents the second phase of the study, the differentiation of these entities on an immunological basis will be considered and the relationship of the illnesses to primary atypical pneumonia will be discussed.

Consideration of the results of the initial experiments in terms of etiology led to the tentative con-

clusions that the illnesses induced in the volunteers were the direct results of inoculation of the various filtrates and were due to uncharacterized filtrable agents, presumably viruses, therein. Several types of data supported such conclusions: (*1*) Two distinct periods of "incubation" existed between the time of inoculation of 3 of the filtrates (ARD, S–CC and CC) and the onset of symptoms in the recipients. (*2*) Symptoms of respiratory disease did not follow the inoculation of a control group of 9 men with autogenous filtrates, thus excluding mechanical irritation and the excitation of latent agents as an explanation of the results. (*3*) There were no consistent alterations in the bacterial flora of the throat at any time, before or after inoculation, in the individuals of any group either with or without illness. The development of streptococcal antistreptolysins was not demonstrable in convalescent phase sera. (*4*) Serological tests excluded the influenza viruses A and B as causative agents. The recognized clinical variability of influenza and its experimental incubation period of 6 to 48 hours (27 to 30) made these tests necessary. Heterophile agglutinins could not be demonstrated. Finally, (*5*) the results of these experiments differed in 2 respects from those in which primary atypical pneumonia was transmitted (18), namely, (*a*) pulmonary infiltration was not demonstrable roentgenographically in any patient and (*b*) the incubation periods were shorter. On these bases, therefore, it seemed reasonable to consider the 2 types of illness induced in the volunteers as separate and distinct virus diseases.

The nature of the infections resulting from the administration of S–CC and CC inocula suggested that a virus similar to, if not identical with, that of the "common cold" virus was operative. Previous transmission experiments in volunteers (31 to 35) and apes (33, 36, 37) have demonstrated a coryza-like illness of short incubation period (8 to 70 hours) following the inoculation of filtered respiratory tract washings obtained from individuals with the "common cold." The data obtained in the present study confirm and extend these observations.

The evidence derived from the administration of ARD inoculum suggested that this filtrate contained an agent which was distinct from that of the "common cold" virus. The sharp difference in incubation period and, clinically, the paucity of nasal symptoms and the prominence of throat symptoms early in the course of disease, were the chief differential features. While such results have not been noted in previous transmission experiments (33, 34), it is of interest that a clinical and epidemiological study of acute minor respiratory diseases by Van Volkenburgh and Frost (8) suggested a "real difference" between cases of "sore throat" and those of "coryza" and "cough," which was "in accordance with the prevailing view that a considerable proportion of the cases of sore throat ordinarily encountered are not related to the common cold."

The small number of infections with variable incubation periods resulting from the inoculation of Br–AP filtrate permitted no conclusions regarding the nature of the agent present in this inoculum. It was anticipated that this group of volunteers would develop moderately severe respiratory illnesses with a long incubation period (approximately 2 weeks), since the donor of the inoculum had a more severe form of respiratory disease which resembled primary atypical pneumonia. None of the recipients, however, developed an infection of comparable degree.

A feature of considerable interest in this study was the mild nature of the illnesses which followed the several types of inoculum. Objective signs of illness, such as fever, or constitutional symptoms were not uniformly observed in patients of the ARD, S–CC and Br–AP groups, as had been noted in the donors.

The explanation for the mildness of the illness is unknown. It seems possible that a combination of circumstances was responsible. On the basis of a history of previous respiratory disease, these individuals had apparently been susceptible to respiratory infections in their ordinary walks of life and presumably were susceptible at the time of inoculation. Several factors, however, may have been operative to increase their resistance. Although the men were isolated and restricted in activity, the living conditions were those generally considered to be favorable for good health, namely, adequate rest, good nutrition, absence of physical fatigue and over-exertion, etc. The investigations were purposely conducted during the summer months when respiratory infections in the general population are usually infrequent and uncompli-

cated. The environmental temperature was relatively constant, so that the potentially adverse effects of dermal chilling (38, 39) and of meteorological changes (40, 41) were avoided. The factor of dosage may have been of importance, but cannot be evaluated. Thus the possibility exists that some of the illnesses would have been more severe had the conditions of the study permitted more variation in the environmental and host factors.

SUMMARY

Minor respiratory illnesses were transmitted to human volunteers by the use of bacteria-free filtrates of pooled nasal and pharyngeal washings obtained from 4 single donors. Two of the donors had experienced coryza-like illnesses (S–CC and CC), 1 had had an infection with sore throat as a principal symptom (ARD), and the fourth suffered from a more severe form of illness (Br–AP) which clinically resembled primary atypical pneumonia. As a control group, 9 single donors were inoculated with autogenous filtered washings.

Two types of illness were induced; one was a coryzal-like infection developing after an interval of 24 to 48 hours and the other, an infection characterized by prominence of sore throat, minimal nasal symptoms and an incubation period of 5 to 6 days. These illnesses were clinically distinguishable. The control group which received autogenous filtrates experienced no illnesses. Primary atypical pneumonia did not develop in any of the subjects.

The results of these experiments indicate that at least 2 filtrable agents, presumably viruses, may induce minor respiratory illness in man.

EXPERIMENTAL TRANSMISSION OF MINOR RESPIRATORY ILLNESS TO HUMAN VOLUNTEERS BY FILTER-PASSING AGENTS. II. IMMUNITY ON REINOCULATION WITH AGENTS FROM THE TWO TYPES OF MINOR RESPIRATORY ILLNESS AND FROM PRIMARY ATYPICAL PNEUMONIA[1].

By THE COMMISSION ON ACUTE RESPIRATORY DISEASES[2]

(From the Respiratory Diseases Commission Laboratory, Regional Hospital, Fort Bragg, N. C.)[3]

(Received for publication March 3, 1947)

INTRODUCTION

In the previous paper (1) it was shown that minor respiratory illnesses were induced in volunteers by means of bacteria-free filtrates obtained from representative cases of acute respiratory disease. Two distinct types of minor respiratory illness resulted: one, a coryza-like infection with a short incubation period of 1 to 2 days (filtrates S–CC and CC); the other, an infection developing after 5 to 6 days and characterized by prominence of sore throat and minimal nasal symptoms (filtrate ARD). A control group of volunteers given autogenous filtrates remained well. None of the subjects developed primary atypical pneumonia following the inoculation of any of these filtrates.

The present paper reports the results of reinoculation of some of the subjects with agents from the 2 types of minor respiratory illness and from primary atypical pneumonia. These investigations were undertaken in order to determine whether or not immunity followed inoculation with the agents. It was found that homologous immunity was present in individuals who had experienced the "sore throat," long-incubation-period disease (filtrate ARD); little or no immunity was demonstrated in those who had had coryza-like illness of short incubation (filtrate S–CC). Cross immunity with either filtrate was not found. Primary atypical pneumonia was induced subsequently in these volunteers who had had prior exposure to ARD and S–CC filtrates.

MATERIALS AND METHODS

Subjects. The volunteer group consisted of 41 healthy adult white males. Of this number, 16 had participated in the previous study; the remaining 25 were replacements.

Isolation procedures. Isolation was continued without interruption in the group of 16 men who remained for the second half of the study. Isolation precautions for the group of incoming men were instituted as soon as practicable after arrival. Partitions in the hallways on the third floor of the hotel separated 20 of the "new" volunteers into 2 groups of 10 men each. Similar partitions on the second floor divided the remaining 21 into groups of 11 and 10 men, respectively. One of these groups consisted of 6 men previously inoculated and 5 replacements; the other consisted of 10 men who had had previous inoculations.

Inocula. The inocula consisted of the same bacteria-free filtrates ARD, S–CC and CC which were utilized in the first half of the study. In addition, a filtrate of respiratory secretions from a patient with primary atypical pneumonia was employed. The illness in this donor began on May 9, 1945, and was characteristic of a moderately severe infection. Constitutional symptoms, pro-

---

Titers of cold hemagglutinins in sera from donor of atypical pneumonia filtrate

Day of illness	Final dilution of serum			
	8	16	32	64
2	2*	±	0	0
9	4	1	1	0
15	2	0	0	0

* 0 = no visible agglutination.
± = doubtful agglutination.
1 to 4 = increasing degrees of agglutination.

ductive cough and substernal pain were prominent features. Pulmonary infiltration was present in the left and right lower lobes. The febrile course lasted 6 days. There was a slight rise and subsequent fall in the titer of cold hemagglutinins in 3' specimens of sera, examined simultaneously (Table I). Specimens of sputum and pharyngeal washings were collected during the febrile period, pooled, and a filtrate prepared. Aerobic and anaerobic cultures of filtrate were sterile.

Plan of study. Four experiments were performed over the course of approximately 7 weeks. Experiment I consisted of the reinoculation of 16 men who had participated in the previous study; 11 men were challenged with ARD or S–CC filtrate and 5 men, formerly inoculated with autogenous washings (Controls), were given filtrate S–CC. Experiment II consisted of the reinoculation of the above 11 men with heterologous filtrates, ARD and S–CC, respectively, and the inoculation of a control group of 5 "new" volunteers with filtrate ARD. Finally, the 21 men above were given filtrate obtained from a patient with primary atypical pneumonia (Experiment III). Additional studies were made in 2 groups of 10 men each who had formerly received filtrates CC and Br–AP (Experiment IV). These men were inoculated with coryza filtrate CC in order to test homologous immunity in one and heterologous immunity in the other.

Inoculation procedure. The technique of inoculation and the type of inoculation in general were the same as those employed in the first half of the study. When adequate amounts of filtrate were available the total inoculum was 10 ml.; this was given to each man in 3 equal doses on a single day. A reduction in total dosage to 6.6 ml. was necessary with one filtrate (ARD) and to 5.0 ml. in the case of another (S–CC). These were administered in 2 equal doses on a single day.

Clinical and laboratory studies. Each of the men was observed daily for the development of symptoms and signs of respiratory disease. The procedures employed have been described (1).

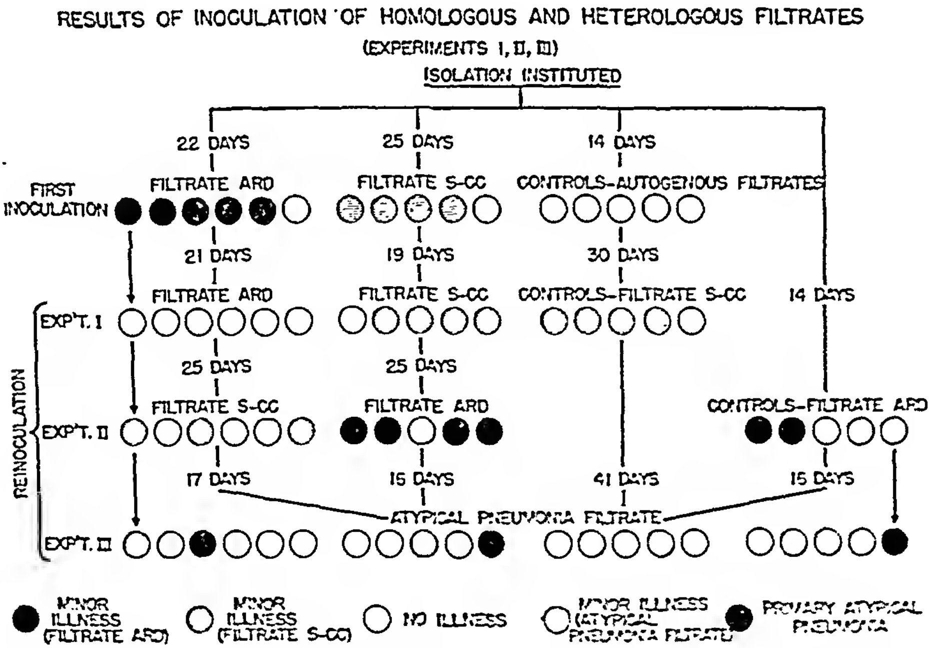

FIG. 1. THE RESULTS OF REINOCULATION OF HOMOLOGOUS (EXPERIMENT I) AND HETEROLOGOUS (EXPERIMENT II) FILTRATES AND OF CHALLENGE WITH ATYPICAL PNEUMONIA FILTRATE (EXPERIMENT III)

Each circle represents a volunteer and the varied shadings indicate the designated type of illness. The sequence of events for each man is indicated by a single vertical column of circles.

RESULTS

The effect of inoculation of homologous filtrate (Experiment I)

Approximately 3 weeks after initial inoculation with filtrates ARD and S–CC, 2 groups totaling 11 men, were challenged with homologous filtrates (Figure 1). Five of the 6 men originally exposed to ARD filtrate had experienced illnesses beginning 5 or 6 days after inoculation; 4 of 5 men given S–CC inoculum had developed characteristic coryzal illnesses after 1 to 2 days. At the same time a control group of 5 men, who had been inoculated 30 days previously with autogenous washings and had remained well, was given filtrate S–CC.

None of the 6 individuals receiving ARD filtrate a second time developed symptoms or signs of respiratory illness during the course of 25 days. In contrast, 4 of 5 men inoculated with homologous S–CC filtrate developed illnesses. Similarly, 4 of 5 men in the control group receiving S–CC filtrate developed illnesses.

The characteristics of the illnesses in these cases receiving S–CC filtrate were in general similar to those previously noted with this type of inoculum. Onset of symptoms occurred on the 1st or 2nd day in 7 of the 8 cases in both groups. Nasal symptoms and signs were the most characteristic features of the illnesses. In general, however, those who had experienced previous illness as a result of S–CC filtrate suffered from a somewhat milder infection upon reinoculation. This was evidenced principally by the short duration of symptoms which averaged 3 to 4 days.

Comment. The results of this experiment indicated immunity to homologous filtrate in subjects developing the "sore throat," long incubation period disease (ARD). Little or none was demonstrated in those experiencing coryza-like illnesses of short incubation (S–CC). The development of illness in the control group showed that filtrate S–CC, at least, was infectious in reduced dosage and still active after an additional month's storage. That filtrate ARD was also infectious at this time was indicated by a subsequent experiment, to be described below, in which illnesses were induced in another group of subjects.

The effect of inoculation of heterologous filtrate (Experiment II)

Twenty-five days after reinoculation of homologous filtrates ARD and S–CC, these 11 men were given heterologous filtrates (Figure 1). Six men, having received 2 inoculations with ARD filtrate, were given S–CC filtrate and 5 men, exposed twice to S–CC inoculum, were inoculated with ARD filtrate. A control group of 5 replacements also received ARD filtrate in order to test the activity of this material. The dosages employed were the same as in Experiment I; namely, 6.6 ml. of ARD filtrate and 5.0 ml. of S–CC filtrate.

As shown in Figure 1, 3 of 6 men given filtrate S–CC and 4 of 5 men inoculated with filtrate ARD developed respiratory illnesses. In the control group 2 of 5 men also became ill.

The types of illness occurring in this experiment were in general the same as those noted previously. The 3 individuals with illness who had been given filtrate S–CC developed onsets of disease on the 2nd and 3rd days after inoculation. Nasal symptoms and signs were prominent in each case. Fever, however, was not present. Those receiving filtrate ARD developed onsets as follows: 2nd day (1 case), 5th or 6th day (4 cases), 7th day (1 case). Symptoms and signs referable to the throat were characteristic. Three individuals displayed fever between the 8th and 10th days, varying between 99° and 100.8° F. One subject whose symptoms began on the 2nd day had fever beginning on the 4th day after inoculation. He was moderately ill over the course of 6 days, the maximum temperature reaching 100.8° F. Constitutional symptoms, sore throat, hoarseness, enlarged tender cervical lymph nodes and signs of pharyngeal inflammation were prominent features of illness.

Comment. The results of this experiment indicated a lack of immunity in subjects given heterologous filtrates ARD and S–CC. There was no indication that antecedent illness, brought about by one filtrate, modified the number or lessened the severity of illness which followed the administration of the heterologous material. Both types of infection, one with a short and the other with a long incubation period, were again induced in subjects even though the inoculum was reduced in amount and all of the individuals had at some

time previously experienced recent respiratory illness.

The effect of inoculation of filtrate from a case of primary atypical pneumonia (Experiment III)

The 21 volunteers who had participated in Experiments I and II were finally inoculated with filtrate obtained from a single donor early in the course of primary atypical pneumonia.

The experimental group was composed of the following: 6 men who had received filtrate ARD on 2 occasions and then filtrate S–CC; 5 men given filtrate S–CC twice and then filtrate ARD; and 2 groups of 5 men, each of whom had received filtrate ARD or S–CC on one occasion. The interval between the last inoculation was 16 or 17 days in 3 of the groups, and 41 days in the case of 1 of the former control groups. The total inoculum administered to each of the 21 men was 10 ml. No additional volunteers were available to serve as a control of this inoculum.

Three cases of atypical pneumonia and 1 of minor respiratory illness were observed (Figure 1). The remainder of the group, 17 individuals, failed to show evidence of respiratory infection. Two of the 3 cases of atypical pneumonia and the one instance of minor respiratory illness occurred in individuals who had experienced recent illnesses as a result of inoculation of both filtrates, ARD and S–CC. The remaining case, an individual with atypical pneumonia, had had no infection as a result of previous inoculation with filtrate ARD. No illnesses occurred in this experiment in any of the 5 men originally given autogenous washings and subsequently exposed to filtrate S–CC.

The 3 individuals with pneumonia had illnesses characteristic not only of the naturally acquired infection (2), but also of the experimentally induced disease (3). Onset of symptoms occurred on the 13th, 14th, and 15th days after inoculation, respectively. The illnesses were of mild severity; fever of 5 to 7 days' duration was present in each case. The maximum temperature in 1 individual was 102.4° F. Unilateral infiltration of one or the other lower lobes was observed in each case. No complications were noted; none of these patients developed cold hemagglutinins in their sera.

The patient with minor respiratory illness first developed symptoms on the 10th day after inoculation. His illness began with sore throat and slight nasal discharge. On the 15th day, headache, malaise, coryza, cough and substernal chest pain were noted. Physical examination revealed no significant abnormalities. Pulmonary infiltration was not detected. Significant fever was not present. The duration of symptoms was 9 days. The patient described this illness as a "chest cold" in contrast to the "head cold" he had experienced following the last inoculation (filtrate S–CC).

Comment. The results of this experiment demonstrate that previous minor respiratory illness did *not* give immunity to primary atypical pneumonia.

These results confirm previous observations that primary atypical pneumonia may be induced in volunteers by means of bacteria-free filtrates (3). In addition, they demonstrate that transmission of the disease may be accomplished with a filtrate obtained from a single donor as well as with the pooled filtrates from several donors. In previous studies, however, it was noted that approximately half of the volunteers developed minor illnesses after inoculation with pooled atypical pneumonia filtrate. Only 1 such illness developed in this experiment.

Additional studies on homologous and heterologous immunity (Experiment IV)

For further studies on the effect of reinoculation of CC filtrate, 20 additional volunteers were available. One group of 10 men had been inoculated with "coryza" filtrate CC; the other group of similar size had received filtrate Br–AP from a patient with respiratory disease termed "bronchitis resembling atypical pneumona" (2). The results of inoculation in the former group had shown 6 coryza-like illnesses with an incubation period of 1 to 4 days. Following the latter inoculation 4 illnesses of ill-defined nature had developed.

Approximately 3 weeks later both groups were reinoculated with 10 ml. of "coryza" filtrate CC. Thus, homologous immunity in one group and heterologous immunity in the other, were tested. The results are shown in Figure 2.

Four minor respiratory illnesses developed in men given the heterologous material and 3 in those who were challenged with the same filtrate (CC). Onset of symptoms in these 7 cases occurred on

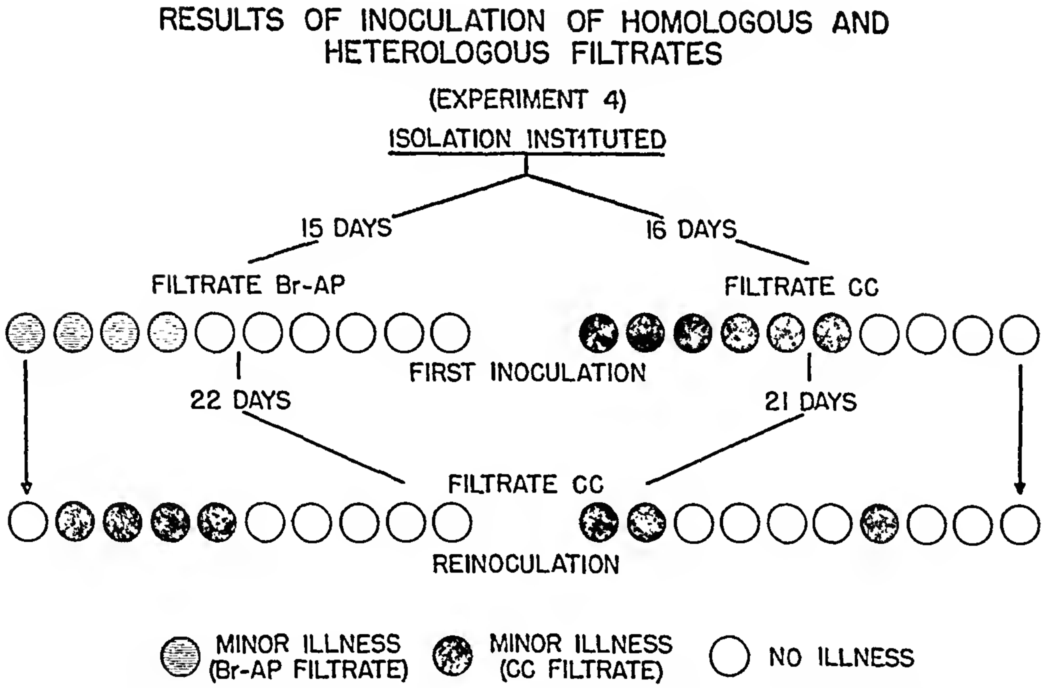

FIG. 2. THE RESULTS OF REINOCULATION, WITH "COMMON COLD" FILTRATE (CC), OF 2 GROUPS PREVIOUSLY EXPOSED EITHER TO THE HOMOLOGOUS FILTRATE (CC) OR TO HETEROLOGUS FILTRATE FROM A CASE TERMED "BRONCHITIS RESEMBLING ATYPICAL PNEUMONIA" (Br–AP)

the 1st and 2nd day in 5 cases and on the 9th day in 2 cases. Nasal symptoms and signs of variable intensity were found in all but 1 case. Cough was noted by 3 patients. Other symptoms noted infrequently were headache, malaise, sore throat and chest pain. The illnesses were afebrile and of 2 to 5 days' duration.

Comment. These results confirm the findings in Experiments I and II to a limited extent. Employing 1 type of "coryza" filtrate CC, subjects challenged with the same filtrate again developed characteristic illnesses. Other subjects previously inoculated with filtrate Br–AP developed illnesses when exposed to heterologous filtrate CC. Thus, little or no evidence of cross immunity was demonstrated. The explanation for the delayed incubation period of 9 days in 2 cases was not apparent.

Laboratory studies. Examination of the throat flora at 2-day intervals in all subjects failed to show any significant change as result of inoculation in the frequency of the pneumococcus, *Beta*-hemolytic streptococci, *Staphylococcus aureus, Hemophilus influenzae, H. hemolyticus, Klebsiella pneumoniae* and gram-negative cocci. Furthermore, the distribution of specific types of pneumococci and of *Beta*-hemolytic streptococci in volunteers, attendants and professional staff revealed no evidence of spread during the course of these experiments.

The total and differential leucocyte counts were within normal limits in all volunteers. No consistent alterations were evident in either type of examination as a result of any of the various types of inoculations. Similarly, the corrected erythrocyte sedimentation rates were normal in all subjects.

A rise in titer of cold hemagglutinins (4-fold increment) was found in the serum of but 1 individual (Table II). This volunteer, during the pre-inoculation control period, showed a cold hemagglutinin titer of 16. Following the administration of autogenous washings and of filtrate S–CC

*Results of cold hemagglutinin tests**

Experiment	Number of observations	Rise in cold hemagglutinin titer		
		4-fold	<4-fold	No rise
I	16	0	1	15
II	16	0	1	15
III	21	1	3	17
IV	20	0	1	19

* Based on weekly samples of serum obtained throughout the period of observation. Titer of the last serum specimen before each inoculation was considered the pre-inoculation titer.

the *maximum* titer on repeated occasions was 8. A titer of 32 was noted in the serum 14 days after inoculation of atypical pneumonia filtrate. He experienced no illness with the latter filtrate.

Appropriate sera from each individual were tested for antibodies against influenza viruses A and B and also streptolysin "O." In no instance was a diagnostic increase in titer observed.

DISCUSSION

The studies in human volunteers presented in this report and in the preceding paper (1) constituted an attempt to segregate "entities" in the group of unclassified respiratory diseases and to define more clearly the relation between minor respiratory illness and primary atypical pneumonia. These objectives were partially achieved. Two types of minor respiratory illness were induced which appeared to be distinct entities having no demonstrable immunological relationship. The inocula giving these 2 types of minor illness did not induce primary atypical pneumonia, nor did they prevent the subsequent development of primary atypical pneumonia. It would thus appear that 3 separate entities have been dealt with in these experiments. Limitations of the data, however, prohibit the conclusion that the agent of primary atypical pneumonia is not associated with minor respiratory illness. The results will be considered further under the following headings: Minor respiratory illness induced by the ARD filtrate, minor respiratory illness induced by the CC filtrate, and the relation of minor respiratory illness and primary atypical pneumonia.

Minor respiratory illness induced by the ARD filtrate. Minor respiratory illness, characterized predominantly by sore throat and an incubation period of from 5 to 6 days, was induced with the ARD filtrate. The inoculation of the same filtrate 21 days later demonstrated an apparently solid immunity. This conclusion appears to be valid since the challenge filtrate produced illness in a control group of "new" men inoculated at a later date; and because there seems to be no reason to assume the existence of a refractory state, such as that observed in the ferret by Stuart-Harris and Francis (4), or the operation of the interference phenomenon (5). Moreover, these subjects were susceptible to S–CC filtrate 25 days after they had been challenged with the ARD filtrate (46 days after their initial inoculation).

The minor respiratory illnesses induced by the ARD filtrate, after an incubation of 5 to 6 days, appear to constitute a new entity which has not been described previously in transmission experiments. It seems possible that this entity, despite its mild nature in the recipients (1), is the same as that observed in recruits and termed "undifferentiated acute respiratory disease" (ARD). Clinical studies of these illnesses in recruits have shown them to be primarily noncoryzal respiratory infections (6). The illnesses likewise may be similar to those termed cases of "sore throat" by Van Volkenburgh and Frost (7) in their studies in a civilian population. Epidemiological observations have not defined the incubation period but have suggested the development of immunity as indicated by the absence of epidemics of ARD in seasoned troops as contrasted with recruits (8). Finally, the washings used in these experiments were obtained from a recruit whose illness was considered clinically to be typical of ARD.

Minor respiratory illness induced by CC filtrates. The minor respiratory illnesses induced by filtered washings from 2 cases, referred to here as "common cold," were characterized by predominance of coryza and an incubation period of 1 to 2 days. No appreciable homologous immunity could be demonstrated in the S–CC and CC groups following inoculation with the respective filtrates at intervals of 19 days (S–CC) and 21 days (CC). Heterologous immunity to the ARD filtrate was not demonstrated. The control experiments, in which autogenous filtrates were employed, indicate that these results were not due to mechanical irritation of the respiratory passages or the result of stimulation of a latent agent already present in the respiratory tract.

Minor respiratory illnesses produced by these CC filtrates appear to be similar to, if not identical with, the illnesses transmitted by Kruse (9), Foster (10), Dochez *et al* (11), and Long *et al* (12), and termed by them the "common cold." The failure to demonstrate immunity to the CC filtrate in the present experiments is contrary to the opinion generally held that such minor infections have an immunity of approximately 3 or 4 months. They

are in accord, however, with findings in the Abel Fund Studies (13). Previous investigators did not attempt transmission experiments during the 3 or 4 months following a cold or an experimentally induced infection.

The frequency with which this minor respiratory illness, which resembles the "common cold," occurs in recruits and seasoned troops has not been adequately determined. It is possible, however, that this disease is similar to the minor illnesses observed in field surveys and in dispensaries during the summer and fall months.

Relation of minor respiratory illness and primary atypical pneumonia. Clinical and epidemiological studies of sporadic and epidemic primary atypical pneumonia have shown, in many instances, an apparent association between this disease and minor respiratory illnesses (2, 3, 14 to 17). These findings have led to the hypothesis that the same agent produces both types of infection and that primary atypical pneumonia may actually be an infrequent manifestation of pulmonary involvement in a prevalent minor respiratory disease. Such a theory seems reasonable and is not novel, since it is in accord with the behavior of such known agents as influenza virus A, the meningococcus, etc. This interpretation may likewise be placed on the demonstration, in 1944, that minor respiratory illnesses and primary atypical pneumonia were induced in 50 per cent and 25 per cent, respectively, of a group of volunteers inoculated with pooled filtered secretions of the respiratory tracts of 6 patients with primary atypical pneumonia (3).

The above evidence alone is not sufficient to prove the hypothesis, however, because the presence of only one agent cannot be established. Moreover, minor respiratory illnesses have been infrequent or absent in some outbreaks of primary atypical pneumonia (18, 19) and have varied in their relative sporadic frequency (20). It is therefore possible that more than 1 agent may cause both sporadic and epidemic primary atypical pneumonia and minor respiratory illness. In support of this assumption may be the occurrence of cold hemagglutinins in some but not all cases of primary atypical pneumonia (21–24).

In the present study, further evidence was sought in 2 ways, (*a*) by an attempt to produce primary atypical pneumonia with washings from each of 2 cases (ARD and Br–AP) considered clinically and epidemiologically to be most closely related to that disease, as well as from 2 unrelated cases (S–CC and CC); and (*b*) by an attempt to demonstrate the presence or absence of immunity to primary atypical pneumonia in individuals who had previously been infected with ARD and S–CC filtrates.

Primary atypical pneumonia was not induced by the administration of inocula from any of the 4 cases, nor did previous inoculation with the ARD and S–CC filtrates prevent the subsequent development of the disease. Moreover, the incubation periods of the minor respiratory illnesses which did follow the initial inoculations—approximately 5 to 6 days with the ARD filtrate and approximately 1 to 3 days with the S–CC, CC and Br–AP filtrates—were much shorter than that found with the AP filtrates; that is, approximately 14 days (3).

It is difficult to interpret the occurrence of only one case of minor respiratory illness following the challenge inoculation of filtrate from a single case of primary atypical pneumonia (Figure 1) because previously uninoculated control subjects were not available. The absence of minor respiratory illnesses was in definite contrast to the results obtained in 1944 when pooled filtrates from 6 donors were employed (3). Theoretical explanations based on the assumption of the presence of 2 agents in the 1944 filtrates, or partial immunity induced by the ARD and S–CC inocula, do not appear to be adequate because of the absence of mild illnesses in the S–CC control group (Figure 1). One possibility appears to be that the agents producing primary atypical pneumonia in the 1944 and 1945 experiments were different. In support of this assumption may be the consistent occurrence of cold hemagglutinins in the experimental cases of primary atypical pneumonia in 1944 and their absence in the 3 cases induced in the present study. Further investigations of this aspect of the problem are needed before a final conclusion can be reached.

SUMMARY

Experiments were undertaken in order to determine the effects of reinoculation of bacteria-free filtrates obtained from representative donors

with acute respiratory disease. Homologous and heterologous immunity was tested. In addition, immunity to primary atypical pneumonia was assessed in subjects who were previously exposed to these filtrates and who contracted minor respiratory illness.

Immunity to reinoculation was found in individuals receiving filtrate ARD which induced minor illness of relatively long incubation period (5 to 6 days). Little or none was found in subjects challenged with filtrate S–CC inducing a coryza-like illness of short incubation (1 to 2 days). Cross-immunity was not demonstrable with either filtrate.

Primary atypical pneumonia developed in 3 volunteers following the inoculation of filtrate from a single donor who had atypical pneumonia. Each of these 3 patients had had 1 or more previous inoculations with ARD or S–CC filtrates; 2 had experienced recent minor respiratory illnesses.

The results of this study provide additional proof that at least 2 filtrable agents, or viruses, may induce minor respiratory illness in man and suggest that these agents are probably distinct from the virus or viruses of primary atypical pneumonia.

ACKNOWLEDGMENTS

The Commission is indebted to the Administrative Staffs of Selective Service, Camp Operatives Division, and to the Mennonite Central Committee, the Brethren Service Committee and the National Service Board for Religious Objectors for the cooperation which made these studies possible.

The Commission takes pleasure in acknowledging the assistance of Brigadier General H. C. Coburn, Jr., M.C., Colonel R. T. Arnest, M.C., Colonel J. N. Williams, M.C., Lt. Colonel H. C. Brownley, M.C., Lt. Colonel J. M. Kinsman, M.C., Lt. Colonel F. K. Herpel, M.C., Lt. Colonel A. Blumberg, M.C., Captain M. Cohen, M.C., and Captain P. T. Myers, M.C.

The technical staff of the laboratory rendered invaluable assistance: Cpl. Alexander Adler, T/4 A. P. Aan, T/Sgt. L. P. Codifer, S/Sgt. G. M. England, Sgt. D. G. Foltz, T/Sgt. N. Gallenson, T/Sgt. E. Gold, S/Sgt. E. F. Hoffman, S/Sgt. M. H. Kaplan, T/4 G. J. Leuty, Mrs. Dorothy C. Mickle, 1st Lt. W. A. Mickle, Jr., Barbara A. Mulliken, Jessie P. Neeley, 1st Lt. T. J. Oliver, 1st Lt. R. L. Robinson, Irene Salamandra and S/Sgt. W. W. Skatrud. Without the efficient services of 1st Lt. Clara B. Kwash, A.N.C., 1st Lt. Mary McCoy, A.N.C., and Captain Aaron Ignatow, M.A.C., these investigations would have been considerably restricted. Special thanks are due Mr. Don Jones who acted as Assistant Director of the Civilian Public Service Unit throughout the course of these experiments. Messrs. L. Allen, R. Catlett, A. P. Gault, J. Hostetler, A. K. Landis, K. E. Matthies, M. D. Reimer, M. H. Schroeder, M. Siemens and D. Wenger voluntarily served as attendants.

Finally, the members of the Commission wish to express their appreciation to the volunteers themselves, without whom these experiments would have been impossible.

THE ESTIMATION OF SERUM SODIUM FROM BICARBONATE PLUS CHLORIDE [1]

By P. M. HALD, A. J. HEINSEN, and J. P. PETERS

(From the Department of Internal Medicine, Yale University School of Medicine, New Haven)

(Received for publication March 5, 1947)

Since the body fluids are nearly neutral and since they contain no appreciable quantities of organic bases, the concentration of cations in these fluids must be equal to the concentration of the inorganic cations found in them, [Na] + [K] + [Ca] + [Mg]. This, in turn, must be equal to the total concentration of anions. The distribution of water between cells and extracellular fluids in the body appears to be governed mainly by the concentration in the extracellular fluids of sodium, the principal one of those osmotically active components which are restrained from crossing the cellular membranes. In addition, sodium constitutes the chief cation of the extracellular fluids. In normal serum it makes up more than 90 per cent of the total concentration of cations. Although the concentrations of the other cations profoundly influence physiological processes, they are so small and vary so little that their effects on osmotic and cation-anion equilibria are trifling. The concentration of sodium is, therefore, the best single criterion of the electrolyte osmotic pressure and the concentration of cations in the serum and extracellular fluids. The measurement of sodium has, however, been so laborious and time-consuming that it has been less useful for clinical than for investigative purposes.

In lieu of direct measurement the concentration of sodium has usually been estimated from the combined concentrations of bicarbonate and chloride. In normal subjects these 2 ions together make up from 85 to 90 per cent of the anions of serum, falling only a little short of equaling sodium. The remainder of the anion column is composed chiefly of protein, with an inconsiderable amount of inorganic phosphate, an almost negligible quantity of sulfate and a small and variable contribution of organic acids. While important variations of the concentrations of cations manifest themselves consistently in the concentration of sodium, variations of the anions are not so consistently evidenced in the concentrations of HCO_3 + Cl. If some other foreign or endogenous anion accumulates in the serum it will displace bicarbonate. In this case [Na] will exceed [HCO_3] + [Cl] by more than the usual quantity and can be estimated only by the aid of inference.

The object of this paper is to examine the accuracy of such inferences. With the flame photometer it will become possible to measure the sodium of serum with sufficient speed and facility to make this measurement clinically available. It is therefore relevant to ascertain the indications for such measurements and the advantages and disadvantages they have in comparison with measurements of [HCO_3] + [Cl] and other combinations of procedures. For routine purposes some selection is desirable for economy of time, facilities, and blood.

MATERIAL

The material on which this analysis is based consists of 205 measurements of sodium, chloride, and CO_2 of serum from 28 normal adults and 63 patients with a variety of diseases, made for various reasons during the years 1932 to 1947. In many instances other analyses were made. The subjects for clinical observation were not selected at random, but usually because some abnormality of sodium or of the relation between sodium and chloride + bicarbonate was suspected.

All normals and most patients were studied in the postabsorptive state before breakfast. Exceptions to this rule were made in emergencies; but in such instances the patients were almost invariably fasting.

METHODS

Blood was drawn and serum was separated and preserved with anaerobic precautions. Chloride was measured by Eisenman's adaptation of the method of Austin and Van Slyke (1) or by Hald's modification of Patterson's micromethod (1); carbon dioxide was measured by the technique of Van Slyke and Neill (1), with the constant volume apparatus. Analyses for sodium were done by the gravimetric method of Hald (2) or by means of the flame photometer (3), or both.

[1] This investigation was aided by a grant from the Fluid Research Funds of the Yale University School of Medicine.

CALCULATIONS

Values for sodium, chloride, bicarbonate and other electrolytic components are given in terms of combining equivalents. Actually the figures for bicarbonate do not represent bicarbonate, since the CO_2 tension of the blood was not determined. They represent total CO_2 minus the CO_2 that would be held in solution and as H_2CO_3 in the serum at 37.5° C. and a pH of 7.35.[2] Since the clinical

[2] For this calculation the value of 6.10 was used for pK_1'; (4).

* One subject was omitted because his [Na] and Δ differed consistently from the mean by more than 3 times the standard deviation.

† One subject was omitted because her [Cl] and Σ differed consistently from the mean by more than 3 times the standard deviation.

material was extremely heterogeneous pH must have varied widely. If it be assumed that it varied from 7.0 to 7.8, the error of assuming a pH of 7.35 would amount to ± 7 per cent of the bicarbonate value. In a serum with a normal bicarbonate concentration of 27 milliequivalents per liter this would be about 2 milliequivalents.

In the text and tables concentrations of Na, Cl and HCO_3, in meq. per liter, are represented with brackets, [Na], [Cl], [HCO_3]. The sum, [HCO_3] + [Cl], is represented by the symbol Σ, the difference, [Na] − ([HCO_3] + [Cl]), by the Symbol Δ.

RESULTS

In Table I the data are presented in summary to indicate the degree of variability of each function in normal individuals and in various types of disease. There is, as has been noted before (4, 5), a statistically significant difference between normal males and females with respect to both [HCO_3] and [Cl]. The former is about 2.5 meq. per liter lower, while [Cl] is about 2.5 meq. higher in females. Because these differences are reciprocally related, Σ is the same for the 2 sexes. In this series the mean [Na] is 2.5 meq. higher in males, but this is not statistically significant. One male and one female, though presumably normal, were omitted from the statistical calculations because their electrolytes departed in certain particulars widely from the means. If they had been included the means would have been only slightly altered, while the differences between the sexes would have been exaggerated. In each sex [Cl] varies less than any other function; but, because of the difference between the sexes, varies more than Σ does in males and females together. Relatively [HCO_3] varies most, but in actual milliequivalents variations of [Na] are almost twice as great. Beyond the reciprocal relation between [HCO_3] and [Cl] in the 2 sexes, no significant correlation can be found between any 2 functions in either or both sexes. Even [HCO_3] and [Cl] bear no significant relation to one another in either males or females. The cause of the variations of Δ is, therefore, not clear from these data. The mean value of Δ in these normal subjects is about 5 meq. per liter, with all but 2 of the observations falling between 0 and 8.5. In normal persons under standard postabsorptive conditions, therefore, [Na] can be predicted from Σ with an error that seldom exceeds 5 meq. per liter.

In pathological conditions this prediction is far less accurate. In 170 observations Δ exceeded 11 meq., its maximum value in normal subjects, 97 times. In 47 instances, or 28 per cent of the observations in disease, Δ exceeded 16 meq. per liter. These figures have no statistical significance since the data were obtained from patients selected, in the main, because some abnormality of serum electrolytes was suspected. They will serve the present purpose, however, because it is in just such cases that knowledge of [Na] is desirable. If it is assumed that the mean value of [Na] is Σ + 5 meq., the concentration of [Na] would have been underestimated by more than 10 meq. in 28 per cent of the pathological subjects of this series.

DISCUSSION

It remains to examine the causes of large values of Δ and to learn whether their presence and magnitude could be inferred from clinical phenomena. The subject can be approached best through an analysis of the separate categories of disease. Although the patients with Addison's disease were studied under a great variety of conditions, as is evident from the wide variations of [Na], [HCO_3] and [Cl], Δ exceeded 11 meq. in 9 of the 37 observations and was slightly greater than 16 meq. once. In this disorder, therefore, Σ gives a reliable estimate of [Na]. Reductions of either [HCO_3] or [Cl] are referable almost entirely to depletion of [Na]. Only in the most critical states is there any appreciable accumulation in the serum of inorganic phosphate or other anions. The one high figure for Δ, 18.2 meq., in this series was found in a young adult male with implants of pellets of desoxycorticosterone. The observation was made immediately after admission. The patient had suffered from diarrhea and vomiting, he was in a state of collapse, and had been anuric for 24 hours. In addition he was cyanotic and had physical signs and x-ray evidence of bronchopneumonia and atelectasis, confirmed at a subsequent autopsy. [Na], [Cl] and [HCO_3] were, respectively, 141.0, 104.7 and 18.1 meq. per liter. Presumably anuria, circulatory collapse and the pulmonary disease prevented him from compensating more adequately for a starvation ketosis. Although the electrolyte pattern of his serum was rapidly restored to normal by the administration of fluids and measures di-

rected to the support of his circulation, he died 4 days later.

The patients with pulmonary disease fall into 2 categories. In the first are subjects with tuberculosis who resemble patients with Addison's disease in their tendency to waste sodium in the urine (6). In only one of these did Δ exceed 11.0 meq. and then only by 0.2 meq. per liter. In the second category are patients with disorders of the respiratory system, such as asthma, which interfere with the discharge of CO_2. This leads to elevation of $[HCO_3]$ with a compensatory depression of [Cl]. In 2 cases of this type Δ exceeded 16 meq., being 20.1 in both. Both patients were intensely cyanotic; the blood nonprotein nitrogen of one was 49 mgm. per cent. Presumably lactic acid, and possibly other organic acids, were responsible for the high concentrations of organic acid. Such acids would ordinarily displace bicarbonate; but the respiratory disability in these cases prohibited compensation by this reaction. Instead bicarbonate was elevated, in 1 patient on 1 occasion to 56.0 meq. per liter.

The high frequency of excessive values of Δ in diabetic patients is to be expected. The acids are probably in most instances ketone bodies. It may be seen from Figure 1 that there is a fair inverse correlation between Δ and $[HCO_3]$. When the quantity of acid in the circulation increases, 2 reactions are called into play: (*1*) the acids are excreted in the urine; (*2*) bicarbonate is displaced by the acid, while the CO_2 thus released is excreted by the respiratory system. The relative amounts of sodium balanced by bicarbonate and by other acids, then, depend on the efficiency of these 2 processes. If the eliminative mechanisms are operating effectively, there should be some degree of inverse correlation between $[HCO_3]$ and Δ. Such a correlation is evident in the observations from diabetic patients.

In patients with renal disease, high values of Δ coincided regularly with gross nitrogen retention. Usually $[HCO_3]$ was coincidently reduced. These bicarbonate deficits have been attributed to the accumulations in the serum of inorganic phosphate and sulfate, but these were not large enough to

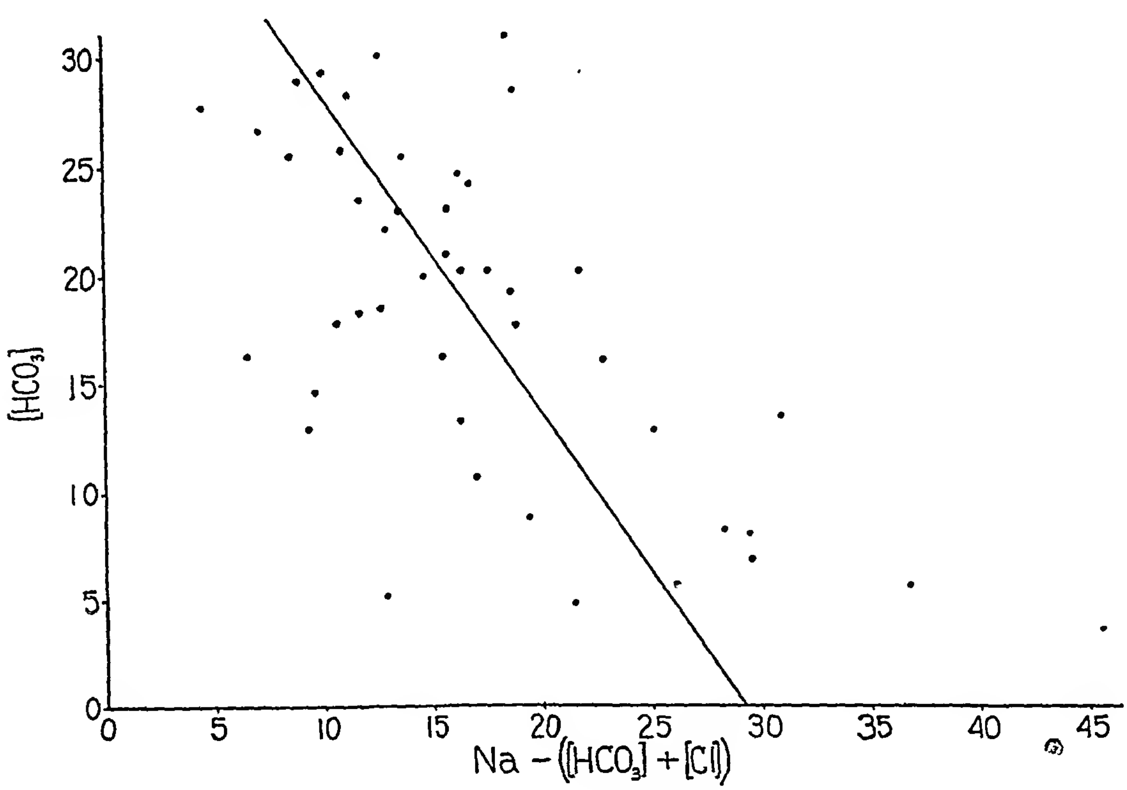

FIG. 1. THE RELATION OF BICARBONATE TO UNDETERMINED ACIDS IN DIABETIC PATIENTS

Values are expressed in milliequivalents per liter. The diagonal line is defined by the equation, $29.31 - 0.685\ [HCO_3] = \Delta$.

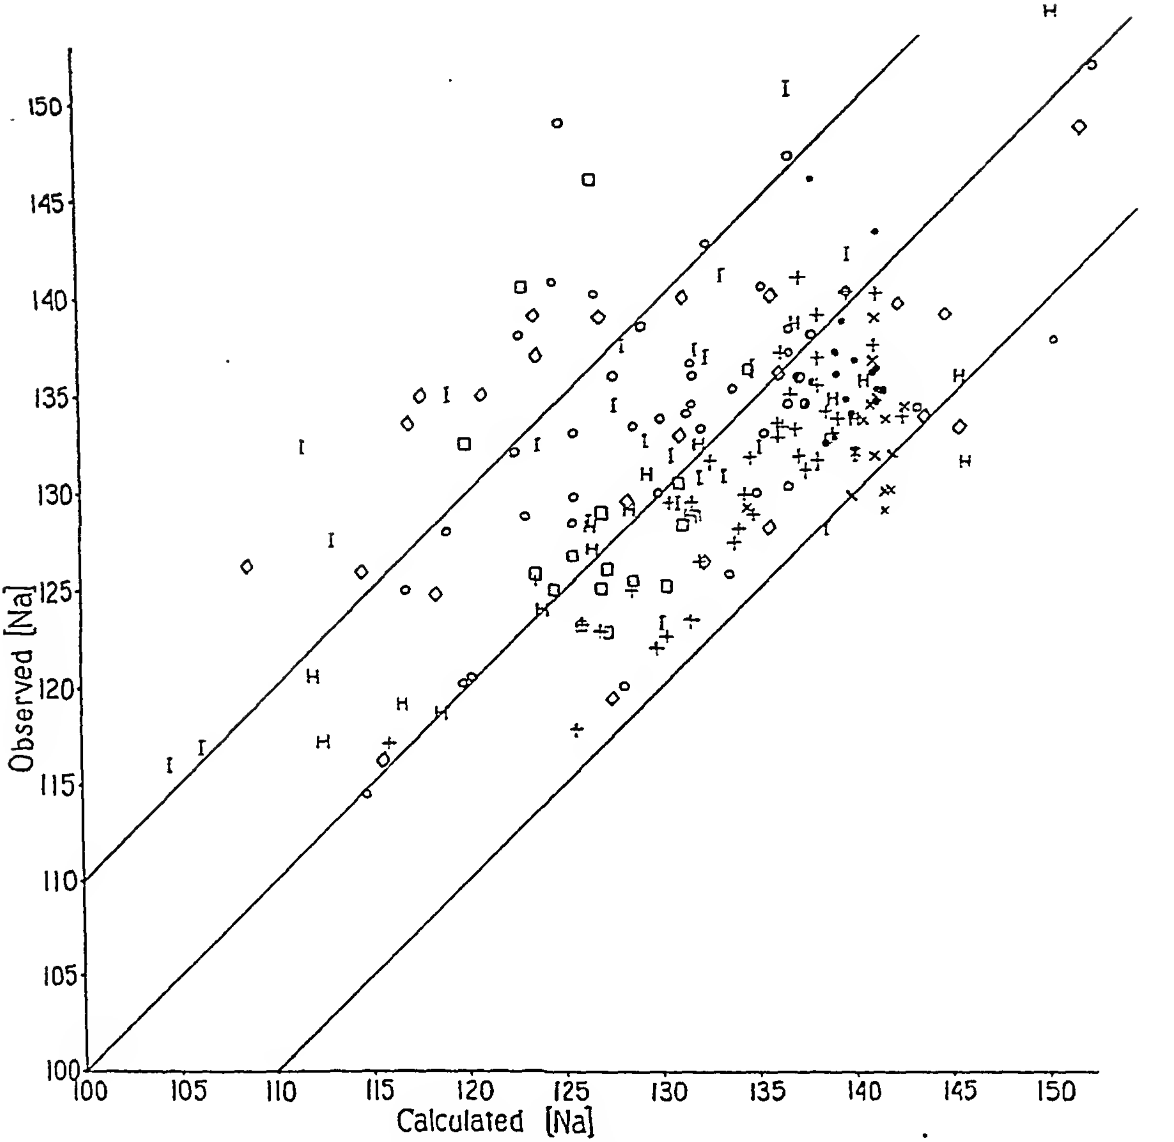

FIG. 2. OBSERVED VALUES OF SERUM [Na] IN MILLIEQUIVALENTS PER LITER COMPARED WITH VALUES CALCULATED BY THE EQUATION,

$$[Cl] + [HCO_3] + 23.2 - 0.50\ [HCO_3] = [Na]$$

The middle diagonal line represents perfect agreement; the 2 lines paralleling it delimit a zone of ± 10 meq. per liter. The point H in the upper right-hand corner should actually be defined by observed [Na] = 167.6, calculated [Na] = 164.4. O = normal male, × = normal female, + = Addison's disease, □ = pulmonary disease, ○ = diabetes mellitus, ◇ = renal disease, H = mercury poisoning, I = miscellaneous disease.

explain both the bicarbonate deficits and the excesses of undetermined acids, which often amounted to 30 meq. per liter or more. Chloride was also reduced in many instances and sodium was seldom elevated. That the high Δ's in renal disease were not referable to impaired renal function alone is suggested by comparison with mercury poisoning. In this condition, in spite of oliguria and high blood nonprotein nitrogen, Δ was usually quite moderate.

The miscellaneous series includes such heterogeneous cases that their analysis as a group cannot be profitable.

The mean line describing the relation of $[HCO_3]$ to Δ in patients with diabetes is defined by the equation, $29.31 - 0.685[HCO_3] = \Delta$, [illegible]

6.61. From Figure 1 it is evident that the distribution of points about this line is somewhat asymmetrical. At high concentrations of $[HCO_3]$ Δ exceeds expectations. When the same line was tested on all observations it did not describe a general relation between abnormal accumulations of anions and $[HCO_3]$. A similar line was, therefore, constructed from all observations. This line is defined by the equation, $23.2 - 0.50[HCO_3] = \Delta$, s.d. $= \pm 7.09$ meq. per liter. With the aid of this relation [Na] can be calculated from $[HCO_3]$ and [Cl] by the equation, $[Cl] + 23.2 + 0.50 [HCO_3] = [Na]$, within $\pm$ 10 meq. per liter in 86 per cent and within $\pm$ 15 meq. in 95 per cent of all observations. The relation between observed and calculated [Na] is shown in Figure 2. Although observed values of Δ are almost always positive, values estimated by the formula are both positive and negative. Some consistent trends are also noticeable. For example, calculated values of [Na] in normal subjects are, with 2 exceptions, greater than observed values. The 2 exceptions are in males. The difference is greater in females than in males. It may be that the line describing the relation of Δ to $[HCO_3]$ is distorted by certain characteristics of one or more pathological groups or that this relationship is actually curvilinear.

Data on the subjects in which the calculated and observed values of [Na] differed from one another by more than 10 meq. per liter are presented in Table II. On 2 occasions in 1 female differences of − 12.4 and − 11.4 meq. were observed, on 3 other occasions the differences in the same subject were − 9.9, −9.9., and − 9.7 meq. per liter (the difference is given the negative sign when the calculated value is greater than the observed value). The observed Δ in the same sera varied from − 1.3 to 3.6. Another of the normal women had a difference of − 11.6 meq. with an observed Δ of 0.4 meq. per liter. These large negative differences were associated with high normal values of [Cl] (106.0 to 106.8 meq. per liter). One other normal female with a [Cl] of 106.8 meq. per liter had a difference of − 8.6 meq. Among the women there is a tendency, not apparent in the men, for the negative error to vary with [Cl], which is consistently greater in females than in males. In the pathological series, calculated [Na] exceeded observed [Na] by more than 10 meq. per liter 4 times, always when [Cl] was greater than 110.0 meq. per liter. In only 1 observation out of 7 in which [Cl] exceeded 110.0 meq. per liter was observed [Na] greater than calculated [Na]. In this case, a diabetic in acidosis, when [Cl] was 122.2 meq. per liter, the difference was 13.3 meq. (observed Δ 1.3 meq.). The observed [Na] on

this occasion was 151.6 meq. per liter. In all other instances high [Cl] was associated with a normal [Na]. It therefore appears that when [Cl] exceeds 110.0 meq. per liter the prediction equation usually overestimates [Na]. If [HCO_3] is depressed by hyperchloremia there is no reason why Δ should be increased. Since the prediction equation is based on the assumption that any depression of [HCO_3] is referable to an increase in the serum of the concentration of anions other than [Cl], it follows that when [HCO_3] is depressed by [Cl] itself the equation will yield too high a value for [Na].

Calculated [Na] was lower than observed [Na] by more than 10 meq. per liter in 2 patients with pulmonary disease. Both had asthma, emphysema, and heart failure. Among the nephritics also, only those with heart failure and pulmonary congestion had large positive differences. This affords an explanation for the absence of such errors in the patients with mercury poisoning, who had no respiratory impairment. Observed [Na] exceeded calculated [Na] by more than 10 meq. in 4 patients with miscellaneous diseases. The first of these, who had encephalitis, at the time of the examination was stuporous, cyanotic, and breathing stertorously. His [HCO_3] was high, [Cl] greatly reduced, with [Na] normal. It may be inferred that he had a primary CO_2 excess. The second case, A78642, besides diabetic acidosis had pyloric obstruction. He was extremely dehydrated and in a state of circulatory collapse. B86345, with a broken neck, had retention of urine and circulatory failure. He was deeply cyanotic, his lungs full of bubbling rales. In all these cases, therefore, a large positive difference was associated with impairment of the respiratory system which interfered with the elimination of CO_2. Invariably [Cl] was reduced; presumably, it was taking over the function of [HCO_3] in making room for the extra load of anions. The latter was also often diminished, especially in the patients with renal disease, but less than it would have been had the respiratory exchange been unimpaired. Consequently the usual inverse proportionality between [HCO_3] and Δ was not maintained. Respiratory insufficiency in these cases was not absolute, but relative.

The last patient, A60444, was in an active stage of familial periodic palsy with a serum potassium of 1.7 meq. per liter. Whether this interfered with his respiratory exchange, it is impossible to say because the analysis was made for routine diagnostic purposes and associated disturbances of his vital signs were not noted.

Of the diabetic cases, 90339 with high [Cl] has already been mentioned among those who had negative differences with hyperchloremia. In the remaining 4 observed [Na] exceeded calculated [Na] by 14 to 24 meq. per liter. Two of these patients, 60404 and 42994, had extreme acidosis and dehydration. It may be that the respiratory system had to assume more than its usual share of the burden because the kidneys were unable under these circumstances to work efficiently. On the other hand, it may be, as was suggested above, that the relation of [HCO_3] to Δ is actually curvilinear. At normal [HCO_3] the prediction equation seemed to exaggerate [Na]; at extremely low [HCO_3] it may yield values that are too low. Errors of this nature and magnitude in extreme diabetic acidosis would not, however, lead to improper impressions or therapy. The other 2 patients had frank evidences of heart failure; in B31839 this was complicated by bronchiectasis, asthma, and emphysema.

It appears, therefore, to be possible to estimate serum [Na] within $\pm$10 meq. per liter from [HCO_3] + [Cl] with the aid of clinical observation. In such estimations account must be taken of the fact that as anions other than [HCO_3] and [Cl] accumulate in the serum Δ increases in inverse proportion to the depression of [HCO_3]. A prediction formula has been devised by which these increases of Δ may be calculated from [HCO_3]. In at least 2 conditions this formula fails. If [HCO_3] is displaced by [Cl] it yields excessively high calculated values for [Na]; if the respiratory elimination of CO_2 is impaired it yields erroneously low values.

There can be no doubt that direct measurement of [Na] will give more precise information; but no other combination of any 2 of the 3 variables, [Na], [HCO_3] and [Cl], will be as serviceable as [HCO_3] + [Cl]. The combination of [Na] and [HCO_3] would obviously be most inadequate because the difference between these 2 would include the largest anion fraction, [Cl], as well as Δ. In diabetic acidosis and other conditions, such as exercise or anoxemia, in which Δ is composed of combustible organic anions, measurements of [Na] and [Cl] would give useful information. In these

conditions it could be assumed that the whole difference, [Na] − [Cl], was potentially bicarbonate, since the sodium liberated by the combustion of these foreign acids would form bicarbonate with CO_2. In renal insufficiency, however, when phosphate and sulfate accumulate in the serum, [Na] − [Cl] would have an altogether different significance and would give imperfect information.

SUMMARY

A prediction formula has been devised by which the concentration of sodium in blood serum may be estimated within ± 10 meq. per liter from the concentrations of CO_2 and chloride. Two conditions have been found in which this formula is inapplicable. In hyperchloremia it yields erroneously high values; when the respiratory elimination of CO_2 is impaired it yields erroneously low values. Since these sources of error are readily detectable they do not detract greatly from the value of the formula.

THE TRANSPORT AND EXCRETION OF URIC ACID IN MAN. I. TRUE URIC ACID IN NORMAL CEREBROSPINAL FLUID, IN PLASMA, AND IN ULTRAFILTRATES OF PLASMA

By W. Q. WOLFSON, R. LEVINE, AND M. TINSLEY

(From the Department of Metabolism and Endocrinology[1] *and the Department of Neurology, Michael Reese Hospital, Chicago, Illinois)*

(Received for publication March 7, 1947)

Human cerebrospinal fluid has been reported to contain a relatively small concentration of uric acid compared to that of plasma (*cf.* Table II). However, it is not known what proportion of these reported uric acid values is due to chromogenic substances similar to those giving the color reaction for uric acid in plasma (1). The introduction of enzymatic methods for determining uric acid specifically (2 to 5) has made reexamination of spinal fluid values advisable, particularly with regard to their relation to plasma ultrafiltrates.

SUBJECTS

Cerebrospinal fluids[2] were obtained by lumbar puncture from individuals suspected of neurosyphilis and from others undergoing routine follow-up after antiluetic therapy. Those fluids which were serologically and Pandy negative were combined into 10-ml. pools, each pool representing 5 individuals. Total protein was then determined on each pool and those with a content of less than 35 mgm. per 100 ml. were considered satisfactory for study.

Ventricular fluids were obtained during diagnostic ventriculography on neurological patients without mass lesions or inflammatory intracranial disease.

Plasma for ultrafiltration was obtained from 2 normal subjects on diets of varying purine content. The results quoted in the text are the average of 8 determinations on one subject and 5 on the second.

METHODS

Uric acid was determined in plasma, plasma ultrafiltrates, and in cerebrospinal fluid by a modification of the method of Buchanan, Block and Christman (2) for the Evelyn photoelectric colorimeter.

The essentials of this determination and the terms used in reporting results are as follows:

1. A 1-ml. aliquot of the specimen is deproteinated and the color developed with the arsenophosphotungstic acid and urea-cyanide reagents. The concentration of uric acid equivalent to the color developed is termed *total urate*.
2. Another (2-ml.) aliquot of the specimen is treated with uricase at pH 9.1 to destroy the uric acid present. It is then treated as above, the color developed being termed *chromogen*.
3. The difference between the values for total urate and for chromogen represents the amount of uric acid destroyed by the specific enzyme and is therefore termed *true urate*.

The actual size of the aliquots given in the preceding paragraph is that used in plasma determinations; cerebrospinal fluid contains so little urate that it is advisable to use twice or 3 times these amounts.

The nature of the chromogenic substances in plasma and urine which give the color reaction for urate has been discussed recently (1) and will be reviewed more comprehensively in a forthcoming publication (6). A portion of the chromogen is non-purine in origin, but another portion is due to an incompletely characterized purine metabolite (or metabolites) of endogenous origin. In addition, methylurates from the methylxanthines of dietary origin contribute to the chromogen.

The normal plasma urate values quoted are based upon repeated determinations on 31 normal individuals and are similar to the values obtained by Bulger and Johns (3) with a uricase method.

Plasma for ultrafiltration was obtained from blood drawn in a heparinized syringe and immediately centrifuged; no attempt was made to preserve the normal carbon dioxide content. Ultrafiltrates of plasma were obtained by a modification of the method of Lavietes (7). The membranes used were DuPont No. 600 cellophane, soaked 3 days at 0° before used.[3]

RESULTS

The results of the urate partition in pooled normal cerebrospinal fluid are given in Table I, together with the average normal concentrations in plasma and the calculated C.S.F./plasma ratios. These data show that normal human cerebrospinal fluid appears to contain, on the average, only 6

Talbott (15)	12 gouty patients	1.79	7.26 serum		0.246

* Depending chiefly upon the hematocrit and upon the type of whole blood method used, C.S.F./blood ratios will average 135 to 200 per cent of C.S.F./plasma ratios. To facilitate comparison of data, where authors determined urate in blood the C.S.F./plasma ratio in the final column has been estimated as 0.75 (C.S.F./blood).

per cent of the true urate present in plasma. Furthermore, application of the uricase method to spinal fluid shows that slightly less than half the chromogenic material present is true urate.

Our results for total urate in cerebrospinal fluid are comparable to those found in previous investigations, which are summarized in Table II. The values found by Katzenellenbogen (12) are somewhat lower than those in other studies because he employed a silver precipitation method which yields values approximately equivalent to true urate under suitable circumstances (1). Normal values in children are reported to be 50 per cent higher than in adults (16).

The C.S.F./plasma ratios reported by different investigators show considerable variation; but most recent studies show a mean ratio of 0.1 to 0.2 for total urate. Reiche (9), by dividing his large material into 3 groups, was able to show a rough parallelism between the blood urate level and the cerebrospinal fluid level.

We have secured a small number of ventricular fluids from patients without mass lesions of the brain or inflammatory intracranial disease. These data, presented in Table III, show merely that the urate content and partition in ventricular fluid do not differ strikingly from that obtained by lumbar puncture.

The difference between plasma and cerebrospinal fluid urate concentrations is so large that it

clearly cannot be explained on the basis of the Donnan phenomenon. Since the only other clearly established cause for such a discrepancy between spinal fluid and plasma constituents is nondiffusibility, ordinarily due to the binding of a substance to plasma protein, we attempted to determine the degree of protein binding of urate by pressure ultrafiltration through cellophane.

Adlersberg, Grishman and Sobotka (17) have reviewed the literature dealing with attempts to demonstrate protein binding of urate. In their own experiments, they found 84 per cent of the plasma total urate ultrafiltrable in normal individuals.

Our experience with ultrafiltration confirms that of Adlersberg and his coworkers. We found 79 per cent of the plasma total urate and 77 per cent of the plasma true urate to be free to ultrafiltration (Table IV). It is obvious that the quantities of true urate in normal cerebrospinal fluid are much less than those which appear to be free in plasma when cellophane ultrafiltration is used to indicate the degree of plasma binding.

DISCUSSION

The data presented above demonstrate the cerebrospinal fluid true urate concentration to be only 6 per cent of that present in plasma. The question therefore arises by what mechanism such an unequal distribution may be maintained.

Cerebrospinal fluid, it is generally agreed, resembles a modified ultrafiltrate of plasma (8, 18, 19). It appears to be subject to alterations predicted by the Gibbs-Donnan rule. Various substances are present in relatively small amounts because of plasma binding and, to a lesser extent, because they may circulate in plasma water in a colloidal state (calcium, bilirubin, cholesterol, salicylate). The quantity of magnesium in cerebrospinal fluid is greater than in plasma and the difference is magnified when plasma binding is considered; it has, however, been suggested that magnesium is a brain metabolite. There remain differences in potassium, glucose, and phosphate partition which cannot be well explained at present.

When true uric acid is considered, there appears to be little resemblance between cerebrospinal fluid and plasma ultrafiltrates. The ultrafiltrate contains 77 per cent of the uric acid concentration of plasma, while the cerebrospinal fluid contains only 1/10 as much urate as the ultrafiltrate.

Three possibilities have been suggested to explain the peculiarity in urate distribution; they will be briefly listed without extended discussion. The first is that true uric acid enters the cerebrospinal fluid in somewhat greater concentration and is converted to substances not fermentable by uricase. Since a small series of determinations of urate partition in ventricular fluid show no differences from fluid obtained by lumbar puncture, this appears not to be tenable.

The second possibility is that the modified ultrafiltration theory of cerebrospinal fluid formation does not apply to true uric acid. Reiche's (9) demonstration of parallelism between blood and spinal fluid urate concentrations makes this appear improbable.

The third possibility is that ultrafiltration *through cellophane* does not truly reflect the diffusibility of urate through biological membranes. Such behavior is observed in the case of p-aminohippuric acid which shows much greater binding in clearance studies than in ultrafiltration studies (20). From electrophoretic experiments, Bennhold (21) concluded that uric acid is bound to plasma albumin by a linkage highly labile to pressure and that the degree of plasma binding was

much greater than could be shown by ultrafiltration. Although it is not clear that non-diffusibility is entirely due to binding to plasma protein, evidence obtained from a study of renal and other biological functions (6, 22) suggests that the true urate content of the cerebrospinal fluid may be essentially equal to the plasma-free true urate.

SUMMARY

The concentration of true uric acid in normal human cerebrospinal fluid has been determined enzymatically. Substances giving the arsenophosphotungstate color reaction for urate are present in considerable amount, but true urate forms only 40 per cent of these substances. The concentration of true urate in normal spinal fluids averages 6 per cent of that in normal plasma.

Approximately 77 per cent of the plasma true urate is ultrafiltrable through a cellophane membrane under pressure, but spinal fluid contains only $\frac{1}{10}$ the true urate which is found in a plasma ultrafiltrate.

The various possible explanations of these findings are briefly considered.

THE TRANSPORT AND EXCRETION OF URIC ACID IN MAN. II. THE ENDOGENOUS URIC ACID–LIKE CHROMOGEN OF BIOLOGICAL FLUIDS

By W. Q. WOLFSON, B. HUDDLESTUN, and R. LEVINE

(From the Department of Metabolism and Endocrinology,[1] Michael Reese Hospital, Chicago, Illinois)

(Received for publication March 24, 1947)

Within recent years, enzymatic methods for the determination of true urate have become available. The introduction of such methods by Blauch and Koch (1, 2) has made it possible to estimate true urate in biological material with a high degree of accuracy (3 to 10).

All uricase methods involve the colorimetric determination of uric acid on two aliquots of a sample, one of which has been treated with uricase to destroy the true uric acid present. The apparent concentration of uric acid in the untreated sample, as determined colorimetrically, is referred to as "total urate"; and the concentration remaining after treatment with uricase is referred to as the "urate-like chromogen" (or briefly, "chromogen"). By substracting the concentration of chromogen from that of total urate, the concentration of "true urate" destroyed by the enzyme is obtained.

Most authors have tacitly assumed that the chromogen was merely an interference with the maximal accuracy of urate determination, but the results we obtained appear to require another explanation. A preliminary report on some of this data has appeared elsewhere (11) and this paper is chiefly concerned with the results of our investigations dealing with the chemical nature and physiological significance of the urate-like chromogen.

METHODS

Total urate, true urate, and chromogen are estimated by our modification of the method of Buchanan, Block, and Christman (3) for the Evelyn photoelectric colorimeter. Details of other chemical and physiological methods and complete data on our normal human subjects and gout patients summarized below will appear in a later publication (12).

Urate solutions for continuous intravenous injection in normal human subjects were prepared by dissolving uric acid in 0.05 N sodium hydroxide. The solutions were neutralized and sterilized by Berkfeld filtration. Only a few such experiments were performed as we, like a number of previous workers, have found these solutions to produce frequently unpleasant reactions, chiefly nausea and vomiting. These reactions could not be ascribed to any possible decomposition products since 100 per cent of the added urate was recoverable as true urate by analysis, even after standing for 1 to 2 days. Nucleic acid was given orally in 1.0-gram gelatin capsules; doses as high as 20 grams appear to be fairly well tolerated. Below 10 grams, there are no untoward effects; but single doses in the 10- to 20-gram range may cause transient malaise, hypotension, and vasodilation in the second hour, presumably attributable to adenosine. Other solutions of purines used in animal experiments were made up in .05 N NaOH.

All determinations were done on plasma or serum rather than on whole blood. Although the Folin uric acid precipitation is supposed to be an "unlaked blood" method (*i.e.* the red cells are precipitated without hemolysis) this is not true (13). In addition, the red cells contain a large amount of ergothionine which gives considerable urate color.

RESULTS

The endogenous origin of chromogen. Table I shows the effect of fasting upon the plasma concentrations of chromogen in man and in the dog. These results, which show that chromogen concentrations do not decline upon fasting, indicate the endogenous origin of this substance or group of substances.

The known urate chromogens. A large number of substances (Table II) are not attacked by uricase but do give color in the uric acid reaction. It is, however, possible to conclude that most of these substances cannot be responsible for the observed plasma concentrations of chromogen.

The non-purine substances with large chromogenic equivalents (ascorbate, resorcinol, cystine, glutathione, and ergothionine) are not present either in plasma or urine in concentrations large enough to account for the amounts of chromogen present. (See Table II.) In addition, the data of Buchanan, Block and Christman (3, 4) appear to indicate that the endogenous chromogen is not precipitated by their silver reagent which precipitates ergothionine quantitatively.

TABLE II*

Ability of certain substances to produce color with the uric acid reagents, with known chromogenic equivalents†

3,7-dimethyluric acid	0.004
1,3,7-trimethyluric acid	trace
7-methyluric acid	trace
6-amino-2,8-dihydroxy-purine	unknown

Substances which do not give color	
Adenine	6-amino-8-hydroxy purine
Guanine	8-hydroxy-purine
Xanthine	6-amino-2-hydroxy purine
Hypoxanthine	2-thioxanthine
Methylxanthines	Allantoin
Oxyacetylene-diurein-carboxylic acid	

* Data chiefly from Buchanan, Block and Christman (3, 4), Booth (29), and Falconer and Gulland (30). We have confirmed the chromogenic equivalents for the methyluric acids and for resorcinol reported by Buchanan, Block and Christman (3, 4). From the observation that uricase action upon uric acid gives rise only to non-chromogenic products, it is inferred that oxyacetylene-diurein-carboxylic acid, the chief reaction product (*31*), is non-chromogenic.

† The *chromogenic equivalent* is the number of milligrams of uric acid required to give a color equal in intensity to that produced by 1.0 milligram of the substance being tested.

‡ Precipitated by silver reagents.

§ When ascorbic acid is added to plasma samples treated routinely with no special precautions to prevent oxidation, the chromogenic equivalent is approximately 0.20.

On the other hand, the methylxanthines of dietary beverages (theophylline, theobromine, caffeine), when oxidized in intermediary metabolism, give rise to methylurates of considerable chromogenic value (4, 14). Coffee, tea, and chocolate, however, can hardly account for the plasma and urine chromogens in the animal, in the fasting human, or in subjects on a purine-free diet.

One substance may deserve more study than it has yet received. Some years ago, Minkowski and other workers (15, 16) found that when large amounts of adenine were fed to animals, a purine derivative was deposited in the cells of the renal tubule. Raska (17) has recently made a similar observation. Upon analysis, this purine proved to be 6-amino-2,8-dihydroxy-purine. It is known to give color with the uric acid reagents and its precursor, oxyadenine (6-amino-2-oxy-purine), has been found in pig blood (18). We are aware of no studies indicating either its occurrence or absence in human intermediary metabolism.

It is apparent that if the endogenous chromogen is of purine origin, as we shall attempt to show, it must be very similar to uric acid in order to give appreciable color. The minimum criteria appear to be the presence of 2 oxygen atoms in the 2, 6, and 8 positions with another radical in the third position or 3 oxygen atoms in these loci. Most of the substituted uric acid derivatives, however, give considerably less color than urate itself. The breakdown products of uric acid are not chromogenic, and precursors as similar as the dihydroxy-purines also are not chromogenic.

Since it is possible on these most elementary chemical considerations tentatively to eliminate most known urate derivatives, the endogenous chromogen appears to be a substance the composition of which is as yet not known.

Occurrence and distribution of chromogen. In Table III we have summarized a large body of data concerning the values for true urate and chromogen in various biological fluids (19). It is ap-

TABLE III

* Plasma and C.S.F. values are milligrams per 100 ml. Urine values are milligrams per minute per 1.73 sq. m. Clearance values are ml. of plasma cleared per minute per 1.73 sq. m.

† Average plasma values were obtained on larger groups of subjects, both normal and gouty, than were urine and clearance values. Urine and clearance results quoted were obtained simultaneously and in the same individuals.

‡ The data for normal C.S.F. are those for pooled normal fluids (10).

parent that the chief constituent of the total urate values in human plasma and urine, both in normals and in persons with gout, is true urate. In fact, the proportion of total urate formed by true urate is so regular that it may safely be estimated by a conversion factor. Similarly, there is little difference between the total urate and true urate clearance, a point of importance when considering the results of earlier investigation.

The clearance of chromogen is similar in magnitude to that of true urate, and is reduced in gout as is that of true urate, observations which again point to its resemblance to uric acid and certainly suggest it to be a purine derivative.

However, in normal human cerebrospinal fluid (10) and in dog plasma (19), the situation is somewhat different. Here, chromogen forms over 50 per cent of total urate values, and the ratio of true urate to total urate is sufficiently irregular so that it appears hazardous to employ a conversion factor.

Observations on ultrafiltrates of human plasma ([10], Table III) show considerably less plasma binding of chromogen than of true urate, when cellophane ultrafiltration is used as the criterion of binding. Moreover, the C.S.F./plasma ratio for chromogen is considerably greater than for true urate ([10], Table I).

We have been fortunate enough to observe a patient with chronic monoblastic leukemia and gout who had an output of urate of 2.95 mgm. per minute or about 6 times normal. In this patient, both true urate and chromogen were excreted in increased amounts, the chromogen excretion being about 4 times normal.

Site of origin of chromogen. In the dog, rabbit, and monkey, removal of the liver (or evisceration), is followed by a rise in plasma uric acid owing to the removal of hepatic uricase which normally converts uric acid to allantoin (20 to 24). If the renal pedicles are ligated, or the kidneys removed, excretion of urate and allantoin is prevented, making it possible to study the peripheral production of urate by observation of the plasma uric acid level. In this eviscerated-bilaterally-nephrectomized preparation, the rise in plasma urate, at least for the first few hours postoperatively, is linear, indicating that, either reduction of urate to its precursors is not affected by rising plasma levels or that breakdown rates and resynthesis rates are so balanced as to mask this effect.

In the eviscerated-bilaterally-nephrectomized dog (Table IV), operation is followed by a rise in both true urate and chromogen. This appears actually to depend upon the rate at which urate precursors are made available, since the injection

TABLE IV

Effect of evisceration and bilateral nephrectomy upon plasma urate partition in the dog

of xanthine or hypoxanthine (Figure 1) into this preparation is followed by a rapid, simultaneous rise in both plasma true urate and plasma chromogen. However, while these data indicate that chromogen may be formed in the peripheral tissue, they do not exclude the possibility that it is derived from urate.

Effect of urate and its precursors in man. In man, the oral administration of large doses of nucleic acid (Figure 3) leads to increased excretion of both true urate and chromogen. Freyberg, Block and Geib (25) have shown that administration of adenine or guanine has similar effects.

Man, however, is particularly suitable for the study of the possibility that chromogen may be formed from urate in the peripheral tissue since he lacks the hepatic uricase of the dog. The results of this experiment (Figure 2) showed that the continuous intravenous injection of urate solutions leads to a rapid rise in both plasma true urate and chromogen. Since it is possible to recover 100 per cent of urate added to plasma or blood *in vitro,* one must conclude that some system, presumably enzymatic, located in the peripheral tissue, or located in the blood and very susceptible to spontaneous breakdown, is responsible.

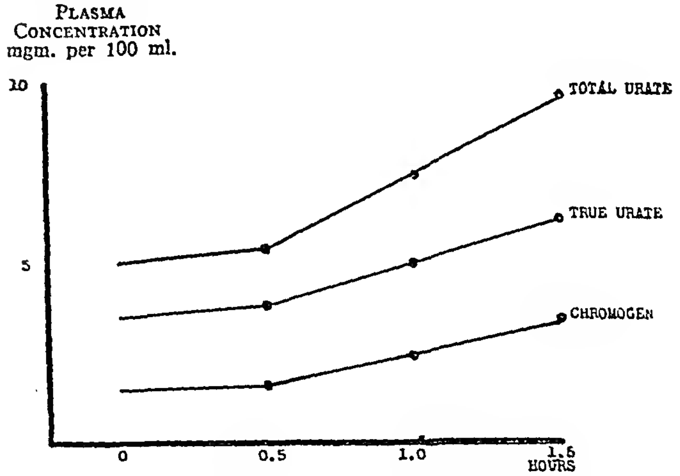

FIG. 2. EFFECT OF CONTINUOUS INTRAVENOUS INFUSION OF SODIUM URATE IN HUMAN

One-half gram of sodium urate solution, 100 mgm. per 100 ml., was injected between 0.5 and 1.5 hours.

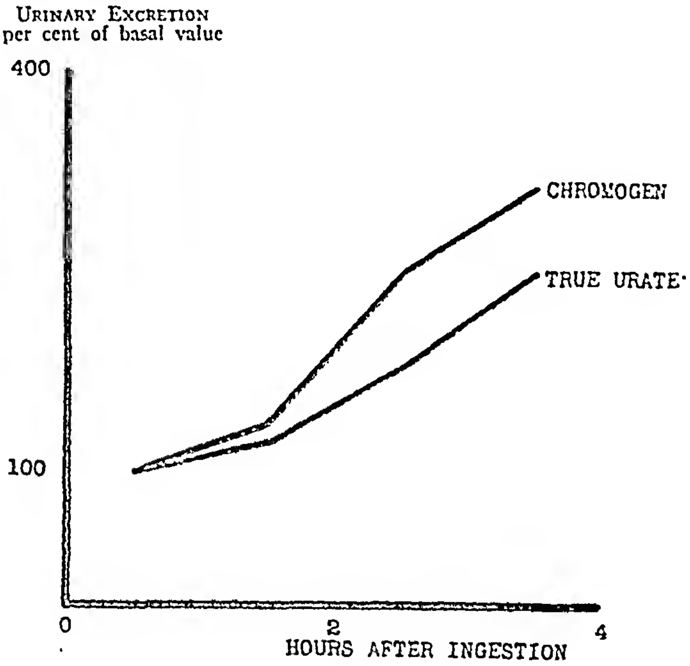

FIG. 3. EFFECT OF A SINGLE 15.0-GRAM ORAL DOSE OF NUCLEIC ACID UPON THE URINARY EXCRETION OF TRUE URATE AND OF CHROMOGEN

Effect of uricosuric drugs on chromogen excretion. Another similarity between urate and chromogen lies in the response to the uricosuric group of drugs, those agents which increase urate output in urine and decrease its plasma level. All the uricosuric drugs so far investigated (cincophen,

salicylate, diodrast) have been found to increase the output of chromogen as well as that of true urate (26). The results of a typical experiment with diodrast are shown in Table V.

The chromogen content of a gouty tophus. Because of the many similarities in the physiological behavior of true urate and chromogen, we were interested to see whether chromogen, like true urate, is deposited in the gouty tophus.

A large surgically removed tophus was made available for analysis.[2] This analysis (Table VI) was distinctly surprising in that it showed the virtual absence of chromogen.

TABLE VI

Chromogen	0.7
True urate	6.6

Apart from its physiological importance as differentiating the behavior of true urate and endogenous chromogen, this finding appears possibly to have practical significance in the management of gout. Ordinarily, coffee, tea, and chocolate are forbidden to the gout patient because it is commonly supposed that they may give rise to uric acid and so increase tophaceous deposits. Actually, the methylxanthines of these beverages are metabolized to methylurates (3, 4, 14); these substances are not attacked by uricase and are therefore chromogens. Since, apparently, no chromogenic substance is deposited in the gouty tophus, it is obvious that the methylurates of exogenous origin do not contribute to tophus formation, and need not be eliminated from the diet on this account.

DISCUSSION

We may now briefly summarize our present data on the endogenous uric acid-like chromogen. This substance (or substances) is shown to be endogenous in origin since its plasma concentration and urine output are not markedly diminished by fasting. It originates spontaneously with urate in the peripheral tissue of the dog and may be formed from xanthine or hypoxanthine by the peripheral tissue of the dog. In man, who lacks uricase and appears to be comparable to the hepatectomized dog, chromogen is also formed from ingested urate precursors, as is true urate. However, injected urate also leads to chromogen production so rapidly as to suggest an enzymatic conversion. The data permit no conclusion as to whether the conversion of endogenous chromogen to urate is reversible physiologically; although it is clear that neither conversion occurs *in vitro*.

Data on a patient with leukemia and gout indicate that when urate is overproduced, chromogen is also overproduced. The chromogen clearance is of the same order of magnitude as the true urate clearance in man; and both are decreased in gout. Furthermore, the uricosuric drugs which increase urate excretion also increase chromogen excretion.

Thus, there are many resemblances between the behavior of true urate and of chromogen, but there also are some differences. Unlike true urate, chromogen is not attacked by uricase. It appears to be somewhat more freely ultrafiltrable from plasma through cellophane than is true urate ([10], Table III). It is not deposited in the gouty tophus (Table VI). There is a suggestion that, unlike urate, it is not precipitated by silver reagents (4). A critical survey of the known purine derivatives which might satisfy these criteria reveals that none appears to be satisfactory. A possible exception is 6-amino-2-8-dihydroxypurine, but so little is known of the physiology of this substance that a decision as to its importance cannot be reached.

In 1939, Ball (27) reported that the endproduct obtained when purified xanthine oxidase acted upon hypoxanthine was a substance not attacked by purified uricase, in spite of the fact that the oxygen consumption was that predicted for uric acid formation. If either crude xanthine oxidase or crude uricase were substituted for the pure enzyme in this experimental system, the reaction continued to completion.

The work of Ball is reminiscent of the much older suggestion of Gudzent (see 13) that both

[2] Through the kindness of Dr. E. F. Rosenberg.

the lactam and lactim tautomers of uric acid might be stable enough to coexist in biological fluids under certain circumstances. It is true that Ball's experiment required extremely precise conditions and, while this is undeniably an objection, it does indicate that in a suitable biological system *in vitro*, there may be a tautomer of uric acid which is not attacked by uricase. Guanase may possibly have such a selective action; this was suggested by the finding that it attacks the methylated derivatives only of the lactam tautomer of guanine (28). A more pertinent objection to identifying Ball's substance with our endogenous chromogen lies in the fact that our chromogen is not attacked by the uricase we use, which is a crude, defatted, kidney extract. At present, our feeling is that the chromogen is more likely to be a tautomer of urate than a substance such as 6-amino-2,8-dihydroxy-purine; but this is based solely on an impression that the amino substitution is unlikely from our present knowledge of the behavior of urate in the body.

Two findings appear to be of practical clinical importance. The observation that a gouty tophus contains only true urate and no chromogen, endogenous or exogenous, when considered in the light of our present knowledge that dietary methylxanthines give rise to methylurates and not to uric acid, appears possibly to indicate that the patient with gout need no longer be penalized by having coffee, tea and chocolate removed from his diet. So far as accelerating the rate of tophus deposition, these beverages appear innocuous.

The other, probably more important, conclusion bears upon the moot question of the reliability of the colorimetric estimation of urate. Our data show quite clearly that the relation between true urate and total urate in normal and gouty plasma and urine is so uniform that, if desired, true urate may be estimated from total urate values by a conversion factor. In addition, a large body of urate clearance data obtained by various investigators before the introduction of the uricase method has been shown to be almost as accurate as if true urate clearances had been studied, since the total urate clearance is almost exactly equal to the true urate clearance.

There is no question that one should use true urate determinations for maximal physiological precision, or when studying material other than human plasma and urine. However, when an estimate of the quantitative rate of nucleoprotein breakdown or turnover is desired, total urate determination appears to give a more complete picture. The chromogens discarded in the true urate determination appear to be as much a part of nucleoprotein metabolism as is true urate and, in fact, may arise from urate in the body. Only under unusual conditions, such as the ingestion of massive doses of caffeine, does the colorimetric determination on human plasma and urine become inaccurate. In contrast, the colorimetric determination of urate in human plasma or urine appears to be an entirely satisfactory method for clinical use and rather gains, than loses, in value because of a slight degree of non-specificity.

SUMMARY

Biological fluids contain material which gives the arsenophosphotungstate reaction for urate but which is not attacked by uricase. A portion of these chromogenic substances appears to be purine in nature and endogenous in origin. In many ways this endogenous uric acid-like chromogen resembles true uric acid, but it also has several differences in behavior.

The chromogen is known to be endogenous in origin since neither its plasma concentration nor urinary output is markedly affected by fasting. Unlike urate, it is not precipitated by silver, and it is somewhat more diffusible through cellophane and through the blood-brain barrier than is true urate. Increased urate production due to leukemia or induced by the feeding or injection of urate precursors leads to increases in chromogen production. This also occurs, however, when urate is injected intravenously. The chromogen clearance is of the same order of magnitude as the true urate clearance, and is similarly reduced in gout. Uricosuric drugs increase the chromogen excretion as well as true urate excretion.

For ordinary clinical pathological studies, the colorimetric determination of urate in plasma and urine, including both true urate and chromogen, appears to give a better picture of the overall rate of purine turnover than does the uricase determination. Moreover, the true urate to total urate ratio in human plasma and urine is sufficiently constant so that true urate may be reliably estimated from total urate. The true urate clearance does not differ appreciably from the total urate clearance. However, in human cerebro-

THE IMPORTANCE OF VOLUME AND OF TONICITY OF THE BODY FLUIDS IN SALT DEPLETION SHOCK [1]

BY J. R. ELKINTON, A. W. WINKLER,[2] AND T. S. DANOWSKI

(From the Department of Internal Medicine, Yale University School of Medicine)

(Received for publication March 24, 1947)

It is not known whether the deterioration in circulatory efficiency which follows sodium chloride loss is related primarily to the hypotonicity, to the changes in the volume of fluid in the various compartments, or to both. In experimental salt depletion produced by means of the intraperitoneal injection and subsequent removal of glucose solution, both of these factors invariably coexist. As sodium and chloride ions enter the intraperitoneal fluid, water moves into the cells in response to osmotic forces. Diminution of the volume of extracellular fluid and plasma, swelling of the cells, and generalized hypotonicity are the inevitable end results (1, 2, 3). Since these changes occur rapidly and almost simultaneously, it is difficult to ascribe the primary causative role in the circulatory collapse which ensues to any one factor. It is conceivable, on theoretical grounds at least, that all of these changes are important. It is quite possible, for instance, that the hypotonic and swollen cells of the cardiovascular system become inefficient, while the blood thickens and becomes more difficult to move through the vessels.

To clarify the relative significance of each these changes in the production of salt deple shock, further experiments have been cond in which hypotonicity and the state of hydra extracellular and cellular fluid have bee in directions other than those seen in o depletion.

MATERIALS AND METH

A. Dilution of the body fluids in ani- *mals.* The effects of an infusion of glucose solution on the composition of th and the efficiency of the circulation were nephrecto- mized dogs on the day followi . The second kidney. The kidneys were nembutal anaesthesia via a retroperito Two to 7 days of convalescence were ng the first operation. The glucose nistered during

a period of 1 hour in amounts sufficien lower the concentration of serum electrolytes to oximately ¾ of the initial value. After 3 to 4 hours animals received additional infusions. Two were 5 per cent saline in volumes sufficient to restore onicity of the body fluids. The third received 6 cent gelatin solution containing sodium chloride w concentrations (0.2 per cent).

B. Restoration of isoto by urea diuresis in salt- depleted animals. Two dogs were first depleted of salt by the standard te of injecting 5 per cent glucose solution intrap lly, 100 ml. per kgm., and withdrawing it aft 4 hours (1). An overnight in these animals by means of diuresis was then 350 ml. of a 15 per cent solution an intravenous i cent solution of urea in 5 per cent and 300 ml. of In one of these animals the effects glucose, resp sion of hypotonic saline, 0.6 per cent, of a subseq were inv

In all Groups A and B, movements of water llular compartment were calculated from from t chloride space (4). Alterations in the chan e were estimated from changes in the relapla ell volume and in the hemoglobin concentra- ti rial blood (1). Changes in the volume of cell were obtained by subtracting the increments or ts of extracellular water from the changes in dy water. These later values were calculated from anges in body weight; in the periods lasting 20 the weight change was corrected for water of oxi- ion according to the metabolic mixture (4). The ssibility of transfers of sodium and potassium between extracellular and cellular compartments were also investigated from the changes in their concentration in extracellular fluid, corrected for the intake and output of these ions. The flame photometer was used in these cation analyses (5). The hemodynamic studies at intervals during the course of these experiments included measurement of: (*a*) the fore-paw to medulla circulation time by means of intravenous sodium cyanide, (*b*) the mean arterial blood pressure by direct arterial puncture, and (*c*) the cardiac output by the direct Fick principle based upon the rate of oxygen consumption and the difference in the oxygen content of arterial blood from the femoral artery and mixed venous blood from the right auricle (6).

* Water content of serum (W_s) calculated from the serum total protein concentration (P_s) by the formula (10): $W_s = 99.3 - 0.889\ P_s$.

† Total ionic concentration was assumed to equal the concentration of Na in extracellular water + 10 milliequivalents per liter (4).

‡ [illegible] total protein and NPN concentrations were not determined because of the presence of gelatin; water content of serum was assumed to be unchanged.

[illegible] Table I.

solution produced hypotonicity, an expansion of the extracellular fluid volume in all experiments, as well as an increase in the water of tissue cells in 2 of the 3 animals (Tables I and II). Despite this marked distortion in the concentration of the electrolytes and a swelling of tissue cells quite as great as that witnessed in salt depletion, circulatory efficiency was not adversely affected. The mean arterial pressure and the circulation time were unaltered. The cardiac output was moderately depressed prior to the dilution of body fluids in the 2 experiments in which initial observations are available. This was presumably related to the recent nephrectomy. It is highly significant, however, that it did not decline further following the intravenous glucose solution. As a matter of fact, in one of the dogs (Experiment 115), the cardiac output rose to a level that was well above normal.[3] These findings are in direct contrast to the profound deterioration of the circulation which accompanies salt depletion (1).

The subsequent restoration of a normal concentration of serum electrolytes in Experiments 110B and 113 by means of hypertonic saline resulted in a normal and a supranormal cardiac output, respectively, in contrast to the previous moderately depressed values. Expansion of the plasma volume without restoration of tonicity in Experiment 115 had no adverse effect on the already high normal level of cardiac output.

B. Restoration of isotonicity by urea diuresis in salt-depleted animals. It is evident from Tables I and II that even though the hypotonicity of the body fluids and the swelling of the cells were partially or fully corrected by this dehydrating procedure, circulatory dynamics either failed to improve or actually deteriorated. The volume of extracellular fluid declined further in both experiments. Replacement of the salt deficit and reexpansion of the extracellular fluid by means of saline partially restored the cardiovascular function which had not been improved by the correction of the hypotonicity (Experiment 114).

In none of the experiments in this group nor in the nephrectomized animals was any significant exchange of extracellular sodium for cell potassium detected. In the nephrectomized animals a large amount of intracellular base was apparently inactivated following the glucose infusion (Table II) (7). This was reflected in the disproportionately large volume of the administered fluid which remained in the extracellular phase. The alternative explanation is that a water gradient was present which decreased between 2.5 and 4.5 hours (Experiment 110B). It is hard to believe that such a long period was necessary for the distribution of water to equilibrium. The unequal phase of distribution could also be accounted for by the entry of chloride into cells; such a phenomenon, however, would in no way affect the calculation of exchanges of total water and total osmotically active base. Following the administration of hypertonic saline or of low salt colloid, this base once again became osmotically active.

DISCUSSION

For purposes of discussion published data on simple dehydration and on salt depletion studies are summarized in Figure 1 for comparison with the dilution experiments in the nephrectomized animals. Analysis of these 3 sets of experiments permits certain generalizations. It is immediately apparent that an expansion of the body water, as in the dilution studies with nephrectomized dogs, does not interfere with circulatory efficiency (Column A). A decrease in the total body water, on the other hand, such as that which occurs in simple dehydration does impair cardiovascular function to a limited degree (Column B). This is evident in the drop in the cardiac output, but the decrease is by no means marked or consistent. In the third group of experiments, those in which salt depletion was produced, profound deterioration of the circulatory efficiency was present (Column C). In these animals the total amount of body water remained essentially unchanged. It is apparent, therefore, that extensive alterations in the total amount of body water can be induced with only moderate, if any, effect on cardiovascular dynamics, and that marked circulatory inefficiency can develop even though the total volume of water in the body remains constant. These findings suggest that factors other than the total body water condition cardiovascular function.

Study of the changes which occur in the various subdivisions of the total body water in these 3

[3] Mean cardiac index in normal dogs was found by the authors to be 5.45 ± 1.43 liters per minute per square meter (1).

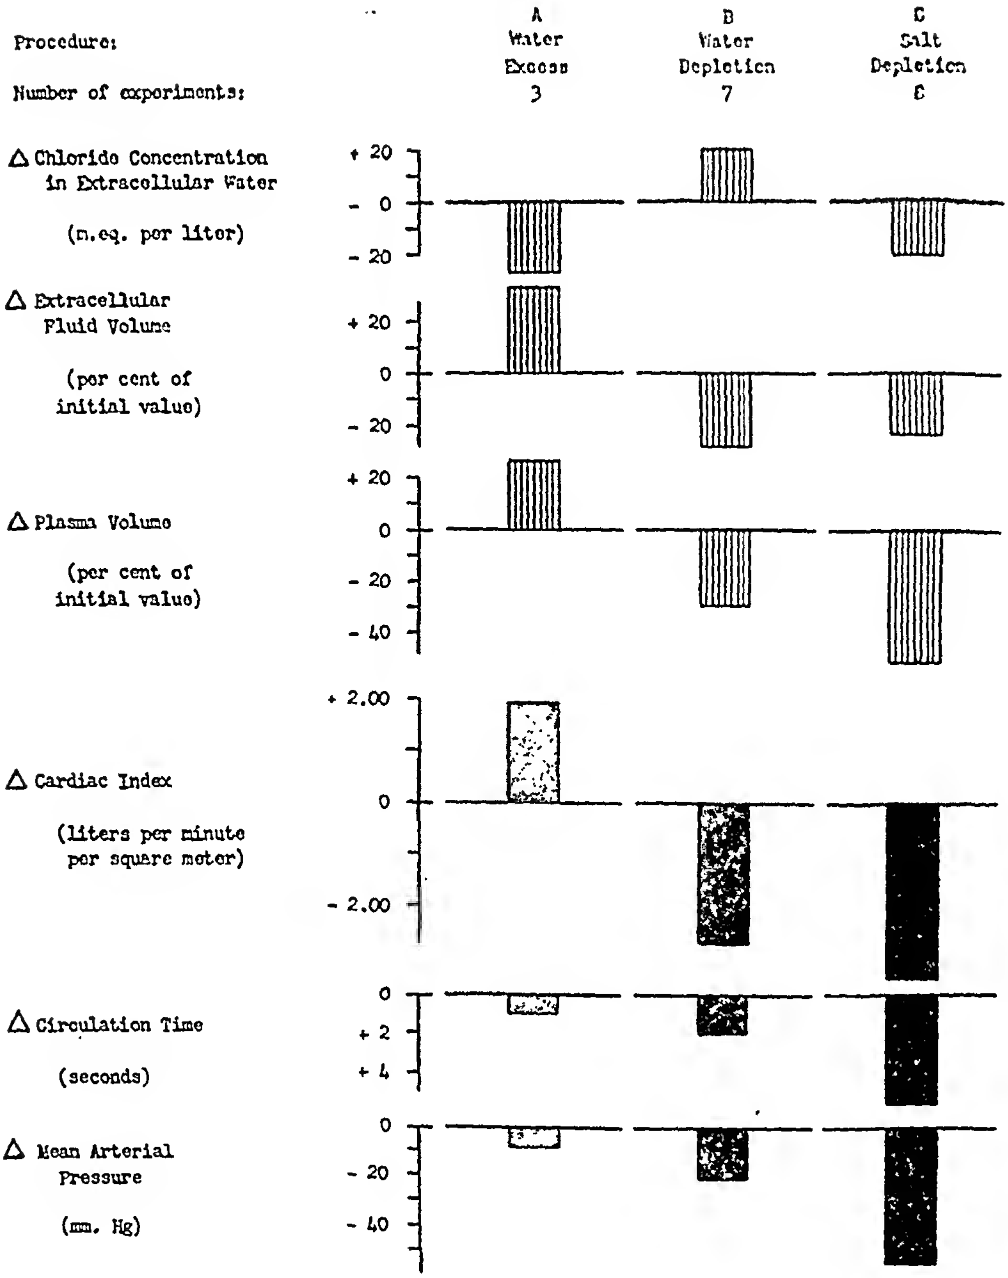

FIG. 1. CHANGES IN CIRCULATORY DYNAMICS FOLLOWING VARIOUS ALTERATIONS IN THE BODY FLUIDS

Each column represents the mean value for the number of experiments indicated. Columns B and C are taken from previously reported data (1). The changes shown were produced in animals with normal body fluids. It is evident that a decrease in both volume and concentration (salt depletion experiments in Column C) causes more profound circulatory deterioration than does a similar change in either volume alone (water depletion experiments in Column B) or in concentration alone (water excess experiments in Column A).

groups of experiments serves to identify some of these factors. In the dilution experiments with the nephrectomized preparations, cell water, extracellular water, and plasma water were all overexpanded without circulatory impairment. In the simple dehydration experiments all of these compartments were contracted in volume with some attendant deterioration of the circulation. In the third group of animals, those depleted of salt, only the extracellular water and the plasma water were decreased, and yet profound shock was present. The decrease in the plasma volume, however, was much greater in the salt-depleted dogs than in the simple dehydrated animals. It would appear, there-

fore, from these experiments, as it has from work on other types of shock, that the volume of plasma is an important factor in the development or manifestations of the salt depletion shock state. The increase in the volume of cell water which attends salt depletion is probably not a contributing factor, since similar degrees of cellular overhydration in the diluted nephrectomized dogs had no deleterious effect on the circulation.

Up to this point no account has been taken of the changes in tonicity which accompany these manipulations of the water in the various compartments of the body. The body fluids of the dehydrated animals were hypertonic, while the salt-

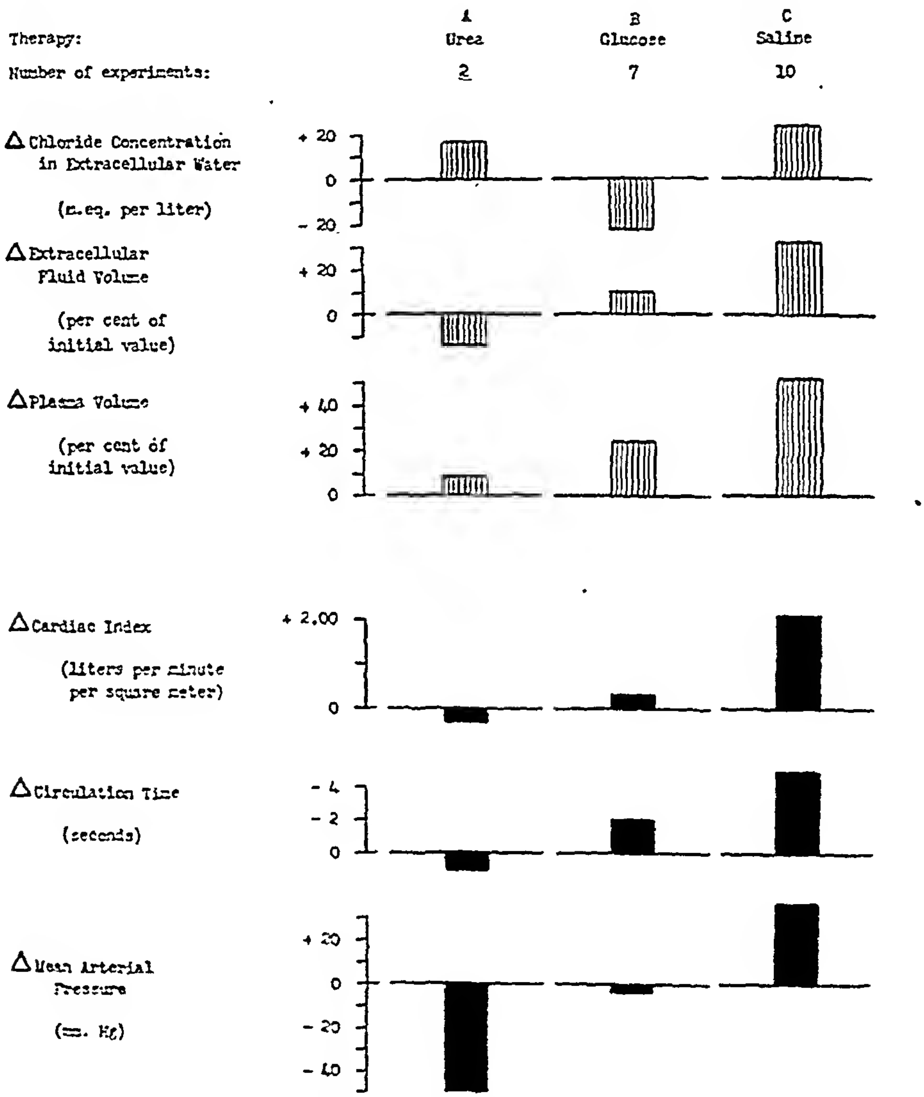

FIG. 2. CHANGES IN CIRCULATORY DYNAMICS FOLLOWING VARIOUS TYPES OF TREATMENT OF SALT DEPLETION SHOCK

Each column represents the mean value for the number of experiments indicated. Columns B and C are taken from previously reported data (2). The changes shown were produced in animals already in salt depletion shock. In such a state, restoration of concentration alone by urea diuresis (Column A), or of volume alone by glucose infusion (Column B), failed to improve the circulation. Restitution of both volume and concentration by infusion of saline (Column C) was followed by prompt recovery from the shock state.

depleted dogs became hypotonic. Since hypertonicity was accompanied by less striking changes in the circulation, hypotonicity, as seen in salt depletion, would appear to have a significantly greater adverse effect on cardiovascular function. Hypotonicity, however, cannot be the sole determinant, since a comparable lowering of the concentration of body electrolytes was produced in the dilution experiments with nephrectomized dogs without impairment of the circulation. In these animals, however, in contrast to those depleted of salt, the volume of body water was expanded rather than contracted.

These facts suggest, therefore, that not only the volume of fluid in the body and its various compartments, but also the concentration of electrolytes present are important determinants of whether or not salt depletion shock develops.

The statement that both the volume of extracellular fluid and plasma and the concentration of electrolytes in the body fluids operate in maintaining the integrity of the circulation can be further supported by analysis of the responses of salt depletion shock to various forms of treatment. From Figure 2 it is immediately evident that restoring concentration alone, as in the urea diuresis experiments (Column A), or restoring volume alone as in the animals given glucose solution (Column B), failed to relieve the circulatory collapse produced by salt depletion. Yet when both volume and concentration were restored by saline infusions (Column C), prompt recovery from shock was observed.

The finding that both the volume of body fluids, especially plasma, and the concentration of electrolytes in them are important factors in maintaining circulatory efficiency has many clinical implications. The most obvious of these lies in the well-known fact that extensive depletion of body water and electrolytes, as in patients who sweat or who have losses of gastrointestinal fluid, can coexist with isotonicity. These normal concentrations, however, can no longer be viewed with the assurance that they protect the organism against salt depletion shock, nor can they be interpreted as evidence against a need for salt and water. This is true even though isotonicity is encountered only in the less severe degrees of salt depletion. Nonetheless, in these patients as well as in those with greater salt deficits, when volume is restored tonicity should be maintained. If salt solutions alone do not restore cardiovascular efficiency, supportive treatment with colloid solutions is indicated.

It should be pointed out, however, that hypotonicity is not necessarily the result of a loss of salt in excess of water. It can also indicate simple dilution, as in anuric or oliguric patients treated with excessive amounts of non-electrolyte containing fluids. The problem becomes even more complicated when both depletion and dilution are present in the same subject, as in nephritics and patients on a limited intake of salt during periods of salt loss. Irrespective of whether the hypotonicity is the result of depletion or dilution, the patient should receive treatment which restores the concentration to normal. Withholding salt in such patients because of the fear of augmenting edema or congestive heart failure may prove to be a serious error, whereas the circumspect use of saline almost always turns out to be either beneficial or benign (8, 9).

SUMMARY AND CONCLUSIONS

1. Hypotonicity of body fluids produced by glucose infusions in nephrectomized dogs with intact body salt stores did not impair circulatory efficiency.

2. Elimination of hypotonicity and cellular overhydration following urea diuresis in dogs in salt depletion shock, without replacement of salt deficits and extracellular fluid reexpansion, failed to improve cardiovascular dynamics.

3. Both the volume of fluid in the body, particularly the volume of plasma, and the tonicity of this fluid are important factors in salt depletion shock.

THE EFFECT OF INCREASED INTRA-ABDOMINAL PRESSURE ON RENAL FUNCTION IN MAN[1]

By STANLEY E. BRADLEY AND GERALDINE P. BRADLEY

(*From the Robert Dawson Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine*)

(Received for publication March 26, 1947)

It is well established that increased intra-abdominal pressure alters renal function. In experimental animals, distention of the abdominal cavity under pressures greater than 15 mm. of mercury usually reduces urine flow and, under pressures greater than 30 mm., stops urine flow altogether (1). In man, a tense accumulation of ascitic fluid may be associated with oliguria and the retention of water and salt, which disappear following paracentesis (1). In one respect, increased intra-abdominal pressure seems to improve the function of the kidney, for the urine may become highly concentrated during the period of oliguria. This effect has found practical application in the hands of radiologists (2, 3), who use abdominal compression during intravenous pyelography to assure maximum density of the contrast media excreted by the kidneys.

Until the present there has been no satisfactory explanation for these alterations in renal function during abdominal pressurization. It has been suggested that they are due to partial urinary obstruction (3), but the radiologic evidence is against this explanation (4). Urine flow may be increased by diuretics during the application of pressure in experimental animals, indicating the absence of obstruction. Thorington and Schmidt (1) have called attention to the possibility that the associated increased renal venous pressure may interfere with normal blood flow through the kidney and disturb renal function.

Recently, abdominal compression has been used as a means of protecting airmen against the ill-effects of centrifugal force (positive G) (5). It was assumed that pressurization prevents the pooling of venous blood in the abdominal veins and sustains the return of blood to the heart. The present study, undertaken primarily to determine whether such procedures have detrimental effects on the abdominal organs (6), revealed that the diversion of arterial blood from large visceral circuits to more vital regions, such as the brain, is also an important factor.

METHODS

The clearance and saturation methods devised by Smith and his coworkers (7 to 9) were used to evaluate renal hemodynamics and tubular activity during abdominal compression in 17 normal human subjects, ranging in age from 17 to 50, almost equally divided as to sex, and clinically free of cardiovascular and renal disease. The effective renal plasma flow was measured by the diodrast or p-aminohippurate (PAH) clearances; and the glomerular filtration rate, by the mannitol or inulin clearances.[2] The maximal rate of tubular glucose reabsorption (glucose Tm) and the maximal tubular diodrast excretory rate (diodrast Tm) were determined to estimate tubular function and to assess the distribution of filtrate and perfusate to tubular tissue.

The pressure within the abdomen was increased by inflating a rubber bladder with air under pressure, beneath a girdle tightly applied to the abdomen. The bladder, sewn into a pocket in the girdle, covered the anterior abdominal wall. Pressures between 70 and 80 mm. Hg were applied during the determination of clearance and Tm values. These pressures were usually endured by the subject without complaint. Occasionally, however, slightly lower pressures were required or the period of application was shortened because of discomfort and respiratory difficulty. Among the subjects of the studies reported here, only very slight changes in blood pressure were observed during pressurization.

All subjects were examined in the basal fasting state, resting quietly in bed. Following the establishment of appropriate plasma levels of the test substances by a

[1] This work was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts Memorial Hospitals.

[2] A supply of sterile solutions of sodium p-aminohippurate (20 per cent) and mannitol (25 per cent) was made available for use in this study through the courtesy of the Medical Research Division of Sharpe and Dohme, Incorporated, Philadelphia, Pennsylvania. Diodrast was obtained in sterile solution (35 per cent) from the Winthrop Chemical Company, New York City; and inulin (10 per cent) from William R. Warner and Company, New York City.

technique described at length elsewhere (7), the bladder was catheterized and washed out with a measured volume of isotonic saline solution. Urine was then collected by catheter at intervals of 10 to 15 minutes and carefully measured. After 2 or more control periods had been obtained, abdominal compression was continuously applied for 10 to 45 minutes and 1 to 3 collections of urine were made during this time. On most occasions, 2 or more urine-periods were obtained after the pressure was released. Samples of venous or arterial blood were taken at 30-minute intervals.

Diodrast, PAH, mannitol, and inulin were determined in cadmium filtrates of plasma (10) and in dilute samples of urine, using methods described by Goldring and Chasis (8). Glucose was determined by the Nelson-Somogyi method (11) in cadmium filtrates of plasma and diluted urine. Clearance and Tm values were calculated by the procedures of Smith (7, 8).

In another group, comprising 15 subjects, a catheter was placed in the renal vein and venous pressures measured during the application of increased abdominal pressure. An extension of the technique developed by Cournand and Ranges (12) for the catheterization of the right atrium was employed. A small incision was made over a median basilic vein under local anesthesia and the vein secured by a suspensory ligature. A small longitudinal incision was then made in the vein with a bayonet scalpel, and an extra-length ureteral catheter [3] with a curved tip (Cournand tip) was introduced into the lumen of the vein. Sterile isotonic saline solution flowed constantly through the catheter at a slow rate throughout the procedure to prevent blockage by clotting. The catheter was next passed into the superior mediastinum under fluoroscopic control and then into the chamber of the right atrium. The orifice of the inferior vena cava was entered with difficulty on many occasions, apparently owing to obstruction by the valve of the inferior vena cava. This obstruction could be passed by rotating the tip of the catheter to the right and posteriorly during passage through the atrium. In the inferior vena cava, the tip was directed to the right and usually passed with little difficulty into the right renal vein. The catheter tip could be localized far out to the right side of the abdominal cavity below the shadow of the liver. The left renal vein was catheterized less frequently and with somewhat greater difficulty. Pressure determinations were made in the renal vein and in the upper portion of the inferior vena cava with a saline manometer after the method of Moritz and von Tabora (13).

In 8 subjects, catheterization of the right renal vein was carried out for the determination of the percentage extraction of PAH by the kidney during abdominal pressurization. In this procedure, a constant plasma level of PAH (1 to 2 mgm. per cent) was established. Samples of blood were obtained simultaneously from the right renal vein and from a peripheral vein in the arm opposite to that in which the infusion was administered. The extraction percentage was calculated by dividing the difference between the concentration of PAH in the peripheral and renal venous blood by its concentration in the peripheral blood. This value, the percentage of PAH removed from each milliliter of blood as it traverses the kidney, was determined before, during, and following application of abdominal pressure.

RESULTS

A. Alterations in renal blood flow and glomerular filtration during abdominal compression

1. *Intra-abdominal pressure and renal venous pressure*

When the rubber bladder of the abdominal pressure cuff was inflated with air at pressures between 70 and 80 mm. Hg, it was found that intra-abdominal pressure measured at various locations within the abdomen averaged 20 mm. Hg, within a very small range. This value was determined with a saline or Hamilton manometer in the stomach, duodenum, and rectum by means of the Miller-Abbott tube (6), and in the bladder and renal pelvis by catheters. Such a uniform elevation of pressure throughout the confines of the abdomen provided evidence in support of the view that the abdomen and its contents could be considered as relatively non-compressible and fluid in character, behaving in accordance with Pascal's law. The difference in pressure between the cuff and the peritoneal cavity probably resulted from the resistance to compression by the abdominal wall and from the resistance to extension of pressure by the diaphragm.

The pressure in the cuff represented, therefore, the average force exerted upon the anterior abdominal wall, and did not necessarily reflect the pressure within the abdominal cavity. As a matter of fact, the intra-abdominal pressure varied considerably depending upon the state of contraction of the abdominal musculature. Thus, the average figure of 20 mm. Hg was typical of complete relaxation, whereas pressures as high as 176 mm. Hg (Table I) were recorded from the renal vein during a strong "bearing down" contraction of abdominal muscles. Contrariwise, increased rigidity of the abdominal wall, in pushing away the inflated bladder, likely altered the transmission of

[3] The catheters used in this study were manufactured by the United States Catheter and Instrument Corporation, Glens Falls, New York. They are 100 centimeters long and terminate in a curved tip (Cournand tip) with 1 eye.

TABLE I

Intra-abdominal venous pressure before, during, and after abdominal compression

Pressure applied to anterior abdominal wall by pneumatic girdle at 80 mm. Hg. Venous pressure was measured with a saline manometer before, during, and after (recovery) the application of pressure. The pressures tabulated under "Strain" were obtained when the subject voluntarily increased his intra-abdominal pressure by a "bearing-down" maneuver, during the application of pressure.

cuff pressure into the abdominal cavity. In certain well-muscled individuals (J. Q., Table II) the absence of renal functional change during abdominal compression was ascribed to this factor.

Owing to the technical difficulties involved in measuring and maintaining constant intra-abdominal pressures, a constant compressional pressure was used during these studies, with the assumption that the averaged results could be discussed in terms of an average intra-abdominal pressure of 20 mm. Hg. This proceeding seemed justified since the voluntary effort of resisting the cuff was fatiguing and not usually sustained. Most subjects quickly adjusted themselves to the compression and relaxed.

Renal venous pressure partook in the generalized rise of intra-abdominal pressure. In 9 subjects (Table I) the control renal venous pressure of 5.8 mm. Hg increased to 18.3 mm. on the average. A similar increase of pressure in the upper portion of the inferior vena cava was observed twice (C. W. and O. C., Table I). It is probable that mean arterial pressure within the abdomen was not altered since extra-arterial pressures lower than diastolic pressure cannot affect intra-arterial mean pressure (14). Hence, the head of pressure at the beginning of the renal circuit probably did not rise during compression while the venous pressure increased 3- to 4-fold. Such a change in the gradient of pressure along the renal vascular tree might be expected to result in a reduction of renal blood flow. This expectation was borne out by clearance studies.

2. *The effective renal blood flow*

Figure 1 illustrates the renal hemodynamic response to abdominal compression. In this subject (J. S.), the effective renal plasma flow (sodium p-aminohippurate clearance, C_{PAH}) remained relatively unchanged during the control periods, but fell strikingly from an average of 827 ml. per minute to 270 ml. per minute during pres-

TABLE II

Effect of increased intra-abdominal pressure on renal plasma flow and glomerular filtration rate

All figures, with the exception of those marked with an asterisk, are averages of 2 or more periods.

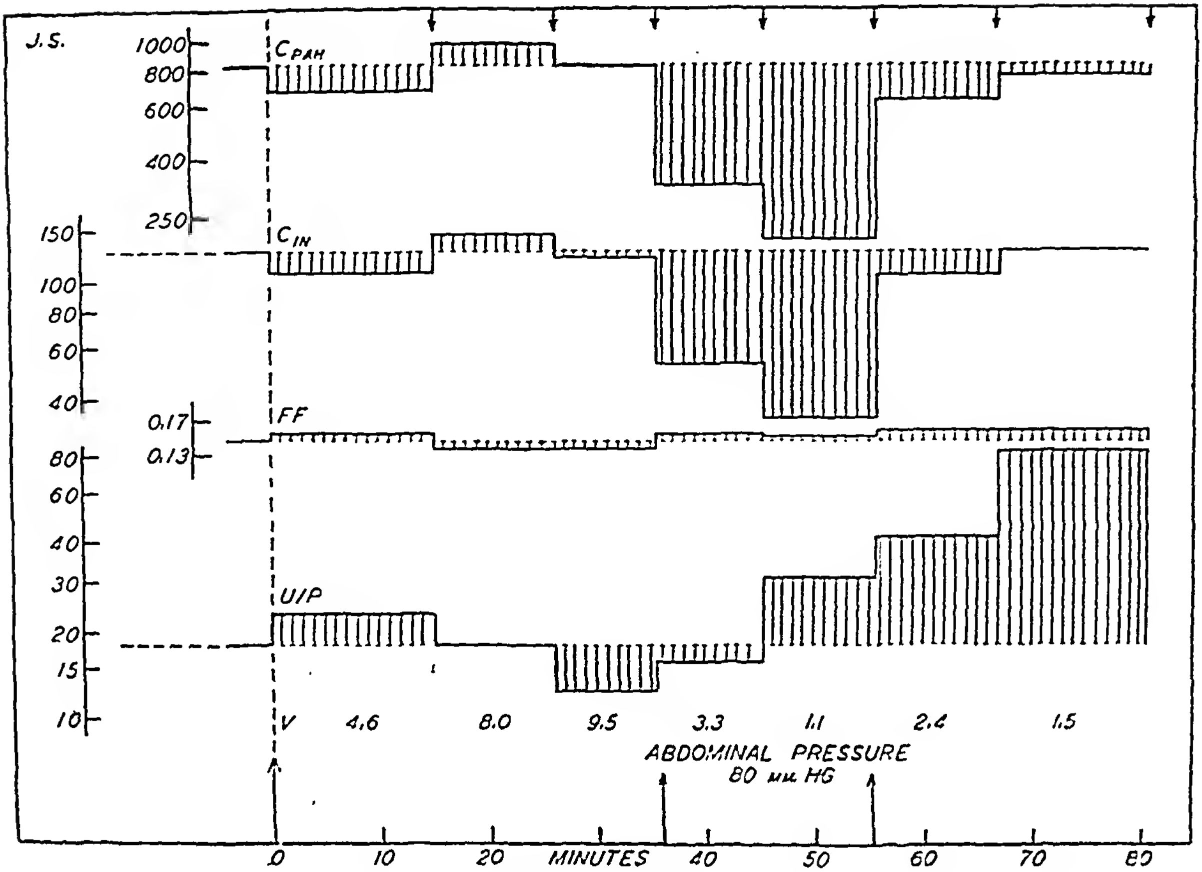

FIG. 1. ALTERATIONS IN EFFECTIVE RENAL PLASMA FLOW AND GLOMERULAR FILTRATION RATE DURING ABDOMINAL COMPRESSION IN SUBJECT J. S.

The effective renal plasma flow (ml. per min.) measured by the p-aminohippurate clearance (C_{PAH}) and the glomerular filtration rate (ml. per min.) measured by the inulin clearance (C_{IN}) were determined during the application of 80 mm. Hg pressure to the abdominal wall. The filtration fraction (FF), the percentage of plasma filtered (C_{IN}/C_{PAH}), remained unchanged throughout. During compression the concentration ratio of inulin (U/P) increased and continued to rise after the pressure was released. Urine flow (V) (ml. per min.) fell markedly. Arrows at the top of the chart indicate the time of urine collection.

surization. There was a rapid return to the control level following the release of pressure.

Likewise, in 7 of the 8 subjects (Table II) in which it was determined, the effective renal plasma flow was reduced, although the *average* reduction was not so large in the other subjects as in J. S. In several individuals, during 1 or more periods immediately after the application of the abdominal cuff, the reduction in effective renal plasma flow was as large as that seen in J. S., but these changes are minimized in the calculation of the average figure by the inclusion of periods in which evidence of circulatory readjustment was observed. In these subjects, where the time of observation was sufficiently prolonged (more than 30 minutes of compression), the effective renal plasma flow and other renal functions (4 of 10 studies) showed a return toward the control values despite continued compression.[4] Nevertheless, when all the figures were averaged disregarding this fact and including J. Q., in whom abdominal compression produced no change (possibly because of abdominal muscular resistance), it was found that effective renal plasma flow was reduced from 673 ml. per minute to 509 ml. per minute, an average reduction of 24.4 per cent.

[4] Figure 2 (J. W.) illustrates [illegible] of the maximal tubular [illegible] excretory rate [illegible] and the glomerular filtration rate [illegible] plasma [illegible]

It is noteworthy that renal hyperemia did not occur following the period of compressional ischemia. Occasionally very short urine periods collected immediately after release of pressure yielded high clearance values. These anomalous values may be attributed to a relatively larger contribution of dead-space urine to the total. Usually, however, high clearance values during recovery were absent. Indeed, the averaged figures of Table II reveal that effective renal plasma flow during recovery tended to be lower than during the control period. The absence of reactive hyperemia in the kidney observed during this study is in agreement with a large body of evidence obtained by others in the study of the renal circulation in man and other mammals (15, 16).

Proteinuria. It has been repeatedly demonstrated that a reduction of renal blood flow following obstruction to renal venous drainage is associated with the appearance of proteinuria (17). With abdominal pressure also, it was found that protein appeared in the urine in variable amounts. In 1 subject who had no history of previous renal disease and who was in good health, a 2 + proteinuria developed during the application of the abdominal cuff. On most occasions, however, the proteinuria was not striking, although it occurred regularly.

Validity of the method of renal blood flow measurement. It is possible that these changes in clearance values were caused by errors inherent in the method of measurement rather than by alterations of renal plasma flow. If pressure reduced the capacity of renal tubular cells to remove PAH from the blood, the clearance value would fall because of incomplete clearance of PAH. Or, if blood were shunted away from tubular tissue into the veins so that an opportunity for complete clearance were lacking, the clearance value might be decreased despite an absence of change (or even an increase) in blood flow.

The determination of renal PAH extraction, using the catheterization technique, provided the answer to this problem. The data summarized in Table III reveal that no change in PAH extraction occurred during compression. Hence, the clearance of PAH and, by analogy, of diodrast, provides an accurate measure of the behavior of renal plasma flow during increased abdominal pressure. In addition, the possibility that arteriovenous shunting occurs during increased pressure is excluded by this evidence.

Storage of PAH or diodrast during compression by nephrons that continue to be capable of excretory activity although unable to contribute to urine formation, might also introduce an error in the clearance determination that would elude detection in the measurement of the extraction ratio. However, this phenomenon would necessarily result in falsely high clearance values during recovery as a result of storage wash-out, and the relationship between calculated filtration rate and effective renal plasma flow would be thus altered artificially. This effect was never observed.

It appears that the clearance technique may be used with confidence under these conditions for the measurement of effective renal plasma flow, since extraction of PAH was not altered and storage probably did not occur.

3. *Glomerular filtration rate and filtration fraction*

The glomerular filtration rate was nearly always greatly reduced. Among the group collated in Table II, filtration fell to 88.4 ml. per minute (on the average) from the control level of 117.2 ml. per minute, a 27.5 per cent decrease. This observation was repeatedly confirmed in other studies in which renal plasma flow was not measured (see Table IV). Of particular significance is the fact that glomerular filtration was reduced to the same extent as the effective renal plasma flow. This equal percentile reduction was not a statistical accident but was observed whenever renal plasma flow decreased, as in Figure 1. Consequently, the ratio between filtration and plasma flow, the filtra-

TABLE IV

Effect of increased intra-abdominal pressure on urine flow and urinary concentration

The urinary concentration is expressed as the concentration ratio of inulin or mannitol calculated by dividing the urinary concentration by the plasma concentration. All U/P ratios are averages of 2 or more periods with the exception of those obtained during compression. These values are the maximal concentrations observed and they are presented with figures for filtration rate and urine flow determined simultaneously. All other values, except those marked with an asterisk, are averages of 2 or more periods.

tion fraction, or the percentage of plasma filtered at the glomerulus, remained constant. This fact is clearly shown in Figure 1 and Table II. Moreover, in most instances, the filtration fraction remained constant during adjustment to compression or during recovery.

B. *Tubular function during abdominal compression*

1. *Tubular reabsorption of water*

Urine flow decreased strikingly immediately after the application of abdominal compression in every subject (Table IV) even in the presence of diuresis during the control period. The reduction in filtration rate had little influence in producing this effect *per se*, since the urinary concentration usually increased markedly, indicating the operation of increased tubular water reabsorption as the cause of the oliguria.

In Table IV, the maximal concentration change is presented in terms of mannitol or inulin urine: plasma concentration ratios denoting the extent to which these substances are concentrated in the tubular urine by the active reabsorption of water.

All other substances examined likewise showed an increase in concentration.

There was no evidence favoring the possibility that ureteral obstruction by the compressing abdominal cuff might account for the oliguria. Following release of the cuff, the urine flow continued to be depressed in most instances. A sudden increase of urine flow following pressure release, due to the outflow of impounded urine, was never observed. Moreover, the change in clearance values and urine flow was observed on 2 occasions when the ureters were catheterized and pressure applied to the abdominal wall.

2. *Tubular transfer maxima (Tm)*

The maximal tubular reabsorption of glucose and the maximal tubular excretion of diodrast were reduced by abdominal compression (Tables V and VI). Glucose Tm was measured in 5 subjects. In 2 (J. Q. and M. E.), the Tm value was not significantly reduced, possibly because of reduced pressure transmission. In the remaining subjects, glucose Tm fell strikingly from 35 to 24.5 per cent on the average. Greater falls during individual periods are masked by the inclusion in the average value of periods in which readjustment had taken place. Among the subjects in whom diodrast Tm was determined, significant average reductions were noted on every occasion during compression. During the recovery phase, the Tm values returned to the control level and, on several occasions, somewhat above it, possibly as a result of dead-space error. It will be noted that the reduction ranged between 39 and 23.4 per cent. In all subjects, exclusive of those in whom no significant change was observed, *the average reduction of glucose and diodrast Tm was of the same order of magnitude as the average reduction of effective renal plasma flow and glomerular filtration.*

When the relation between filtration rate and the simultaneously determined Tm value was examined, it was found that the maximal tubular transfer of either glucose or diodrast varied more or less directly with the filtration. Figures 2 and 3 illustrate this relationship. It can be seen that the ratio between Tm and filtration rate remained relatively constant throughout. Table V reveals that this ratio did not change significantly on the average in the case of maximal tubular glucose reabsorption. In 2 of the 5 subjects in whom diodrast Tm was measured, however (Table VI), there was a significant depression of the ratio (L. R. and M. P.). In these instances the inclusion of high values observed in the control period and the possible operation of intra-renal vasoconstriction may have been responsible for the alteration. On the whole, it appeared that the maximal rate of tubular transfer of glucose and diodrast was reduced by abdominal compression to about the same extent as the glomerular filtration rate and effective renal plasma flow.

Validity of the methods of the measurement. The observed reduction in maximal tubular transfer capacity could be ascribed to inadequate loading of the intracellular mechanisms by glucose or

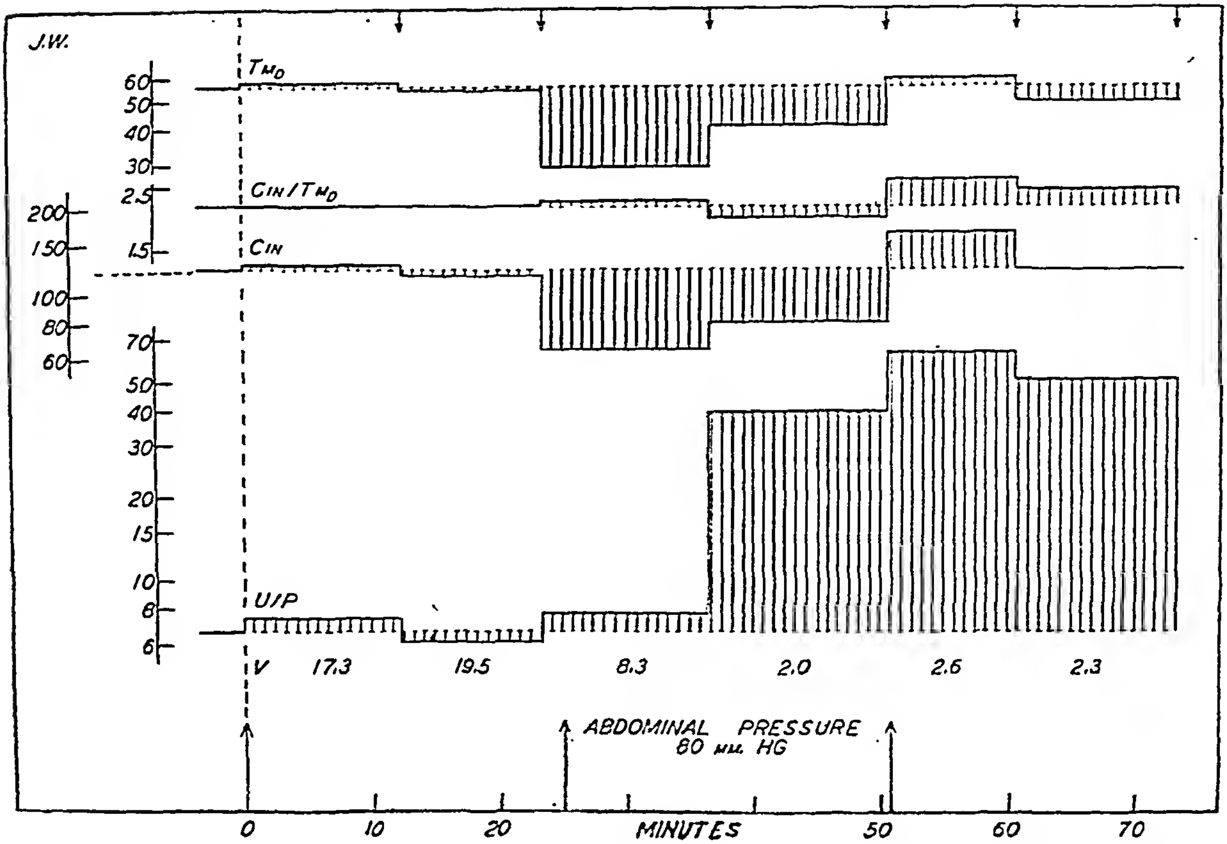

FIG. 2. ALTERATION IN MAXIMAL TUBULAR DIODRAST EXCRETORY RATE (DIODRAST TM) AND GLOMERULAR FILTRATION RATE DURING ABDOMINAL COMPRESSION IN SUBJECT J. W.

Diodrast Tm (Tm_D) (mgm. per min.) and glomerular filtration rate (C_{IN}) (ml. per min.) fell during increased intra-abdominal pressure while the inulin U/P ratio rose. The relation between glomerular filtration rate and diodrast Tm (C_{IN}/Tm_D) remained unchanged throughout. It can be seen that both diodrast Tm and the filtration rate increased late in the period of pressure application. Urine flow (V) (ml. per min.) was markedly depressed.

diodrast, either as a result of over-all renal ischemia and lowered filtration rate or focal ischemia and localized slowing of filtration. In the first instance, the smaller carriage of diodrast or glucose would result in a failure to supply sufficient material for saturation of the whole kidney and, in the second, adequate over-all loading would mask focal ischemia and failure to saturate tubular transfer mechanisms in discrete localized regions.

a. over-all loading. The calculated load of glucose presented to the tubules for reabsorption should exceed the tubular capacity by 20 per cent and the quantity of diodrast carried in the plasma to the tubules [3] should exceed the excretory capacity by 100 per cent (8) to assure adequate saturation. In every instance the load to Tm ratio for glucose was greater than 1.2 (Table V). On 2 occasions (M. S. and L. R.), the diodrast load fell below the prescribed limit (Table VI). Considering the fact that the decrements in diodrast Tm in

[3] The load of glucose brought in the glomerular filtrate to the tubule cells for reabsorption was calculated as the arterial plasma concentration of glucose (mgm. per ml.) times the filtration rate (ml. per min.). The diodrast load is the amount of diodrast carried in the plasma to the tubules less that removed by filtration. It was calculated as the plasma concentration of diodrast (mgm. per ml.) times the estimated effective renal plasma flow, less the plasma concentration of diodrast (mgm. per ml.) multiplied by the filtration rate (ml. per min.) and a factor (0.72) to correct for protein binding. Since effective renal plasma flow cannot be determined at high plasma levels of diodrast, it was estimated on the basis of the observed filtration rate, assuming a normal value of 20 per cent for the filtration fraction.

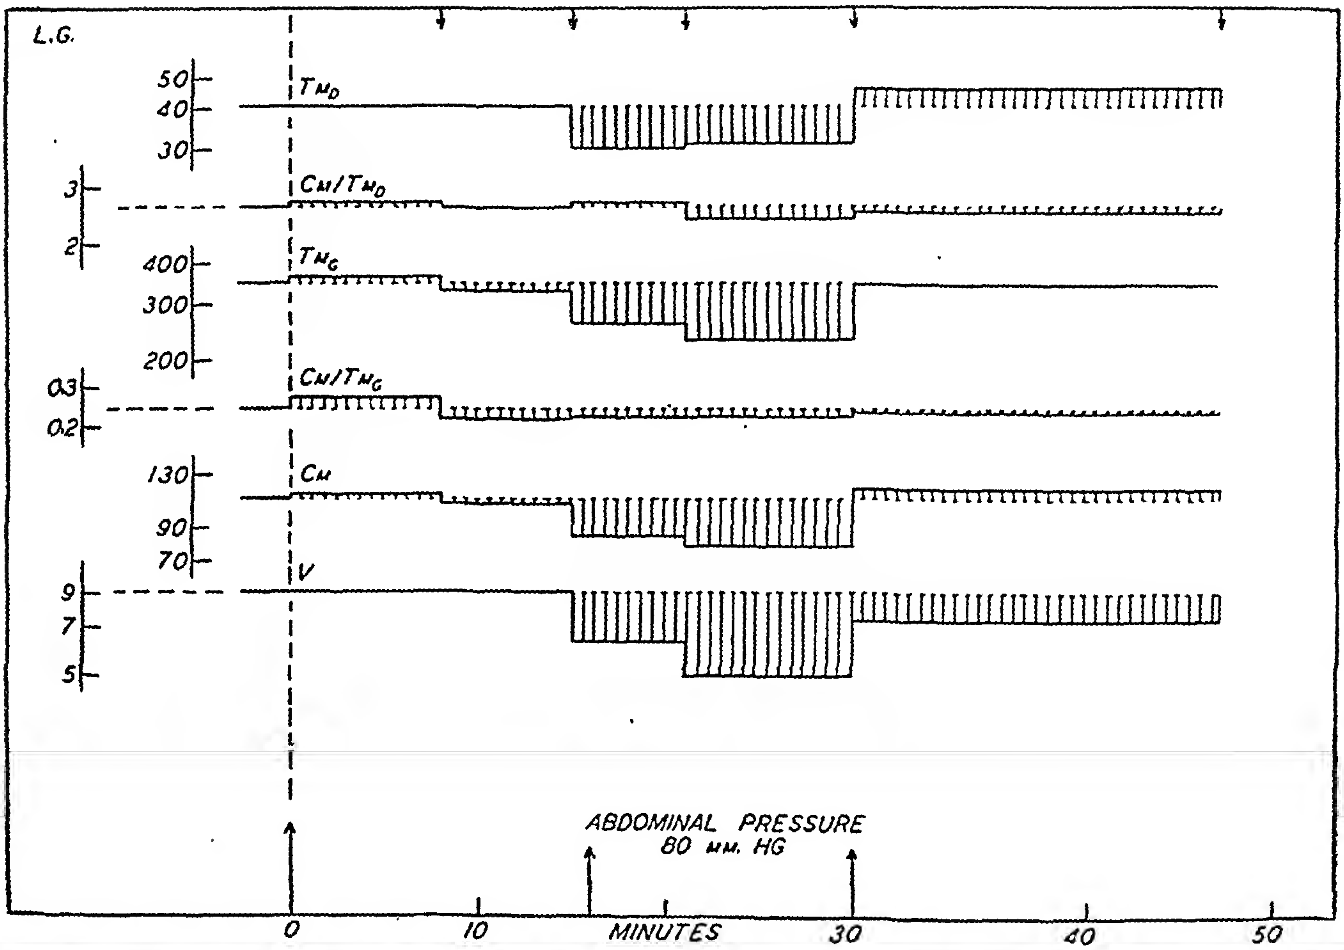

FIG. 3. ALTERATIONS OF MAXIMAL TUBULAR DIODRAST EXCRETORY RATE (DIODRAST TM) AND MAXIMAL TUBULAR GLUCOSE REABSORPTION RATE (GLUCOSE TM) DURING ABDOMINAL COMPRESSION IN SUBJECT L. G.

Diodrast Tm (Tm_D) (mgm. per min.) and glucose Tm (Tm_G) (mgm. per min.) fell equally during compression. *The relationships between the Tm values and the glomerular filtration rate measured by the mannitol clearance* (C_M) remained constant. Urine flow (V) decreased, but returned toward the control level following the termination of the period of pressure.

these cases during pressure were of the same magnitude as those where the calculated loads were sufficiently high, it is possible that the calculated loads were erroneous. The calculation of diodrast load requires an estimation of the renal plasma flow on the basis of the filtration rate, assuming a normal filtration fraction of 20 per cent. It is not unlikely that this assumption was in error in these instances and that the actual plasma flow was much greater. In any case, it is evident that inadequate loading cannot be the cause of the reduction in tubular activity during increased intra-abdominal pressure in most of these studies.

b. focal loading. Despite the demonstration that adequate loading did not prevent the fall in Tm observed during pressure, it might be argued that these figures, referable to the kidney as a whole, may fail to reveal focal inadequacies. This argument may be visualized and examined as follows.

For the purposes of discussion, the kidney may be divided into 4 concentric zones (Table VII)

TABLE VII

Zone	Reduction	Filtration rate	Plasma flow	Load glucose	Reabsorbed glucose	Load diodrast	Excreted diodrast
		ml. per min.	*ml. per min.*	*mgm. per min.*	*mgm. per min.*	*mgm. per min.*	*mgm. per min.*
I	80%	6	25.0	36	36	6.3	6.3
II	50%	15	62.5	90	90	15.5	13.0
III	10%	27	112.5	162	100	27.8	13.0

Over-all effect	35%	78	325.0	468	326	80.6	45.3
Total reduction	35%	35%	35%		18.4%		12.9%

throughout each of which blood flow and filtration are regularly distributed, although great differences may exist between zones.[6] It may be further assumed that the effect of compression is different in each zone (as the result of a gradient of pressure, for example, so that the compressional force is greater at the periphery than at the center), but that the effect in each zone is constant and regular throughout the entire region. During the control period, prior to compression, the over-all glomerular filtration rate, blood flow and transfer maxima of glucose and diodrast are equally divided among all the zones. The over-all glomerular filtration rate may be taken as 120 ml. per minute, the renal plasma flow as 500 ml. per minute, glucose Tm, 400 mgm. per minute, and diodrast Tm, 52 mgm. per minute, while the glucose and diodrast plasma levels are maintained at 600 mgm. per cent and 30 mgm. per cent, respectively. With the application of a compressional force, the plasma flow and filtration rate may be assumed to undergo reductions of 80, 50, 10, and 0 per cent in zones I to IV, respectively. The data tabulated in Table VII reveal that the percentile reductions in over-all Tm thus produced do not equal the percentile reductions in plasma flow and filtration rate, and the reductions in diodrast and glucose Tm are not equivalent. The discrepancy in Tm values could be expected to vary greatly, depending upon the relative loading of the 2 tubular mechanisms. Therefore, it appears that the changes in tubular function observed during abdominal compression cannot be ascribed to focal ischemia due either to focal vasoconstrictive activity or to the operation of a gradient of pressure across the kidney.

DISCUSSION

It has been found that abdominal compression increases the pressure equally throughout the abdominal cavity and in doing so produces striking renal functional changes. Renal plasma flow and glomerular filtration are almost always reduced, together with the tubular activities of maximal glucose reabsorption and maximal diodrast excretion. All these functions are reduced to the same degree. Water reabsorption, on the other hand, is always enhanced, the urine flow decreases, and the urine becomes more concentrated.

Every effort was made to eliminate experimental error. Determinations of the renal extraction of sodium p-aminohippurate have validated the use of the clearance technique in measuring the changes of renal blood flow. Arteriovenous shunting has been definitely ruled out by this method. Likewise, the alterations in glucose and diodrast Tm may be accepted as indicative of changes in tubular function, since it appears that inadequate loading or focal ischemia may be excluded as possible misleading factors.

On the basis of the averaged data, it seems likely that the increase of venous pressure during abdominal compression is usually sufficient to account for the reduction of renal plasma flow. Excluding J. S. and J. Q. (Table II) from consideration, the averaged figures may be used in calculating the reduction to be expected on the basis of an increment of venous pressure alone.[7] If the pressure gradient across the renal circuit is assumed to change from 85 mm. Hg to 70 mm. Hg during compression as a result of an increase of renal venous pressure from 5 mm. Hg to 20 mm. Hg (the mean renal arterial pressure remaining constant at 90 mm. Hg), and, if the renal resistance does not change, the average renal plasma flow of 621 ml. per minute would fall to 512 ml. per minute. Actually, it was observed to fall to 488 ml. per minute, a somewhat greater decrease, which would require a venous pressure increment of 18 mm. Hg. It can be seen that the elevation of venous pressure alone is approximately sufficient to account for the observed change.

The reduction of renal plasma flow was much greater than average immediately following the application of pressure in many subjects and

[6] It is obvious that the kidney may be further subdivided until each zone refers to a single nephron. Hence, what is said here with reference to 4 arbitrary and regularly placed renal zones would apply with equal force to discrete units distributed irregularly through the kidney.

[7] In any vascular bed of constant resistance, the relation of blood or plasma flow to the loss of pressure from the beginning to the end of the circuit remains constant. This relationship may be expressed as follows, where F is the initial renal plasma flow; P, the initial difference in renal arterial and renal venous pressures; F' and P', these values when the pressure difference has been altered as with an increment of venous pressure

$$F'/F = P'/P \text{ and}$$
$$F' = P'F/P$$

throughout the entire study in J. S. Although these facts may indicate the operation of vasoconstriction, it is not at all unlikely that venous pressure, in these instances, was higher than average as a result of compressional contraction of the abdominal musculature. The intra-abdominal pressure may be raised as high as the arterial pressure by this maneuver. On the other hand, muscular contraction may lower intra-abdominal pressure by thrusting away the pressure girdle, and it is possible that the adjustment to compression noted in some instances, where renal function gradually improved, may have arisen from this factor rather than from the release of vasoconstriction.

Although the increase in renal venous pressure seems to provide an adequate cause for the reduction in renal blood flow, it is at first difficult to account for the other changes in renal function on this basis. Certainly one might expect a change in filtration fraction similar to that attributed to efferent arteriolar vasoconstriction (18), since the elevation of the pressure gradient in the renal vascular bed should increase effective filtration pressure and the filtration rate should remain relatively constant despite the reduction in blood flow. Since an increment of venous pressure is equally effective in all parts of the renal vascular bed, there is no reason to expect a fall in diodrast and glucose Tm. The fall in these values indicates the cessation of function in a number of nephrons and glomeruli proportional to the decrement in Tm (19).

The closure of afferent arterioles would produce changes in renal function similar to those observed. In obstructing blood flow, arteriolar closure would halt filtration in the glomerulus and, in consequence, abolish glucose reabsorption and diodrast excretion in the nephron dependent upon it. Although the tubule might remain in a normal state, it is obvious that glucose would no longer be brought to it for removal and that excreted diodrast would not be washed into the renal pelvis. Hence, the nephron would cease to contribute to Tm and the values for it would be reduced. In the remainder of the kidney, renal blood flow and glomerular filtration rate must continue undisturbed, since the filtration fraction and the relation between the clearance values and Tm are not altered by compression. Thus, afferent arterioles would be required to close completely or remain unconstricted. While this hypothesis satisfactorily accounts for many of the changes in renal function, it fails to consider the implications of the elevation of venous pressure.

It has been pointed out above that the increase in venous pressure is probably sufficient to account for the observed reduction in renal blood flow, but, under the conditions of afferent arteriolar constriction, it would be necessary to assume that increased resistance to flow is entirely responsible and that the venous pressure increment is without effect. It must be admitted, however, that diminished resistance in the remainder of the renal vascular bed is necessary to offset the rise in venous pressure. If such a vasodilation occurred in the efferent arterioles it is possible that blood flow and filtration rate might maintain a constant relationship to one another and to the Tm values as observed. However, it seems extremely unlikely that both vasoconstriction and vasodilation occur simultaneously in the kidney. An adjustment of efferent arteriolar tone in response to renal venous pressure has not been observed in other conditions, and it seems highly improbable that it occurs during abdominal compression. For these reasons the hypothesis that afferent arteriolar vasoconstriction results in functional amputation of a portion of the renal parenchyma may be dismissed as unacceptable.

In the discussion thus far, the fact that the pressure rises in the renal pelvis, opposing the outflow of urine, has not been considered. If the resistance to the flow of urine differs in different nephrons (as it may, since the tubules vary considerably in length), there may be a wide range of pressures at the terminal ends of the tubules. Elevation of pelvic pressure would then block urine outflow from those tubules in which the terminal pressures are lower than pelvic pressure. As a result, Tm values and the glomerular filtration rate would fall. In this situation the blood perfusing inactive glomeruli would continue to be cleared of diodrast or p-aminohippurate by neighboring operative tubules and the filtration fraction would *fall* as a result of the reduction of filtration rate independently of blood flow. Since the renal venous pressure rises during abdominal compression, however, the filtration fraction in the active glomeruli would be *increased* and might be expected to mask the

effect of the clearance of diodrast or p-aminohippurate from blood perfusing inactive glomeruli.

This hypothesis has the advantage of providing a simple explanation for all the changes observed in this study. Vasoconstriction would be unnecessary, the fall in blood flow being entirely accounted for by the increment in renal venous pressure. The demonstration by others (18) that the filtration rate in man tends to remain unchanged is supported by the finding that it does not change in the residual active glomeruli. Such reduction of filtration rate and Tm values as occurs is entirely attributable to the blockage of flow from "low-pressure" nephrons by the elevated pelvic pressure. It should be noted that equal elevations in renal venous pressure and pelvic pressure produce equal percentile changes in renal blood flow and in the mass of functioning tubular tissue, respectively, according to this hypothesis. The implications of such a relationship are not clear and are under further investigation.

Increased intrapelvic and intratubular pressure may be instrumental in raising the urinary concentration by stimulating the mechanisms of water transfer to greater activity. However, the psychic and physical stimulus of compression should provoke the release of antidiuretic hormone by the pituitary, since less severe stimuli have been found to have this action (20). In 1 subject with documented diabetes insipidus presenting marked diuresis as a result of withdrawal of pitressin, abdominal compression caused oliguria.

The pathological renal physiology of increased intra-abdominal pressure has been clarified by this study. Under the conditions imposed, retention of water and probably of salt occurs in spite of the presence of factors conducive to diuresis. The reduction of glomerular filtration rate and oliguria, if maintained for any length of time, would certainly prevent the normal excretion of urea, and azotemia would develop.

For the short period of time during which positive G is experienced by airmen, abdominal compression sustains the cardiac output by the expression of blood into the thorax from the abdomen and by minimizing the gravitational effects upon the flow of blood from the inferior venous chamber into the superior chamber. The simultaneous reduction of arterial blood flow into the splanchnic bed also results in the diversion of a greater proportion of the cardiac output to the brain. It is likely that prolonged application of increased intra-abdominal pressure may be detrimental because the cardiac output is ultimately reduced by about the same extent as the blood flow through the kidneys and liver (21, 22). Hypotension and faintness were observed on several occasions during the course of this study in subjects not reported herein.

SUMMARY

The effective renal plasma flow, glomerular filtration rate, and tubular function have been measured in 17 normal human subjects by the clearance and saturation techniques during the application of a pneumatic abdominal girdle under pressure. Measurement of the venous pressure in the inferior vena cava and renal vein following venous catheterization revealed that the compressional pressure of 80 mm. Hg used in this study raised intra-abdominal venous pressure to about 20 mm. Hg.

The effective renal plasma flow and glomerular filtration rate were always reduced by increased intra-abdominal pressure, on the average of 24.4 per cent and 27.5 per cent, respectively. The filtration fraction, or the percentage of the plasma flow filtered at the glomerulus, showed no significant change.

It was found that the elevation of renal venous pressure was probably sufficient to account for the reduction of renal plasma flow.

The extraction of sodium p-aminohippurate by the kidney was not altered, indicating the validity of the clearance method for measuring renal plasma flow under these conditions and demonstrating the absence of arteriovenous shunting.

Maximal tubular diodrast excretion (diodrast Tm) was reduced significantly in all 5 subjects, while maximal tubular glucose reabsorption (glucose Tm) fell significantly in 3. The percentile decrease in both values was equal to that in effective renal plasma flow and glomerular filtration rate. It appears that this phenomenon cannot be attributed to inadequate loading of tubular transfer mechanisms, as a result of either diffuse or focal ischemia.

The theoretical implications of these findings are discussed.

THE DIALYZABILITY OF THE PRESSOR AND ANTIDIURETIC ACTIVITIES OF PITRESSIN

By WAYNE DONALDSON

(*From the Research Laboratories, Parke, Davis and Company, Detroit, Michigan*)

(Received for publication April 4, 1947)

According to the present extent of our knowledge it appears that the pressor and the antidiuretic activities of Pitressin[1] both reside in the same substance. Since Kamm (1) showed that the pressor activity dialyzes from aqueous solution, the antidiuretic activity should dialyze also. But Ralli (2) found that when Pitressin mixed with normal urine was dialyzed against water the full antidiuretic activity for rats remained in the non-dialyzable fraction. This suggested that urine might in some way inhibit the dialysis of Pitressin. On the other hand, if pressor activity dialyzes and antidiuretic does not, dialysis would provide a means of separating the 2 activities.

Others (3) have reported that antidiuretic activity does not dialyze. However, Smith (4) early showed that all 3 posterior pituitary activities dialyzed, and Walker (5) demonstrated the presence of antidiuretic activity in the dialysate.

The purpose of the present experiment is to report the pressor activity for dogs and the antidiuretic activity for humans of the non-dialyzable residue following dialysis of Pitressin mixed with water and mixed with normal urine. The results suggest that both the pressor and the antidiuretic activities do dialyze, whether mixed with water or with urine.

PREPARATION OF SOLUTIONS

Five tests were made on each of 4 human subjects using the following preparations:

A. No injection—control
B. Pitressin (not dialyzed)
C. Pitressin dialyzed from water
D. Pitressin dialyzed from urine I
E. Pitressin dialyzed from urine II

Solution C. Twenty-five ml. of Pitressin containing 20 p.u. per ml. (total 500; p.u. = pressor units) was dialyzed for 6 hours in 24/32 inch Visking tubing against running distilled water at room temperature and with agitation of the tubing. The dialysis residue was diluted to 100 ml. with water containing 0.5 per cent chloretone. The solution (representing 5 p.u. per ml.) was filtered through a Seitz filter using a 1-inch E.K. pad.

Solution B. With no dialysis, 25 ml. of Pitressin was diluted in the same way and subjected to the same Seitz filtration. This filtration of the control would make it possible to detect any adsorption of pressor or antidiuretic activity by the filter pad.

Solution D. Ten ml. (200 p.u.) of Pitressin was mixed with 26 ml. of diuretic urine from a normal human being. This urine contained 2.41 mgm. of solids per milliliter. The mixture was dialyzed as above; the dialysis residue was made to 40 ml. with water and Seitz filtered. The final solution represented 5 p.u. per ml.

Solution E. To eliminate the possibility that the urine effect described by Ralli was quantitatively dependent on some urinary constituent, it seemed desirable to increase the ratio of urinary solids to pressor units. Ten ml. (200 p.u.) of Pitressin was mixed with 1,000 ml. of normal human urine having pH 5.82, solids 36.6 mgm. per ml. This solution was dialyzed overnight (17 hours) to specific resistance 14,100 ohms and pH 6.05. One-fourth of the dialysis residue was dried by appropriate means, and the resulting powder was taken up in 10 ml. of sterile water containing chloretone. The preparation was an amber liquid containing suspended material. Each milliliter represented 5 p.u. and 25 ml. of the normal urine.

PROCEDURE

The antidiuretic activity was tested in 4 normal human subjects who continued their usual work during the test period. Each solution was tested in all 4 subjects on the same day. No food or water was taken after 10 p.m. of the preceding night, the bladder was emptied at 8 a.m., the test solution was injected, and 1,000 ml. of water was taken by mouth at the same time. The dose in each case was 0.1 ml. representing 0.5 p.u., which was given into the muscle of the upper arm. Urine was voided at 30-minute intervals and the cumulative excretion plotted against time as shown in Figure 1. Each solution was also assayed for pressor activity in dogs.

RESULTS

In every subject urine excretion was significantly delayed by 0.5 p.u. of undialyzed Pitressin, as shown in Figure 1. On the other hand, none of the dialyzed samples, whether from water or urine, resulted in a comparable delaying effect; the effect

[1] Pitressin is a registered trade mark of Parke, Davis and Company.

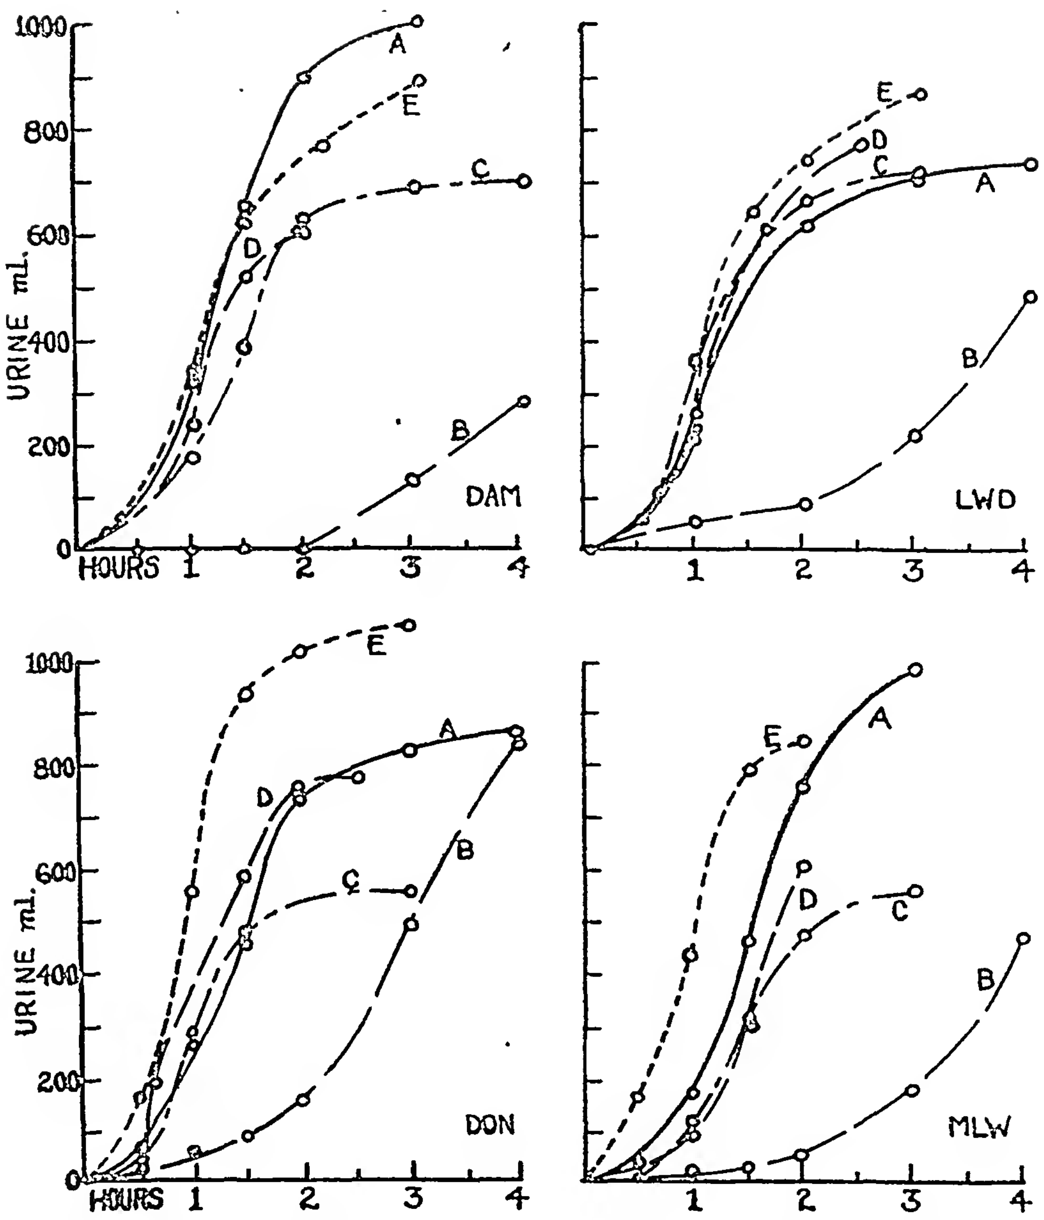

Fig. 1. Effect of Dialysis on Antidiuretic Activity of Pitressin Solutions

A. No injection—control.
B. Pitressin not dialyzed.
C. Pitressin dialyzed from water.
D. Pitressin dialyzed from urine I.
E. Pitressin dialyzed from urine II.

of such samples was more nearly like that of "no injection."

The pressor assay report was as follows:

B. Pitressin. Not dialyzed— 4.5 p.u. per ml.
C. Pitressin dialyzed from water— Much less than 0.1 p.u. per ml.
D. Pitressin dialyzed from urine I— Less than 0.1 p.u. per ml.
E. Pitressin dialyzed from urine II— Less than 0.1 p.u. per ml.

Thus, the pressor activity remained in the undialyzed preparation, but was lost from all dialyzed solutions.

CONCLUSIONS

When mixtures of Pitressin with water or with urine were dialyzed, both the pressor and antidiuretic activities disappeared from the dialysis residue.

The author wishes to express appreciation to Dr. D. A. McGinty for helpful suggestions, to Mr. L. W. Rowe for pressor assays, to Miss M. L. Wilson, Mr. D. C. Neubaum and Miss S. C. McKinsey for technical assistance.

PROTEINS IN THE COLLOIDAL GOLD REACTION

By JOSEPH BERNSOHN and EARLE K. BORMAN

(From the Bureau of Laboratories, Connecticut State Department of Health, Hartford, Connecticut)

(Received for publication April 5, 1947)

The colloidal gold test developed almost 35 years ago by Lange (1) has been utilized in studies of cerebrospinal pathology and of liver dysfunction with little more than a general understanding of the basic reasons for the production of the several reaction patterns. Rationalization of the mode of reaction by experimenting with blood protein fractions obtained by the usual salting out methods is difficult, if not impossible, because the fractions so obtained are mixtures (2) of proteins defined arbitrarily.

A promising line of attack upon the problem has been opened up by newer methods for the separation of the blood proteins (3, 4, 5), particularly those separable as electrophoretically homogeneous fractions. It has already been established (6, 7) that the gamma globulin fraction is responsible for the coagulation of the gold sol. The protective action postulated for the serum albumin, however, never has been demonstrated conclusively with concentrations likely to be encountered in body fluids. In investigating the use of the colloidal gold reaction for the detection of liver damage, the authors have used blood protein fractions prepared by the newer methods in an attempt to determine the relationships between relative concentrations of the protein fractions and the reaction curves obtained.

MATERIALS

The blood protein fractions[1] used in this study were described as follows:

Fraction	Plasma preparation no.	Distribution of electrophoretic components						
		γ	F	β_2	β_1	α_2	α_1	Alb.
II–1,2	184	96		4				
V	185					1	2	97
III–0 total*	175		18	13	64	5		
IV–1*	185			9		18	40	33‡
IV–3,4†	184			2	35	26	21	16

* Rich in lipoprotein.
† Poor in lipoprotein.
‡ Figures for albumin and α_1 are approximate due to difficulty in resolving fraction.

METHODS

The methods of preparing the gold sol and performing the tests were those recently described by Lange (8, 9, 10). Thus, the tests were performed with comparable gold sols on dilutions of experimental material in phosphate buffer, pH 7.4, and the results were read by comparison with prepared standards of graded color values.

In all cases, the plasma protein fractions were prepared in desired concentrations by dissolving them in the phosphate buffer. In later phases of the investigation, concentrations were based upon protein content as calculated from Kjeldahl determinations ($N \times 6.25$).[2]

In performing the tests, serial dilutions of each solution under test, 0.5 ml. per tube, were prepared in such manner that the dilutions increased by one-third with each successive tube. To each of these, 2.5 ml. of colloidal gold sol were added and the tubes were shaken and allowed to stand at room temperature for 2 hours. Readings were then made against a graded series of standards varying from 0 (unchanged) to 20 (colorless) after the manner suggested by Lange (8).

RESULTS

Figure 1 shows graphically the differing effects of equivalent concentrations of the several protein fractions upon the gold sol. These graphs have been plotted for each fraction from results obtained on 20 serial dilutions prepared after the manner described above. The horizontal axes of these

[1] The products of plasma fractionation employed in this work were developed from blood, collected by the American Red Cross, by the Department of Physical Chemistry, Harvard Medical School, Boston, Massachusetts, under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University. The authors wish to express their gratitude to Dr. John T. Edsall of Harvard University who furnished these materials.

[2] The use of the conventional nitrogen factor for fractions containing alpha and beta globulins with lipids results in some inaccuracy.

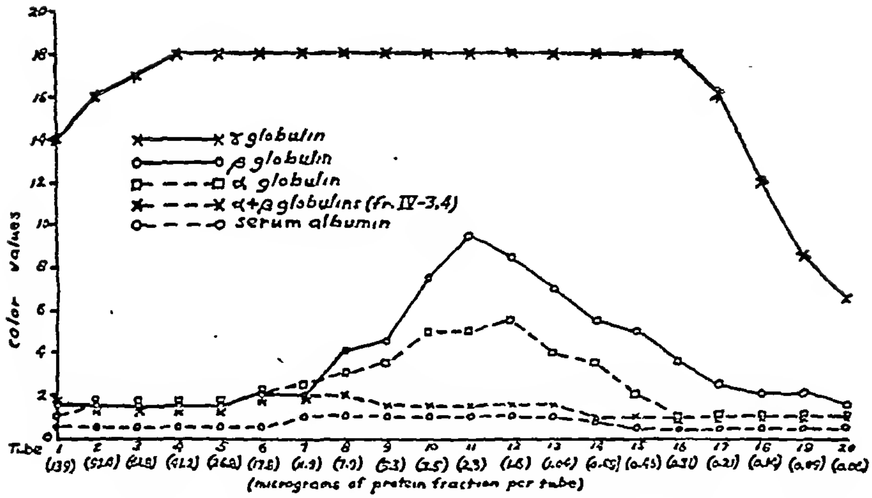

FIG. 1. EFFECT OF PROTEIN FRACTIONS ON 2.5 ML. GOLD SOL (pH 7.4)

graphs and of those to follow show uniform spacings between successive dilutions; this gives the same effect as a semi-logarithmic scale with the abscissa showing the logarithms of increasing dilutions. It will be noted that neither serum albumin nor fraction IV-3,4 containing a mixture of alpha and beta globulins exerted any significant coagulatory effect upon the gold sol whereas the gamma globulin was the only fraction with unequivocally coagulatory effects. Fractions III-0 and IV-1, one containing alpha globulin and the other beta globulin, showed such slight reactivity in the range of concentrations between 1 and 5 μg. per tube that it seems unlikely that this resulted from any specific coagulatory effect exerted by these globulins *per se*. Such minimal activity is more likely to have resulted from the presence of other substances in these mixtures. Likewise, the possible role of impurities in the gamma globulin fraction acting as protective colloids cannot be ignored entirely in the interpretation of the apparent slight protection of the sol by concentrations of that fraction above 60 μg. per tube.

Figure 2 shows the apparent effect of serum albumin upon the coagulatory action of the gamma globulin fraction. Critical analysis of the graphs shows that the protective action of this fraction is nil[3] since the critical point at which the coagula-

[3] Since these experiments were completed Lange has published data obtained with the use of horse serum al-

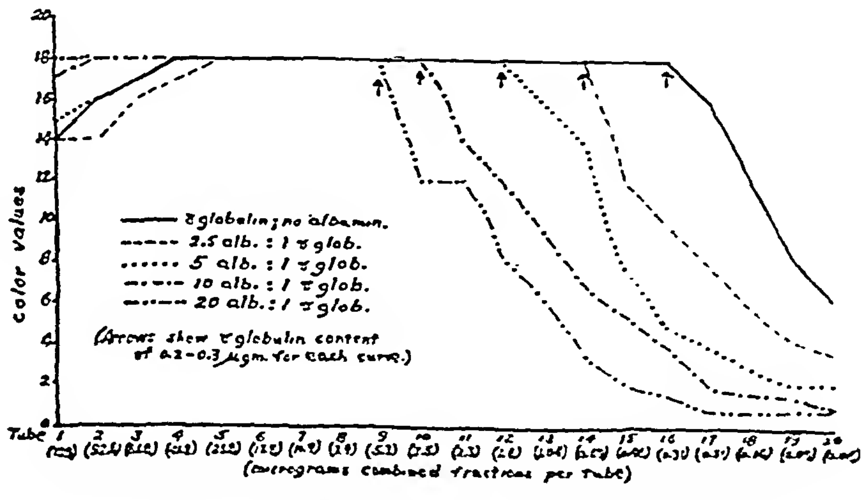

FIG. 2. EFFECT OF SERUM ALBUMIN ON γ GLOBULIN CURVE (pH 7.4)

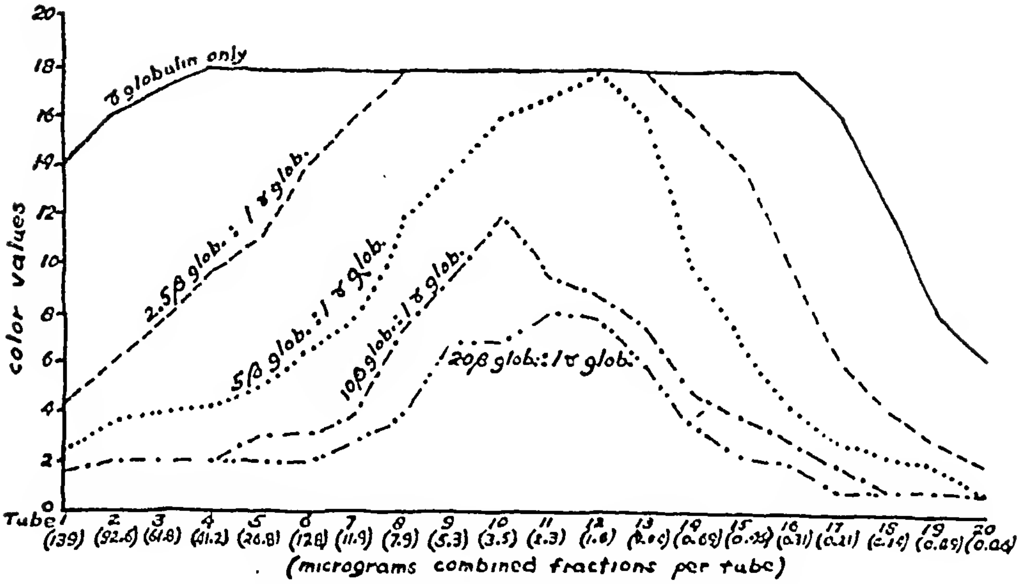

FIG. 3. EFFECT OF β GLOBULIN (FR. III-0) ON γ GLOBULIN CURVE (pH 7.4)

tory reaction diminishes sharply is determined by the actual amount of gamma globulin present in the tube and not upon the albumin to globulin ratio. This critical point is reached when the concentration of gamma globulin drops below 0.3 μg. per 2.5 ml. of gold sol as shown by notations on the chart.

The effect of the lipoprotein fraction III-0 (beta globulin) upon the coagulatory action of the gamma globulin fraction was in marked contrast to that produced by serum albumin. This is shown graphically in Figure 3. Here 2 manifestations of protective action are indicated plainly: (*1*) Progressive inhibition of coagulatory action of gamma globulin with increasing beta to gamma ratios shown in the graph by longer prozones with ratios of 5: 1 and below, and (*2*) suppression of the ability of gamma globulin to induce complete coagulation of the gold sol as shown by the occurrence of intermediate maximum color values when the ratios rose to 10: 1 and above. In this series of graphs, the existence of a critical point (or concentration) beyond which the coagulatory action of gamma globulin suddenly diminishes with decreasing concentration is again apparent. Except for the graph illustrating the results with a beta to gamma ratio of 20: 1, this is seen to occur at a concentration of 0.3 μg. gamma globulin per 2.5 ml. gold sol. The discrepancy shown in the graph of the 20: 1 ratio may be due to technical error since it represents a single determination.

Protective action was also evidenced by fraction IV-1 (alpha globulin) but was somewhat less than that exhibited by beta globulin.

Since fraction IV-3,4 (mixed alpha and beta globulins) contained relatively little lipid as compared with both the fraction labeled alpha globulin and that labeled beta globulin, its protective action

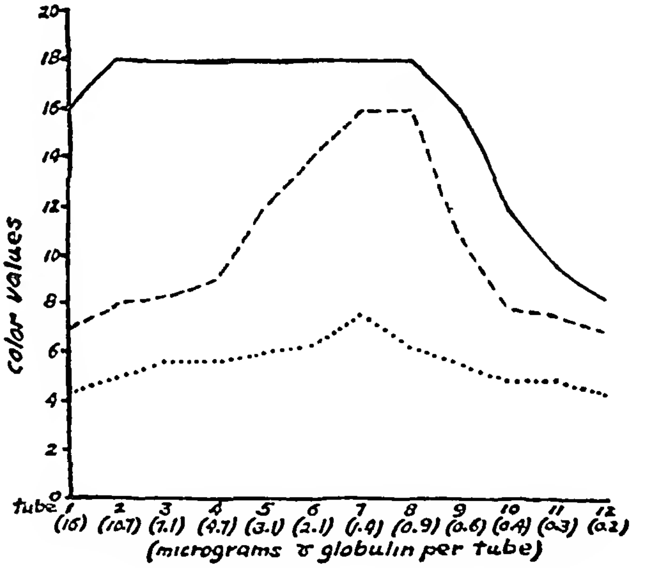

FIG. 4. PROTECTIVE ACTION OF FRACTION IV-3,4 ($\alpha\beta$) (pH 7.4)

bumin subjected to repeated salting out with $(NH_4)_2SO_4$ which substantiate this observation—*cf.* C. Lange, Theory of the colloidal gold reaction. I. Reactions between gold sol and isolated protein fractions. J. Lab. and Clin. Med., 1945, 30, 1006.

was investigated and results were obtained as shown in Figure 4. The protein concentrations used for this series of tests were adjusted on the basis of Kjeldahl determinations (N × 6.25). The graphs show an effect similar to that produced by the protective action of the beta globulin fraction but somewhat more pronounced. In addition, the smallest concentration of gamma globulin capable of producing maximum coagulation of the sol in the presence of this fraction was about 3 times greater than that noted in previous experiments. These results appear to indicate that the lipid material bound to the proteins in fractions III-0 and IV-1 played no important role in the protective action of those fractions.

The authors have tried, by combining the fractions in various proportions, to reproduce the curve obtained when diluted normal blood serum (pool of 20 serums) reacts upon a colloidal gold sol. In making these trials it has been assumed that 0.5 ml. of a 1:300 dilution of normal serum contains about 16 μg. of gamma globulin. The normal serum curve shows its maximum, nearly colorless reaction at a dilution of 1:17,000 (about 0.3 μg. gamma globulin). The initial dilution of 1:300 shows but a slight reaction indicating a high degree of protection, while less protection occurs as the dilution increases until the maximum coagulation occurs. In serial dilutions above 1:17,000 the reaction diminishes rapidly. While similar curves have been obtained with some "artificial serums," these all contained greater quantities of the protective proteins than normal serum. In fact, ratios of protective globulin fractions to gamma globulin as high as 3:1 did not show so great protective action as that apparent in normal serum.

DISCUSSION

The experiments reported have been performed in the presence of a uniform hydrogen ion concentration. The authors have unpublished data indicating that blood proteins other than gamma globulin will act as coagulants in the colloidal gold test at pH's on the acid side of their respective isoelectric points and that the coagulant action of gamma globulin is enhanced by lowering the pH. Hence, it is understood that the discussion which follows is predicated upon performance of the test at pH 7.4.

Although it is probable that the gamma globulin fraction used was not composed of a single chemical entity, there seems little doubt, as others have shown, that gamma globulin is the coagulatory protein involved in the colloidal gold reaction of blood serum. The role of serum albumin, however, is not protective; in fact, it is inert toward colloidal gold in a milieu buffered at pH 7.4. The experiments reported leave little doubt that one or more beta globulins (and probably alpha globulins) are the proteins in blood serum which play the major protective role in this reaction. These considerations pose a number of interesting questions which merit investigation by others with technical and clinical facilities which the authors do not have available.

It seems logical to postulate that abnormal colloidal gold reactions arise from either or both of 2 conditions: (*1*) Significant change in the gamma globulin content ot the body fluid and (*2*) alteration in the relative proportions of beta globulin (and possibly alpha globulin) as compared with gamma globulin. Thus, if this theory is true, a spinal fluid giving the typical colloidal gold reaction of general paresis (zone I curve) should contain significantly less of the protective globulins and, in many instances, more gamma globulin than normal spinal fluid. Furthermore, a spinal fluid giving the type of curve associated with the bacterial meningitides (zone III curve) should contain significantly greater quantities of all globulins, particularly of the beta type, than a normal fluid. Reaction patterns associated with certain other conditions, *e.g.*, non-paretic CNS lues (zone II curve), would be explainable on the basis of a moderately altered ratio of the protective globulins to the gamma globulin. Reactions obtained on blood serum in certain types of liver dysfunction are generally of the type which on this basis would be interpreted as arising from a relative decrease in protective globulin content, a hypothesis consistent with the theory that these globulins are elaborated by liver cells while gamma globulin ordinarily is produced elsewhere. The authors are convinced that careful study of the reaction on the basis of these postulates will lead to a more nearly quantitative interpretation of the colloidal gold test.

The utility of the colloidal gold test for the close estimation of gamma globulin content merits fur-

ther careful investigation. The results reported suggest that there is a critical dilution of gamma globulin beyond which complete coagulation of 2.5 ml. of a standardized gold sol does not occur at pH 7.4. With the sols used, this dilution was found to correspond to a concentration in the neighborhood of 0.3 μg. of the gamma globulin fraction. Even in the presence of protective colloids within the range of concentrations normally encountered in body fluids, the highest dilution giving the maximum coagulatory action in a series of dilutions appears to depend upon a critical gamma globulin concentration. In the experiments reported, the critical concentration of gamma globulin in the presence of protective colloids is not so sharply defined as in their absence but the authors feel that more nearly exact knowledge of the actual protein content of the experimental material and greater accuracy in measurements than that afforded by the serial dilution technic are needed before this effect can be judged critically. The experiments indicate that relatively pure gamma globulin fractions may be used to advantage in comparing the sensitivities of different gold sols and in standardizing upon a uniform and reproducible type of sol. Conversely, the possibility of using standardized gold sols in testing the purity of protein fractions seems worthy of further study.

The significance of the fact that various combinations of the several protein fractions failed to reproduce the colloidal gold curve yielded by normal human blood serum cannot be ignored. It is not impossible that some fraction other than those investigated comes into play in the reaction of normal serum, but it is also feasible to assume that alterations in the physical state of the proteins involved may occur, even with newer methods of fractionation, and so influence the properties of their artificial admixture as compared with those of serum.

SUMMARY

Experimental data showing the individual effects of blood fractions on uniformly prepared colloidal gold sols at pH 7.4 are presented which confirm the coagulatory action of gamma globulin and which show that one or more beta globulins (and possibly alpha globulins) are responsible for the protective action of normal body fluids as distinct from the serum albumin which is inert. The use of gamma globulin in determining whether or not 2 batches of gold sol are comparable is suggested. Conversely, a standardized gold sol may be found useful in the analysis of blood fractions. In a discussion of the implications of these results, hypotheses are advanced to account for the usual types of colloidal gold reactions exhibited by body fluids in a milieu buffered at pH 7.4.

THE EFFECT OF LOCAL COOLING ON THE FILTRATION AND ABSORPTION OF FLUID IN THE HUMAN FOREARM

By ELLEN BROWN,[1] CHARLES S. WISE,[2] AND EDWIN O. WHEELER[3]

(From the Department of Physiology, Harvard Medical School, Boston, Mass)

(Received for publication April 10, 1947)

Studies relating to the effects of cold on the permeability of human capillaries to protein and fluid have assumed practical importance in recent years because of current interest in refrigeration anesthesia and cryotherapy, as well as because of the casualties caused by exposure to cold during the recent war. Clinical (1) and experimental (2, 3) studies have shown that true frostbite increases the permeability of the capillary wall to both protein and fluid, but less is known quantitatively concerning the immediate effects of temperatures not sufficiently low to freeze the tissues but still injurious enough to produce serious lesions such as "immersion foot" (4).

Lewis showed (5) that immersing the hands in water at various temperatures produced least change in their volume in the range from 15° to 20° C. At 10° C. or less, and at 25° C. or more, their volume increased. After prolonged immersion at 5° C., aspirated edema fluid contained approximately 3 per cent protein. These results suggested strongly that capillary permeability was increased by moderate cold but were not conclusive because the observed changes occurred while venous pressure was elevated and because changes in vascular volume could not be entirely excluded. At about the same time Lange (6) came to the opposite conclusion, viz. that the permeability of cutaneous capillaries in man and the rabbit is decreased by cold because the appearance in the skin of intravenously injected fluorescein was delayed at a temperature of 10° C. However, the rapid diffusibility of this dye makes it a very uncertain indicator of capillary permeability; it seems more likely that reduced blood flow, not decreased permeability, was responsible for the observed delay in staining of the skin.

To obtain more quantitative information, the pressure plethysmograph of Landis and Gibbon (7) was used to measure changes in the volume of extravascular fluid in the forearm during exposure to external temperatures ranging from 44.5° to 4.5° C. It was found that moderate cooling (*a*) increased the extravascular volume of the forearm even when venous pressure was normal, (*b*) decreased the rate of filtration produced by a given increase of venous pressure and (*c*) decreased the rate at which extravascular fluid was reabsorbed. The evidence is consistent with the view that the human capillary wall becomes increasingly permeable to protein and fluid as environmental temperature falls below 25° C., but it also appears that other factors influence the rate at which edema develops during exposure to cold.

METHODS

The pressure plethysmograph of Landis and Gibbon (7, 8) was used throughout. The particular advantage of this method is that the volume of a segment of forearm can be measured very precisely while it is exposed intermittently for brief periods to an external pressure of 200 mm. Hg. This pressure is sufficient to collapse the blood vessels and thus to exclude almost completely the large and unpredictable changes in volume which are caused by vasodilatation or vasoconstriction. By excluding such changes in vascular volume, the accumulation of relatively minute amounts of extravascular fluid could be measured with little error. The effects of temperature could also be studied because the plethysmograph had double walls between which water at any desired temperature could be circulated. The apparatus and general methods used in this study were essentially the same as those described by Landis and Gibbon (7) to whose paper the reader is referred for a detailed description and diagrams.

One important modification in procedure was introduced. Landis and Gibbon (7) began their observations after the subjects had reclined for 30 minutes with the forearm in the plethysmograph. In the observations now described the subjects reclined with the forearm supported in a vertical position for a total of 90 minutes, during the last 30 minutes of which the plethysmograph was being adjusted and filled. This was done in order to insure complete absorption (by the capillaries) or drainage (by the lym-

phatics) of any extravascular fluid that might have accumulated as a result of previous activity or dependency of the forearm. This prolonged preparation increased the accuracy of the method and also led to modification of certain conclusions reached by Landis and Gibbon (7).

Temperatures were measured at intervals of 5 minutes or less by appropriately placed thermal junctions, viz. in the water surrounding the arm in the plethysmograph, on the skin of the forearm within the plethysmograph, on the skin of the wrist just outside the plethysmograph, and in room air near the plethysmograph. Water from a cool or warm reservoir was circulated at a rate of 5 liters per minute through the space between the inner and outer walls of the plethysmograph and through a jacket surrounding an accessory vessel between the plethysmograph and the burette (7). This kept the water surrounding the arm in the plethysmograph at the desired levels within 1° C. except for transient deviations of not more than 1.5° C., about the average which occurred occasionally as water moved rapidly into or out of the plethysmograph during determinations of volume. For the sake of brevity, only average temperature, *i.e.*, 4.5° for 4° to 5° or 14.5° for 14° to 15°, etc., will be given in the text, it being understood that the range was about plus or minus 0.5° C. as indicated in the charts and tables.

The midpoint of the plethysmograph, with the forearm vertical, was placed level with the manubrium sterni. A pneumatic cuff, 15 cm. in width, was wrapped around the upper arm. Before beginning observations, this was inflated to determine the lowest cuff pressure which would cause an increase in total arm volume. This precaution was taken to avoid possible errors which might arise if the diaphragms of the plethysmograph were applied so snugly that they themselves produced venous congestion. The same cuff was used in certain experiments to produce venous congestion. For this purpose, pressure in the cuff was raised to the desired level plus the additional correction required because of the position of the forearm and the water surrounding it in the plethysmograph (7).

Each determination of "reduced" or "avascular" forearm volume involved application of a pressure of 200 mm. Hg to the water in the plethysmograph for a period of 2 minutes, during which burette readings were made every 30 seconds. Only the last of each set of readings was used to calculate the change in reduced forearm volume that had occurred since the preceding determination. Pressure was usually applied for 2 minutes out of every 10, 8 minutes being allowed for recovery. When venous congestion was imposed between successive determinations, the interval was increased so that the actual time during which filtration occurred and the forearm was not exposed to external pressure was 10 minutes. In certain control observations for special purposes, pressure was applied for 2 minutes out of every 5, 20, or 60 minutes.

At the conclusion of each experiment the upper and lower circumferences of the segment of forearm within the plethysmograph were measured and the approximate volume of the segment was calculated.

Four normal individuals, 3 male and 1 female, aged between 20 and 33, served as subjects throughout. A few supplementary observations were made on another female subject.

OBSERVATIONS

1. *Control studies of "reduced forearm volume" at 34.5° C.*

Landis and Gibbon (7) observed a significant decline in reduced forearm volume during control observations at this and other temperatures. By making few or many determinations over a period of 1 hour or more they concluded that this decline in volume was due chiefly to a real absorption of fluid and only slightly to the mechanical effects of the repeatedly applied external pressure. They omitted, however, the preliminary "emptying" of the forearm which in the present observations reduced the volume of extravascular fluid to a minimum prior to each experiment. When this precaution was taken the existence of a systematic mechanical artefact became clear.

In 2 experiments on each of the 4 regular subjects, reduced forearm volume was measured repeatedly at intervals of 10 minutes for 60 to 80 minutes while the water in the plethysmograph was kept at a neutral temperature, viz. 34.5° C. As shown in Figure 1 (solid dots and solid line) re-

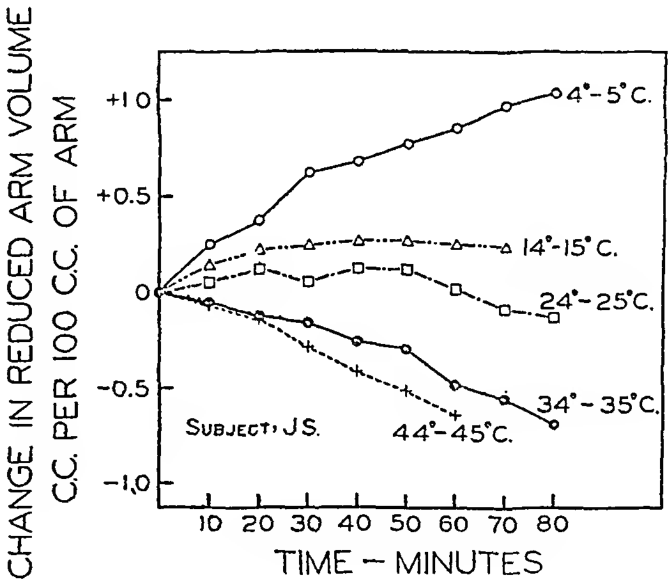

FIG. 1. CHANGES IN REDUCED FOREARM VOLUME, IN ML. PER 100 ML. OF FOREARM, UNDER RESTING CONDITIONS AT PLETHYSMOGRAPH TEMPERATURES OF 4–5°, 14–15°, 24–25°, 34–35°, AND 44–45° C.

A pressure of 200 mm. Hg was applied to the contents of the plethysmograph for 2 minutes out of every 10 for determination of reduced forearm volume. Subject J. S.

duced forearm volume decreased steadily; this was true of all 8 experiments. In 62 measurements of reduced forearm volume the average change per 10-minute period was − .08 ml. per 100 ml. of forearm tissue (range from + .11 to − .33 ml. per 100 ml. of tissue; standard deviation .073). For the 3 male subjects the average change of reduced forearm volume per 10-minute period was between − .06 and − .08 ml. per 100 ml.; for the female subject, − .13 ml. per 100 ml. In 2 similar experiments using a second female subject the average change per 10-minute period was − .16 ml. per 100 ml.

To determine whether this slight but definite decrease in volume was due to true absorption of extravascular fluid or was simply a pressure artefact, serial determinations were made for a period of 1 hour at intervals of 5, 10, and 20 minutes. It was found that the rate of decrease in control volume was related to the number of readings (and number of periods of external pressure) and not to total elapsed time. Thus, over a period of 60 minutes, 12 determinations decreased the volume by an average total of −.79 ml. per 100 ml. of forearm, 6 determinations decreased it by − .55 ml. per 100 ml., and 3 determinations by − .28 ml. per 100 ml. The mean decrease of reduced forearm volume per determination at 5-minute intervals was −.06 ml. per 100 ml., and, at 20-minute intervals, − .10 ml. per 100 ml. Both were within the limits of the probable error of the mean (− .03 to − .13) observed when determinations were made every 10 minutes.

In a single experiment, one pair of determinations 10 minutes apart was separated by a 60-minute interval from another pair of readings 10 minutes apart. Reduced forearm volume did not change between the determinations separated by the interval of 1 hour and the total change in volume in 80 minutes during which pressure was applied 4 times, was only − .15 ml. per 100 ml. Hence, if the forearm is first prepared by reducing excess tissue fluid as much as possible it appears that the gradual decrease in reduced forearm volume at normal venous pressure is due not to true absorption of residual extravascular fluid via the capillaries nor to lymphatic drainage, but to mechanical and progressive squeezing out from the plethysmograph either of the plastic tissues of the forearm or of a slight amount of residual fluid.

The adequacy of the precautions taken in preparing subjects was tested further by 3 experiments in which the amount of extravascular fluid was purposely increased by prior venous congestion with a pneumatic cuff inflated to 55 cm. water for an hour. After the usual 90 minutes of preparation, reduced forearm volume was measured every 10 minutes for an hour. The average decreases in forearm volume per application were − .13 to − .21 ml. per 100 ml., *i.e.*, slightly greater than in the control experiments but still not significantly different because they were still within the 95 per cent probability range of the control experiments (+ .07 to − .23 ml. per 100 ml.).

The 90-minute preparation period was therefore considered sufficiently long to allow for removal from the forearm of such excess fluid as might have been present when the subject first reclined. Because the gradual decrease in volume of the forearm during control observations was apparently a mechanical artefact, the average decrease per application of pressure at 34.5° C. for each subject was used as a correction factor in all quantitative interpretations of the remaining experimental results.

2. *The effects of temperature on reduced forearm volume (or the volume of extravascular fluid) under resting conditions and normal venous pressure*

The temperature of the water in the plethysmograph was constant within the limits given in Table I except for occasional transient excursions of not more than 1° C. beyond these limits during deter-

minations of volume. At plethysmograph temperatures above or below 34.5° C. the skin within the plethysmograph was rarely at the same temperature as the water because (*a*) a thin sheet of rubber separated the water from the skin, and (*b*) skin temperature was affected by blood flow, which was not interrupted except during the brief periods when external pressure was applied. Hence, as shown in Table I, during exposure to water at 4.5° C. skin temperatures were usually between 8.5° and 12.5° C. (This was about as much cooling as could be tolerated without unbearable pain over the 1½ hours required for a complete observation.) The temperatures of the skin and the plethysmograph were most nearly equal at 34.5° C., which can be regarded therefore as a close approach to "neutral" temperature.

The extent to which the forearm was exposed to cooling during the 30 minutes prior to beginning observations varied somewhat depending upon the ease or difficulty of the preliminary adjustments. Room temperatures ranged from 20° to 29.5° C. and, with one exception, changed not more than 2.5° C. during any experiment.

Figure 1 illustrates for one subject the changes in reduced forearm volume when measured at 10-minute intervals during continuous exposure of the uncongested arm to 5 temperatures ranging from 4.5° to 44.5° C. for periods of an hour or longer. At 4.5° C., the volume of the forearm increased rapidly at first and then more slowly; a similar but less marked increase in volume occurred at 14.5° C. It has been mentioned that the apparent decrease at 34.5° C. is an artefact so that, in absolute terms, volume increased slightly even at 24.5° C.

Table II summarizes the results obtained in 4 subjects; observed and, for quantitative comparison, also the corrected figures are given. The latter were obtained by adding to each observed reduced forearm volume the total mechanical decrease in volume expected to result from 6 applications of pressure at 34.5° C. (6 times the average decrease per application of external pressure at 10-minute intervals as determined for the same subject in the control experiments).[4] The average increase in volume of extravascular fluid at 14.5° C. was almost double and at 4.5°C. almost triple that at 24.5° C. Only small and inconsistent changes occurred at 44.5° C. It seems clear, however, that the regular and progressive change in volume between 4.5° C. and 34.5° C. is arrested or possibly reversed at some temperature between 34.5° and 44.5° C. The changes resulting from cooling were largest in E. B. and least in C. W.

[4] To test the assumption that the pressure artefact was the same at low temperatures as at 34.5° C., 2 experiments were done at 4.5° C. in which 2 pairs of determinations 10 minutes apart were separated by an interval of 60 minutes. In each case the total increase in reduced forearm volume during 60 minutes of exposure to cold without applications of external pressure was considerably greater than that observed during exposure to cold for the same time when readings were made in routine fashion every 10 minutes. The validity of the assumption was also demonstrated quantitatively because the difference in volume at the end of 60 minutes of cooling with and without readings at 10-minute intervals was approximately equal to that expected from 6 applications of external pressure at 34.5° C.

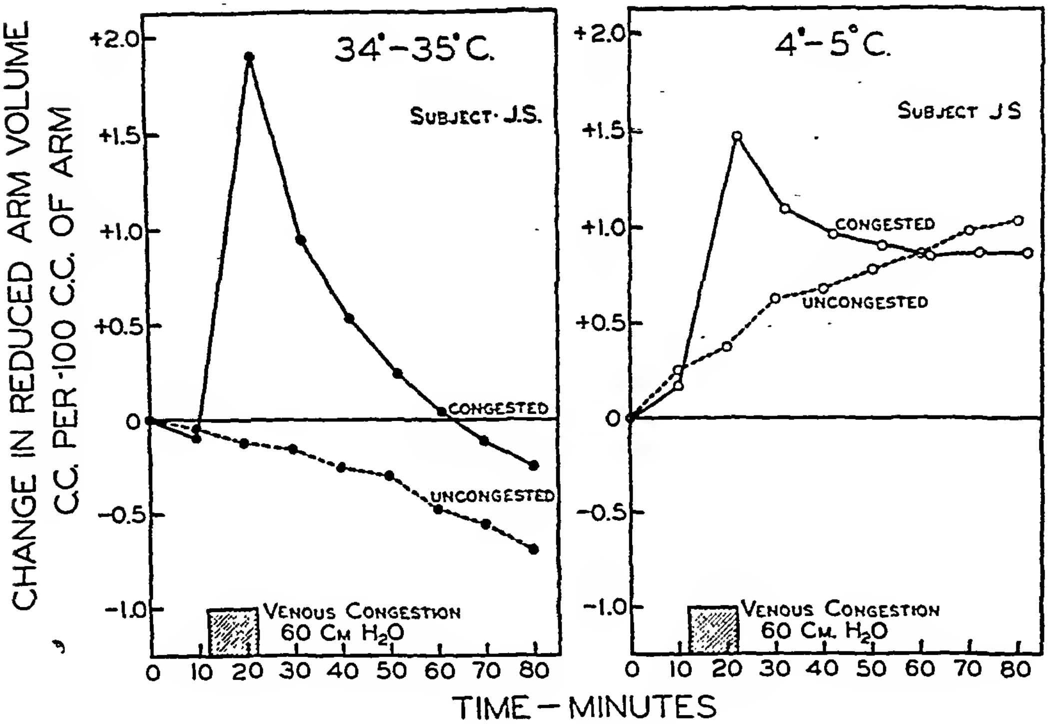

FIG. 2. CHANGES IN REDUCED FOREARM VOLUME, IN ML. PER 100 ML. OF FOREARM DURING AND AFTER A 10-MINUTE PERIOD OF CONGESTION AT 60 CM. WATER VENOUS PRESSURE. PLETHYSMOGRAPH TEMPERATURES 34–35° AND 4–5° C.

Changes in reduced forearm volume under resting conditions at the same temperatures (see Figure 1) are indicated by dotted lines. Subject J. S.

and E. W.; this relation was fairly consistent throughout the whole series suggesting a real difference between individual subjects.

3. The effect of temperature on the relation between venous pressure and filtration of fluid

Landis and Gibbon (7) observed that during congestion at a given venous pressure, *e.g.* 60 cm. water, for 10 minutes, the volume of fluid which was filtered was greatest at 44° to 45° C. and least at 14° to 15° C., but they did not test the effect of still lower temperatures. Hence these observations were extended by experiments similar to those shown in Figure 2.

After the usual preparation (totaling 90 minutes) 2 determinations of reduced forearm volume were made, 10 minutes apart. As external pressure was released after making the second reading, venous pressure was raised abruptly to 20, 40, or 60 cm. water by inflating the pneumatic cuff around the upper arm. Venous congestion was continued for 10 minutes; the cuff was then deflated and reduced forearm volume was measured immediately. Determinations of reduced forearm volume were then repeated at intervals of 10 minutes for totals of 40 to 60 minutes in order to measure the rate at which the recently filtered fluid was reabsorbed or conducted away by the lymphatics.

At 34.5° C. (solid line, Figure 2, left) the observed increase in reduced forearm volume resulting from 10 minutes of congestion at a venous pressure of 60 cm. water was almost 2.0 ml. per 100 ml. of forearm. After release of the congesting cuff, the volume of excess tissue fluid which had accumulated as a result of congestion decreased rapidly. For comparison, the changes in reduced forearm volume which took place in the same subject at 34.5° C. when no congestion was applied are also shown (dotted line, Figure 2, left). At 4.5° C., the effects of a similar period of congestion differed as follows: (*a*) reduced forearm volume began to increase even before venous pressure was elevated, (*b*) the total volume of fluid filtered dur-

ing congestion was less than at 34.5° C. rather than more as might have been expected if the only effect of cold were an increase in capillary permeability, (*c*) the rate of removal of excess fluid after release of the congesting cuff was slower, and (*d*) reabsorption stopped when the volume of excess tissue fluid was approximately equal to that present after exposing the arm to a temperature of 4.5° C. for the same time without congestion (dotted line, Figure 2, right).

The results pertaining to filtration in a series of such experiments are summarized in Table III, in which all figures have been corrected to exclude the pressure artefact. In agreement with Landis and Gibbon (7), the volume of fluid filtered was always greater the higher the venous pressure at any given temperature. When venous pressure was 60 cm. water the average rate of filtration was greatest at 34.5° C., least at 14.5° C., and then rose again to an intermediate value at 4.5° C. At a venous pressure of 40 cm. water, average filtration at 4.5° C. was clearly less than that at 34.5° C., but the difference was not striking. At a venous pressure of

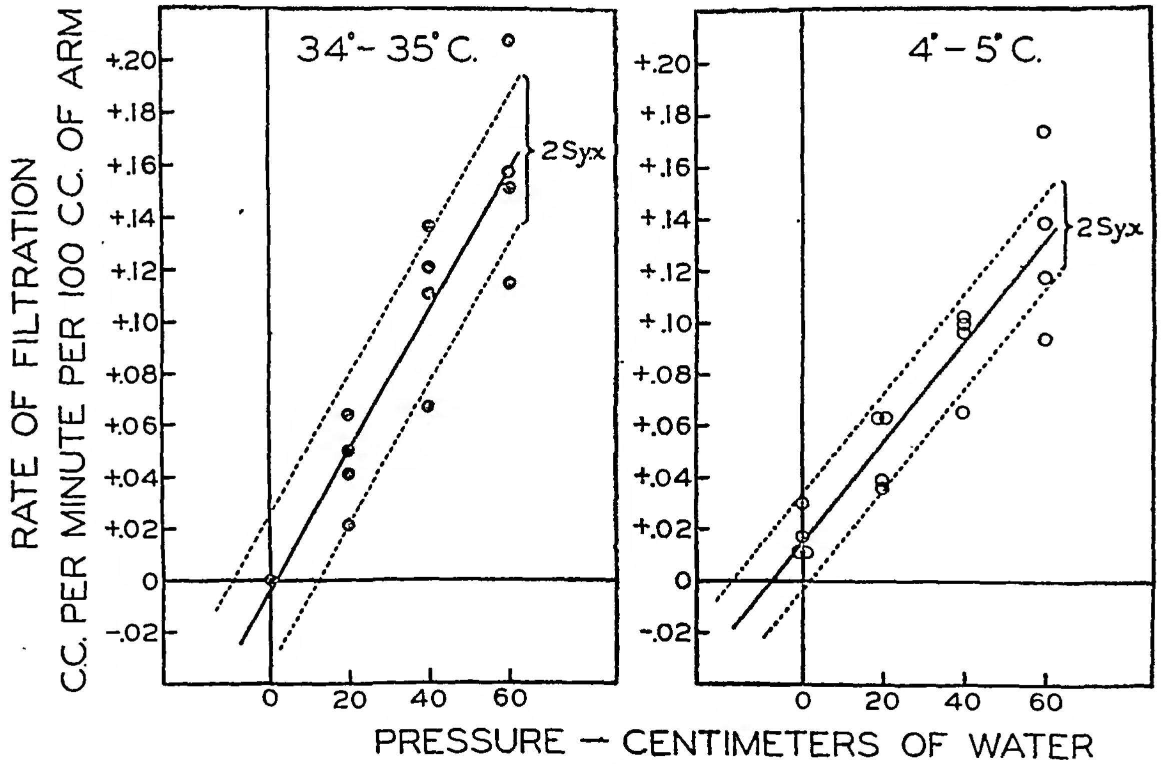

FIG. 3. RATE OF FILTRATION, IN ML. PER MINUTE PER 100 ML. OF FOREARM DURING 10-MINUTE PERIODS OF VENOUS CONGESTION WITH CUFF PRESSURES OF 20, 40, AND 60 CM. WATER. PLETHYSMOGRAPH TEMPERATURES 34–35° AND 4–5° C.

Changes in reduced forearm volume under resting conditions appear as filtrations at zero congesting pressure at 4–5° C. Four subjects. Results corrected to exclude pressure artefact.

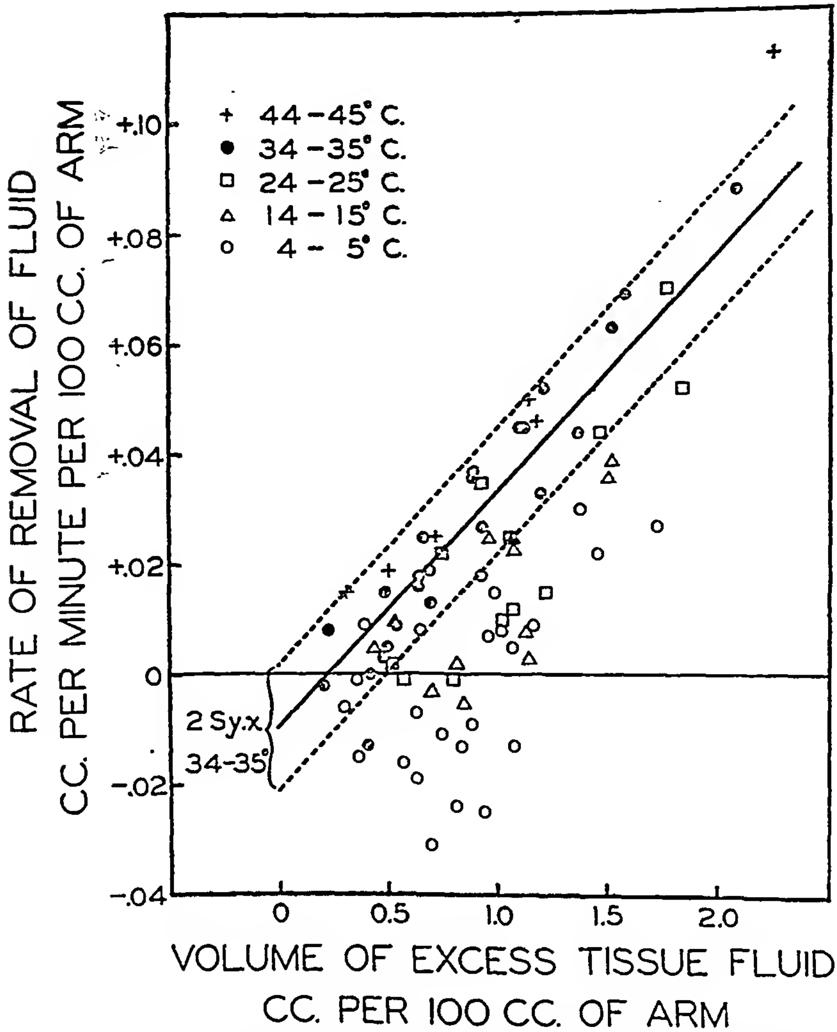

FIG. 4. RELATION BETWEEN THE VOLUME OF EXCESS TISSUE FLUID PRESENT, IN ML. PER 100 ML. OF FOREARM, AND THE RATE OF REABSORPTION OF FLUID, IN ML. PER MINUTE PER 100 ML. OF FOREARM. PLETHYSMOGRAPH TEMPERATURES 4–5°, 14–15°, 24–25°, 34–35°, AND 44–45° C.

The volume of excess tissue fluid was obtained from the first 2 observations of reduced forearm volume after 10 minute periods of congestion at venous pressures of 20, 40, and 60 cm. water. Four subjects. Results corrected to exclude pressure artefact.

20 cm. water the filtration rates were approximately the same at 4.5° and 34.5° C. because (*a*) at this relatively low venous pressure the effects of venous congestion were complicated by the swelling described above for the uncongested arm (Figure 1), and (*b*) the error for any single measurement was relatively great when small volumes of filtrate were involved.

The linear relation between rate of filtration and grade of venous congestion is shown for 34.5° C. and for 4.5° C. in Figure 3. Reasons have been given above for believing that after prolonged preparation of the forearm and at a temperature of 34.5° C. the corrected, reduced forearm volume is practically constant. Hence, all 4 points relating to the resting forearm (zero congesting pressure) at 34.5° C. have been placed at zero filtration (Figure 3, left). At this temperature filtration began as soon as venous pressure was raised above the resting level and increased linearly with increasing grades of venous congestion. At 4.5° C., filtration occurred at a rate of about .02 ml. per minute per

100 ml. of forearm even at zero congesting pressure. At this temperature filtration also increased with increasing congesting pressure, but less rapidly than at 34.5° C.

The slopes of these lines permit estimation of the unit rate of filtration, *i.e.,* the rate of filtration resulting from each centimeter rise of venous pressure, at each temperature. At 34.5° C. the unit rate of filtration was .0027 ml. per minute per 100 ml. of forearm per cm. venous pressure (standard deviation .00025); at 4.5° C., it was .0019 ml. per minute per 100 ml. of forearm per cm. venous pressure (standard deviation .00020). The chances are better than 3 out of 4 that this reduction of 30 per cent in the unit rate of filtration was not due to errors of random sampling (k 1.18).

It is noteworthy that at 4.5° C. the extension of the mean line crosses the line of zero filtration at a pressure of − 9 cm. water. The shift of the intercept toward the left (with respect to the intercept of the line fitting points obtained at 34.5° C.) is consistent with the view that cold (4.5° C.) increased the permeability of the capillary walls to protein and that the swelling of the forearm at normal venous pressure (Figure 1) was due to a reduction of the effective colloid osmotic pressure of the blood amounting to approximately 9 cm. water.

4. The effect of temperature on the rate at which recently filtered extravascular fluid is reabsorbed after congestion

Landis and Gibbon (7) observed that small amounts of excess tissue fluid sometimes were removed from the forearm less rapidly during cooling (14° to 15° C.) than at higher temperatures. This effect of cold is far more striking at 4.5° than at 14.5° C., as shown in Figure 4 where the rate of removal of fluid is charted against the volume of excess tissue fluid present at the time reabsorption was measured. These values were obtained from measurements of reduced forearm volume 10 minutes and 20 minutes after release of the congesting cuff in experiments similar to those illustrated in Figure 2. At each of the 5 temperatures designated, the rate at which fluid was removed was greater when larger volumes of excess tissue fluid were present because tissue pressure was raised by the accumulated fluid (7). At 34.5° C., a linear relationship became clear (correlation coefficient + .88); at other temperatures the points were more scattered. However, for any given volume of excess tissue fluid, the rate of reabsorption was clearly least at 4.5° C. In agreement with earlier results (7) the rates of removal at 14.5° C. were not always reduced and the difference was less conspicuous. The results at 24.5° and 44.5° C. were so nearly within the zone of results obtained at 34.5° C. that conclusions are not warranted.

The marked effect of cold (4.5° C.) on reabsorption of tissue fluid and the importance of this factor in "immersion foot" are shown more graphically in Figure 2. At 34.5° C., reabsorption was almost complete within 60 minutes after the end of the period of congestion; at 4.5° C. reabsorption was slower and remained incomplete, less than half of the filtered fluid having been absorbed at the end of 60 minutes. At 34.5° C., in 4 subjects, between .43 and 1.19 ml. of fluid were removed per 100 ml. of forearm tissue during the first 30 minutes after a prior congestion at 60 cm. water for 10 minutes. At 4.5° C. during a similar period only .10 and .32 ml. of fluid were removed in 2 subjects and in 2 others the volume of tissue fluid increased by .05 and .59 ml. per 100 ml. of forearm tissue. This disturbance of fluid removal is compatible with a reduction of the effective colloid osmotic pressure of the plasma amounting to approximately 10 cm. water.

DISCUSSION

Determination of the volume of tissue fluid by means of the pressure plethysmograph was made more accurate by having the subject recline with the forearm supported in a vertical position for 90 minutes before observations were begun. This period of preparation permitted capillary absorption and lymphatic drainage to evacuate any excess tissue fluid that had accumulated during immediately prior activity or dependency so that equilibrium was established between the circulating blood and the volume of tissue fluid. Landis and Gibbon (7) did not use this precaution and concluded that successive applications of external pressure did not *per se* change limb volume consistently and that the decrease in volume was due to continued absorption. It appears now that they observed this transitory absorption because the

forearm contained tissue fluid remaining from previous activity or dependency. If excess tissue fluid has been removed by suitable preparation, neither filtration nor absorption occurs at 34.5° C. when the forearm is placed at heart level in the plethysmograph, and the importance of a small and uniform correction for a pressure artefact becomes clear.

The correction for this artefact differed even in normal subjects, being almost twice as great in 2 female subjects as in 3 male subjects. This may be related to differing proportions of muscle, subcutaneous tissue, and skin in their forearms; but the possibility that small amounts of tissue fluid, or even intracellular fluid, are expressed from the regions near the ends of the plethysmograph cannot be excluded. In any case it is important to eliminate any differences in the volume of tissue fluid which may be present in the forearm prior to each experiment and to determine the pressure artefact for each subject, especially if patients with edema are to be studied.

This small correction was relatively unimportant when large volumes of fluid were filtered (*e.g.* Figure 2 and Table III) but became very important in measuring fluid movement at normal venous pressure and in locating the lowest venous pressure at which filtration began. Thus, without special preparation of the forearm, Landis and Gibbon found that at 34° to 35° C. venous pressure had to be raised by 10 to 17 cm. water before a definite increase in the uncorrected volume of the forearm could be produced. With proper preparation and correction for the pressure artefact the line relating venous pressure and filtration passes very close to zero, which is more nearly in accord with the Starling hypothesis (Figure 3, left).

It seems quite clear that cold can produce significant filtration of fluid at resting venous pressure (Figures 1, 2, and 3). This is consistent with direct or indirect injury of the capillary wall, increased capillary permeability to protein, and lowering of the effective colloid osmotic pressure of the plasma. The changes actually observed during cooling of the plethysmograph to a given temperature corresponded to smaller changes of tissue temperature because (*a*) the temperature of the skin was always somewhat higher than that of the water in the plethysmograph (Table I), and (*b*) deep tissue temperature was even higher than skin temperature (9). Yet slight changes were observed when the plethysmograph was cooled to only 24.5° C. and when skin temperature was only 5 degrees below the levels usually found when exposed to comfortable environmental air. The effects became progressively more severe as temperature was reduced further. It was not possible to find any critical temperature at which a great increase in filtration appeared abruptly. Table II suggests that at some plethysmograph temperature between 34.5° and 44.5° C. (skin temperature between 34.5° and 42° C.), the volume of the forearm remained most nearly constant. Above and below that temperature the volume of tissue fluid increased, on the average, even while venous pressure was normal.

The possibility must be considered that the increase in extravascular volume of the uncongested forearm during exposure to cold was due to swelling of cells and not to accumulation of intercellular fluid. This was probably not the case for several reasons. In the first place such increase occurred at rates characteristic of fluid movement through the capillary wall which has a permeability to fluid between 100 and 3000 times greater than that of a typical cell membrane (10). At 4.5° C., fluid accumulated on the average at a rate of .017 ml. per 100 ml. of forearm tissue per minute. Continued accumulation at this rate would produce definite pitting edema in about 10 hours, though developing tissue pressure would decrease the rate of filtration and thus make this period considerably longer. Second, fluid known to be filtered during venous congestion was not reabsorbed fully so that at the end of 80 minutes at 4.5° C. the extravascular volume after congestion and partial recovery tended to equal that of the uncongested arm after the same period of exposure (Figure 2, right). Third, Lewis (5) was able to obtain several samples of edema fluid containing approximately 3 per cent protein by inserting needles into the subcutaneous tissues of the cooled hand.

Other things being constant, it would be expected that capillary injury would lead not only to filtration of fluid at normal venous pressure, but also to conspicuous increase of filtration rates observed during venous congestion. While the former was observed (Figure 1, Table II), the latter was not (Figure 3).

This may have been due, in part, to the necessity of exposing the forearm to some cooling during the period of 30 minutes required for adjusting the plethysmograph. Any fluid filtered at resting venous pressure during this time would raise tissue pressure and thereby impede further filtration. It is also possible that increased viscosity of the filtered fluid may have affected filtration, but the differences were greater than would be expected on this basis alone. Of more importance, however, were the concomitant effects of temperature on blood vessels and blood flow in the cooled forearm.

Even while cold was beginning to increase capillary permeability, it was also producing arteriolar constriction, reducing blood flow (9), reducing the gradient of capillary pressure (11), and probably reducing the area of capillary wall available for continued filtration by stopping blood flow in some vessels entirely. Recent studies (9) have shown that blood flow in the forearm is about 17.6 ml. per 100 ml. of tissue per minute at 45°, 4.3 ml. at 35°, 0.7 ml. at 25°, and 0.5 ml. at 10 to 15° C. Blood flow in the hand is affected similarly except for an increase below 15° C. (12), but this reactive hyperemia has been ascribed primarily to the opening of arteriovenous anastomoses in the finger tips (13). Incomplete studies (14) have shown that the collective volume of the blood vessels, *i.e.*, the vascular volume, of the forearm is reduced to ½ by cooling from 34° to 24° C. and to ⅓ by cooling from 34° to 14° C. Unfortunately, exact figures are not available for lower temperatures but there is little reason to expect an increase in either blood flow or vascular volume in the forearm at skin temperatures below 10° to 15° C. because there are few arteriovenous anastomoses in this region.

It should be noted that such a decrease in blood flow would be expected to reduce the rate at which a diffusible dye such as fluorescein would enter the cooled skin. The results of Lange (6) can therefore be explained on the basis of diminished transport of dye to the cooled tissues and do not indicate that capillary permeability is decreased by cold. In similar fashion the decreased unit rate of filtration observed during exposure to cold was probably a secondary effect of vasoconstriction and hence not evidence against an increase of capillary permeability to protein.

The degree to which permeability to protein was increased by cold can be estimated in terms of the amount by which the effective colloid osmotic pressure of the plasma was reduced, as shown by the observed filtrations and absorptions. During the most extreme cooling, extravascular fluid accumulated in the uncongested forearm at an average rate of .017 ml. per minute per 100 ml. of tissue which, according to Figure 3, left, is equivalent to the effect of increasing venous pressure (or decreasing the effective colloid osmotic pressure) by 7.5 cm. water. Comparison of the intercepts in Figure 3 indicates that effective colloid osmotic pressure was reduced by approximately 9 cm. water at 4.5° C. The delayed absorption at 4.5° C. shown in Figure 4 is consistent with a reduction of effective colloid osmotic pressure amounting to approximately 10 cm. water. The effective colloid osmotic pressure of the plasma would be lowered as much as this (7 to 10 cm. water) by the passage of a capillary filtrate containing 2 per cent protein (15) rather than the normal 0.3 per cent or less (16).

Efforts to substantiate this conclusion by determining the concentration of plasma protein in capillary filtrate by a modification of the method described by Landis *et al* (16) were unsuccessful; values obtained varied too widely to be conclusive. It may be recalled, however, that Lewis found approximately 3 per cent protein in edema fluid aspirated from the tissues of the hand after prolonged exposure to cold. Despite possible contamination of these samples by blood plasma from mechanical injury or rupture of capillaries, these figures agree well with those calculated from plethysmographic measurements of filtration and absorption at low temperatures.

In contrast to these effects in man it is noteworthy that Brown and Landis (17) found that the frog's capillaries were affected quite differently by cold as is, in fact, necessary for the survival of a poikilothermic animal, exposed for long periods to very low temperatures. When local temperature was decreased 20° C. the permeability of the walls of single capillaries in the frog's mesentery decreased 73 per cent and there was a significant increase in the total effective osmotic pressure of the blood. The cause for the latter is not clear although thermosmosis or the development of a transient effective osmotic pressure by

plasma constituents other than proteins are possible explanations that need further study. If either of these factors plays any part in man, the results are unrecognizable because the injurious effects of cold produce more conspicuous changes in the opposite direction.

In the human being, the effect of cold on the balance between blood and tissue fluid is chiefly the result of interplay between capillary injury and reduction of filtering (and absorbing) area. The first, by permitting the passage of protein, reduces the effective colloid osmotic pressure of the blood and favors the formation of edema even when venous pressure is normal. It also prevents the reabsorption of filtered fluid. The second reduces or delays, but does not prevent, filtration when venous pressure is raised as in a dependent extremity. It also delays conspicuously the reabsorption of such tissue fluid as has been filtered previously. If temperature becomes sufficiently low, the edema-producing effects of injury may exceed the edema-preventing factors related to lessened filtering area and reduced blood flow. In Table III, it is shown that filtration during congestion at 60 cm. water declined from 34.5° to 14.5° C. but rose sharply again at 4.5° C. The appearance of striking edema in "immersion foot" (4) is explicable on this basis because the syndrome appears when the dependent extremities are exposed for brief periods to very low temperatures or for longer periods to temperatures which are only moderately low.

SUMMARY

1. The pressure plethysmograph was used to measure changes in the extravascular ("reduced") volume of the forearm in 4 normal human subjects, in order to determine the effects of local cooling on (*a*) the volume of tissue fluid under resting conditions, (*b*) the rate of filtration of fluid per unit increase of venous pressure and (*c*) the rate of reabsorption of excess tissue fluid after release of venous congestion.

2. The accuracy of this method for measuring minute changes in the volume of tissue fluid has been improved (*a*) by elevating the forearm for 90 minutes to remove residual tissue fluid before each observation, and (*b*) by measuring for each subject the small error or artefact introduced each time a volume is read while applying to the forearm an external pressure of 200 mm. Hg.

3. Cold produced filtration of fluid and increased the volume of tissue fluid even in the uncongested forearm. The average rate of filtration at 4.5° C. was .017 ml. per 100 ml. of forearm tissue per minute. Smaller rates of filtration were observed at 14.5° and 24.5° C. At 34.5° and 44.5° C. reduced forearm volume did not change significantly.

4. The rate of filtration remained directly proportional to the increase in venous pressure even at 4.5° C., but the unit rate of filtration (ml. fluid per 100 ml. of forearm per minute per cm. rise of venous pressure) was 30 per cent less at 4.5° C. than at 34.5° C.

5. Cold reduced the rate of reabsorption of previously filtered fluid conspicuously at 4.5° C. and slightly at 14.5° C.

6. The results collectively indicate that cold increases the permeability of the human capillary wall to protein. In the forearm exposed to water at 4.5° C., this reduces the effective colloid osmotic pressure of the blood by 7 to 10 cm. water.

7. The relation between these findings and the pathogenesis of edema in extremities exposed to cold, *e.g.* "immersion foot," is discussed.

ACKNOWLEDGMENT

It is a great pleasure to have this opportunity to thank Dr. E. M. Landis for his guidance during the planning and conduction of the experiments and the preparation of this report.

ABNORMAL RENAL TUBULAR BACK-DIFFUSION FOLLOWING ANURIA

By JULES REDISH, JOSEPH R. WEST, BETTY W. WHITEHEAD, AND HERBERT CHASIS

m the Departments of Medicine and Pediatrics, New York University College of Medicine; and the Third (New York University) Medical and Pediatric Services, Bellevue Hospital)

(Received for publication April 21, 1947)

.ive value for $T_{m\text{p-aminohippurate}}$ was ob- a patient with sulfathiazole intoxication 4 days of anuria and 5 days of marked This negative T_{mPAH} is interpreted as in- not only that the tubule cells had lost their .o excrete PAH but that a portion of the iltered by the glomeruli was escaping from ›ular urine by back-diffusion. It is the pur- e of this paper to describe quantitatively the ›rn of glomerular and tubular functional ;es following the period of anuria to apparent functional recovery.

On March 1, 1945 an 8-year-old white female developed sore throat and fever. There was no history of previous renal disease. She received approximately 3.0 grams of sulfathiazole in the form of chewing gum from March 3 to March 6. On March 6, vomiting occurred and continued for 10 days; March 7, anuria appeared and persisted for 4 days, followed by marked oliguria for 5 days. On the third day of anuria, a discrete, macular, erythematous rash appeared on all 4 extremities, and extended during the next 2 days to involve the face and become confluent on the upper extremities. On the fourth day of anuria, bilateral conjunctivitis appeared. The rash and conjunctivitis were present for 10 days. Systolic blood pressure ranged from 130 to 120 mm. and the diastolic from 96 to 80 mm. Hg from the fifth to the ninth day following onset of anuria. Three weeks later, the blood pressure was 110/64 mm. Blood non-protein nitrogen was 214 mgm. per cent 5 days following the onset of anuria and fell gradually to 21 mgm. per cent over a period of 3 weeks. Carbon dioxide combining power was 48 and 57 volumes per cent on the sixth and eighth days following the onset of anuria. Plasma chlorides rose from 71 milliequivalents to 104 in 3 weeks. The red blood cell count, hemoglobin and plasma proteins were normal. Four days following onset of anuria, the patient voided 15 ml. of urine in which a trace of protein was present, red and white cells were absent, and sulfathiazole crystals were seen; the plasma level of sulfathiazole at this time was 2 mgm. per cent. On the seventh and eighth days following onset of anuria, the urine contained moderate amounts of protein, 20 to 50 red blood cells per high power field, and innumerable white blood cells. In 3 weeks, the urine contained no protein or cellular elements. Spontaneous diuresis occurred on the tenth day following the onset of anuria and apparently was not related to any specific therapeutic measure.

The patient was discharged from the hospital 39 days after the onset of anuria, and has been observed for a period of 92.5 weeks following the onset of anuria at the Nephritis and Hypertension Clinic, New York University Clinic. She has attended the clinic at regular intervals and has been symptom free; edema has been absent and the blood pressure has varied from 110/74 to 92/66 mm. Hg; proteinuria reappeared and has persisted, varying from a trace to 2 plus. Hematuria and pyuria have been absent.

METHODS

The rate of glomerular filtration, the effective renal plasma flow, and the maximal tubular excretory capacity (T_{mPAH}) were measured according to the technique described by Goldring and Chasis (1).[1] Intravenous infusion for maintaining plasma levels and bladder catheterization to insure complete bladder emptying were employed.

RESULTS

The results of 5 determinations of specific renal functions are presented in Table I. Two weeks after the onset of anuria, the mannitol and p-aminohippurate clearances were markedly below the

TABLE I

Time from onset of anuria	Plasma clearance*		T_{mPAH}	Filtration fraction (C_m/C_{PAH})	Proteinuria
	Mannitol (C_m)	PAH (C_{PAH})			
weeks	*ml. per minute*		*mgm. per min.*	*per cent*	
2.0	17.2	14.6	−1.1		Trace
3.5	75.0	220.4	−9.4	34.0	None
4.5	79.6	443.0	20.3	17.7	None
7.0	108.4	448.5	42.7	24.2	Trace
92.5	91.0	586.0	85.6	15.6	Two plus

* All clearance values corrected to 1.73 square meters surface area.

[1] Clearances corrected as suggested by Barker and Clark (2).

mean normal values for females (117 and 594 ml. per minute, respectively) and Tm_{PAH} had a negative value of -1.1 mgm. per minute as compared to the normal value of 82.2 mgm. per minute (3). This observation was made 1 week after spontaneous diuresis had occurred and while the blood urea was 93 mgm. per cent.

Three and one-half weeks after the onset of anuria, the mannitol and p-aminohippurate clearances had increased significantly, while Tm_{PAH} continued to have a negative value.

Four and one-half weeks and 7 weeks after the onset of anuria, the mannitol clearance had returned to the normal range, the p-aminohippurate clearance was aproaching normal, and Tm_{PAH} had increased to significant positive values. The blood urea at this time was normal and the urine contained no protein or abnormal cellular elements.

Ninety-two and one-half weeks after the onset of anuria, the above renal functions were in the normal range. The urine contained a moderate amount of protein.

DISCUSSION

Skin rash, conjunctivitis, anuria, sulfonamide crystalluria, and sulfonamide in the plasma 5 days after the onset of anuria are interpreted as manifestations of sulfonamide intoxication. Proteinuria persisting for a period of nearly 2 years can be attributed either to sulfonamide intoxication or to some other concurrent process, *e.g.* diffuse glomerulonephritis. The possibility that acute diffuse glomerulonephritis was superimposed cannot be excluded; but it does not change the significance of the pattern of acute renal functional impairment, which we believe is related to the prolonged period of anuria, rather than to a specific noxious agent. The total dosage of sulfathiazole is relatively small, but it is known that sulfonamide intoxication does not bear a uniform quantitative relationship to the amount of drug administered. Death from renal insufficiency has been reported in a 1-year-old child following the administration of 0.65 gram of sulfathiazole (4).

Smith has emphasized the limitations of the clearance methods in the diseased kidney (5). The use of mannitol as a measure of glomerular filtration is based on the assumption that none of the filtered mannitol is reabsorbed by the tubules. The markedly decreased mannitol clearance first observed following anuria cannot be taken as an accurate measurement of glomerular filtration, since the reduction may have been caused in part by tubular back-diffusion. However, we believe that the mannitol clearance is a reliable index of glomerular filtration 4½ weeks after the onset of anuria, since back-diffusion had apparently disappeared, as indicated by the positive value for Tm_{PAH} and the normal value for the blood non-protein nitrogen. Had tubular damage been extensive enough to permit back-diffusion of mannitol at this time, it is logical to assume that the more diffusible urea would also have diffused back, causing an elevation of the blood non-protein nitrogen. The anuria and azotemia during the acute episode may be attributed in part to glomerular and in part to tubular damage.

It is probable that the PAH extraction ratio was reduced in the first 2 series of observations. A decrease in this extraction ratio has been reported after extreme reduction of renal blood flow in the dog (4, 6 to 8). Hence, until the last observation, the PAH clearance cannot be taken as accurately indicating the renal blood flow. Although the normal value of the filtration fraction at 4½ weeks implies a normal extraction ratio at this time, tubular impairment was still present at 7 weeks, as manifested by the reduced value of Tm_{PAH}.

The negative Tm_{PAH} value after anuria indicates that PAH was diffusing back through the tubules at some point.[2] It may be suggested as a mere speculation that the tubular segment most susceptible to anoxic injury is the thin limb of the loop of Henle; on the supposition that PAH is excreted by the proximal tubule, a negative value of Tm_{PAH} does therefore not necessarily imply that this process of excretion was specifically impaired. though some impairment is certainly to be anticipated after a prolonged period of glomerular damage or vascular spasm. Such marked functional disorganization is probably indicative of wide-

[2] The maximal urine mannitol blanks observed in patients in uremia have been approximately 3.76 mgm. per minute (9). Such a correction applied to those determinations in this patient in which negative T_m values were observed would not result in positive values for T_m. However, in view of the low mannitol clearance, it seems probable that some back-diffusion of both mannitol and PAH occurs.

spread changes involving glomeruli, tubules, and interstitium, such as have been described at necropsy in patients with fatal sulfonamide intoxication (4). Luetscher and Blackman (10) reported an unusual increase in the concentration of serum sodium and chloride in patients with sulfathiazole intoxication at a time when oliguria and nitrogen retention were diminishing, and they correlated this finding with the renal lesions observed in the tubules at necropsy. At 3½ weeks, despite the fact that glomerular function had apparently returned to the normal range, the persistent negative value for $T_{m_{PAH}}$ indicates that the tubular cells were still so disorganized as to permit abnormal back-diffusion. It was not until 4½ weeks after the onset of anuria that a positive value for $T_{m_{PAH}}$ was obtained. The eventual return of $T_{m_{PAH}}$ to normal indicates that the tubular injury in this patient did not result in permanent loss of excretory capacity. Bradley (11) and Rubin (7) have observed negative values for $T_{m_{PAH}}$ in patients with diffuse glomerulonephritis.

The primary disturbance producing immediate and subsequent renal injury during anuria, whether the anuria is associated with diffuse glomerulonephritis, post-transfusion reaction, sulfathiazole intoxication, crush syndrome, battle casualties with peripheral circulatory failure, or ureteral trauma, may be renal ischemia. Theoretically, the course of events in this patient may have started with marked renal ischemia initiated reflexly from the ureter or from intrarenal pathology.

SUMMARY

Marked reduction in renal function was observed early in the postanuric stage in a patient with sulfathiazole intoxication.

The filtration rate returned fairly rapidly to normal. Tubular excretory capacity, however, was impaired for a longer period of time, but eventually returned to normal.

A negative value for $T_{m_{PAH}}$ indicating abnormal tubular back-diffusion of PAH persisted for approximately 4 weeks from the onset of anuria.

THE EFFECT OF CYTOCHROME C UPON THE RESPIRATION OF TISSUE SLICES

By WILLIAM R. CHRISTENSEN and OLOF H. PEARSON[1]

(From the Department of Biological Chemistry, Harvard Medical School, Boston)

(Received for publication April 25, 1947)

Recent studies of the effect of added Cytochrome C upon the respiration of tissue homogenates (1, 2) have led to the conclusion that the organ content of this respiratory enzyme is less than optimum (2, 3). This has led to intensive investigation of the results of its parenteral administration to normal and anoxic animals and its effectiveness in clinical conditions characterized by tissue anoxia (2 to 8). In view of the theoretical and practical implications of these observations, the effect of Cytochrome C upon the respiration of normal and anoxic tissue slices has been investigated.

EXPERIMENTAL

Wistar strain rats, varying in weight from 100 to 400 grams, were used throughout this study. They were fed Purina Dog Chow ad lib, and were not fasted before sacrifice. In all experiments the rats were killed by a sharp blow on the head. The heart or liver was excised as rapidly as possible and placed in an iced, phosphate-buffered medium which contained 0.2 per cent glucose and whose ionic composition was as follows:

Cation	Concentration	Anion	Concentration
	meq. per l.		*meq. per l.*
Na	150	Cl	142
K	4	HPO_4 }	15
Ca	2	H_2PO_4 }	
Mg	1		

The pH was 7.4.

Liver slices approximately 0.5 mm. in thickness were prepared by means of a modified Stadie and Riggs tissue microtome (9). Heart slices of similar thickness were made by hand, using a razor blade as cutting tool and a glass slide as a template. Both types of slices were placed in an aliquot of well-oxygenated incubation medium at room temperature until placed in Warburg vessels.

Respiration was measured at 37° C. by the direct method of Warburg. Each vessel contained 3.0 ml. of the incubation medium in the outer compartment and 0.2 ml. of 10 per cent KOH plus filter paper in the center cup. Approximately 20 mgm. of tissue (dry weight) were used in each vessel. The vessels were equilibrated with varying mixtures of oxygen and nitrogen while being shaken in the constant temperature bath at the rate of 120 oscillations per minute. Readings were started about 30 minutes after the animals had been sacrificed. The tissue was removed at the end of the experiment and the dry weight obtained. All determinations were made in duplicate or triplicate. The results for the liver slices usually checked within 10 per cent and for the heart slices within 15 per cent. Respiration rate curves were plotted and the best linear relationship obtained from the observed points. Results were expressed as QO_2 ($mm.^3$ of O_2 per mgm. of dry weight of tissue per hour).

Cytochrome C was prepared according to the method of Keilin and Hartree (10). The preparation was carried only as far as the stage known to yield a product containing .34 per cent iron. The purity of the material was based on its spectrophotometric analysis using a Beckmann spectrophotometer with 1 cm. cells. The optical density of a solution containing a known amount of the preparation was determined at a wave length of 550 mμ and a spectral interval of 1.5 mμ. The concentration was then calculated using the absorption constant proposed by Drabkin (11). The preparation used consisted of 55 per cent Cytochrome C and 45 per cent sodium chloride. Solutions were freshly prepared from the lyophilized powder on the day of each experiment. The amount of Cytochrome C added to the suspending medium was equal to or in excess of the normal concentration in the tissue studied (12).

RESULTS

The results of respiration measurements on liver slices at varying oxygen tensions with and without added Cytochrome C are summarized in Table I. Respiration was measured over a period of 1 hour in slices equilibrated with 2.5 to 20 per cent oxygen, following which 100 per cent oxygen was introduced and the respiration during recovery measured for a second hour. In addition, liver slices were equilibrated with commercial nitrogen (ca. 0.5 per cent oxygen) for a period of 40 minutes following which 100 per cent oxygen was introduced and the rate of respiration measured for 1 hour. During the period of equilibration with nitrogen, there was no measurable respiration. It is apparent from the data presented

that the addition of Cytochrome C had no demonstrable effect upon the rate of respiration of surviving liver slices. The metabolism of those slices which were exposed to oxygen concentrations below 100 per cent was reduced in all cases. The magnitude of the depression was roughly proportional to the oxygen tension. Moreover, restoration of such anoxic slices to an atmosphere of pure oxygen resulted in a marked increase in the QO_2. All returned to a level of approximately 6.5. However, the presence of Cytochrome C in concentration of 500 gamma per ml. did not cause an increase in oxygen consumption either during the period of exposure to low oxygen tension or after the tissue was returned to an atmosphere of pure oxygen. The oxygen consumption of liver tissue subjected to varying degrees of anoxia was in no way affected by the presence of greater than physiological

* Single determination.

concentrations of Cytochrome C in the suspending medium.

Table II comprises a summary of essentially similar data resulting from studies of heart slices. It is apparent that the metabolism of heart slices was depressed by anoxia to a greater extent than in the case of liver slices exposed to the same oxygen tension. However, they did not show the same degree of recovery when returned to an atmosphere of 100 per cent oxygen. Cytochrome C had no effect upon the respiration of heart slices under any of the conditions considered.

CONCLUSIONS

1. The addition of Cytochrome C to the incubation medium did not alter the rate of oxygen consumption of surviving liver or heart slices equilibrated with 100 per cent oxygen.

2. The reduction of respiration of heart and liver slices induced by lowering the oxygen tension was not affected by the addition of Cytochrome C to the suspending medium.

3. The presence of Cytochrome C in the incubation medium of anoxic tissue slices did not affect their respiration after restoration to an atmosphere of 100 per cent oxygen.

4. The failure of added Cytochrome C to affect the rate of respiration of surviving tissue slices may have been due to non-penetration of Cytochrome C into the tissue cells or, if it penetrated, the increased concentration of Cytochrome C did not stimulate the rate of oxygen consumption.

The authors wish to express their appreciation to Professor A. Baird Hastings for his support and guidance.

THE EFFECT OF FATAL *P. KNOWLESI* MALARIA ON SIMIAN CIRCULATORY AND BODY FLUID COMPARTMENT PHYSIOLOGY [1]

By RICHARD R. OVERMAN AND HARRY A. FELDMAN [2]

(From the Departments of Physiology and Preventive Medicine, University of Tennessee, College of Medicine, Memphis)

(Received for publication October 30, 1946)

Although some objective measurements of the altered physiology of the malarial host have been made in human patients with therapeutic *P. vivax* and *P. falciparum* infections (1), almost no such studies have been made of the circulatory and fluid compartment volumes in fatal malaria. Numerous conclusions regarding the altered fluid physiology of the monkey with fatal *P. knowlesi* infections have been made by Knisely, *et al* (2), but these were, essentially, inferences based on microscopic observations of the capillaries (omentum, stomach, intestine and peritoneum) of living animals. The present investigation was made to elicit objective information concerning the altered physiological mechanisms in monkeys fatally ill of malaria.

MATERIALS AND METHODS

The following control determinations were made in 23 normal *Macacus mulata* monkeys who varied in weight from 2.45 to 4.40 kgm.: (*a*) total plasma volume by a modification (3) of the T-1824 dye dilution method of Gibson and Evans (4), (*b*) NaSCN ("extracellular") volume by a modification (3) of the method of Crandall and Anderson (5), (*c*) plasma protein concentration by the $CuSO_4$ method of Phillips, Van Slyke, *et al* (6), (*d*) arterial and venous blood oxygen content by the microgasometric procedure of Roughton and Scholander (7), (*e*) circulation times by a modification (3) of the fluorescein method of Fishback, *et al* (8), and (*f*) venous hematocrit values using Wintrobe tubes and centrifuging the heparinized blood for ½ hour at 3,000 r.p.m.

The total blood volume (TBV) was calculated from the measured plasma volume and average venous hematocrit value. The circulating red cell mass (TRBC) was calculated by subtracting the plasma volume from the total blood volume. The total circulating protein (TCPr.) was derived from the plasma protein concentration and the plasma volume. Each fluid volume measurement was related to the body weight of the animal at the time of the determination.

Immediately following the control determinations, 16 of the animals were infected with *P. knowlesi* by intravenous injection of small amounts (0.25 to 2.00 ml.) of whole blood from other animals with acute infections. The survival period of these experimental animals was 4 to 12 days with an average of 7.1 days. A total of 32 sets of the above determinations were carried out on the 16 animals, beginning on the second day post-inoculation and extending up to within ½ hour of death. Determinations of the level of parasitemia were made at least daily on each animal.

Following the withdrawal of the last dye-NaSCN sample, 1 ml. of femoral arterial and 1 ml. of femoral venous blood were airlessly withdrawn as near simultaneously as possible (within 2 minutes) and the oxygen content *immediately* determined by the Roughton-Scholander method. Immediate measurement of the O_2 content is imperative in the blood of the malarious animal (especially those at high parasitemic levels) because the parasites use oxygen at a rapid rate. Allowing the samples to stand, even using the precaution of storage at low temperatures as described by Roughton (7) for normal blood, will lead to gross errors in the true O_2 content of paludic blood.

At the end of each set of determinations, *i.e.*, after the O_2 content of arterial and venous blood and the circulation time had been measured, the femoral triangle was closed by 3 or 4 skin clips and the animal returned to the cage. Since no sterile precautions were observed on exposing the artery and vein, some of the animals were given 10,000 units of penicillin intramuscularly to minimize local infection. However, such precaution was not always taken and the few skin-clip infections which developed were treated as soon as they were discovered. The right and left femoral triangles were alternated for serial studies. Local anesthesia was employed by infiltration of the femoral triangle region with 2 ml. of 2 per cent procaine.

More pronounced alterations in fluid and circulatory physiology were anticipated as the parasitemic level rose. Multiple measurements at each parasitemic level were desirable, but not always feasible. Consequently, the results have been analyzed by grouping the data in a logical but arbitrary manner. It was noted that if less than 10 per cent of the red cells of the monkey were parasitized, the animal, while showing definite clinical signs (increased body temperature, reduced hematocrit, increased "extra-

[1] The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the University of Tennessee.

[2] Lieutenant-Colonel, M.C., AUS.

cellular" fluid volume), is not acutely ill. At such levels the fatal course may be readily averted by adequate chemotherapy. Likewise, such animals are alert and active; peripheral blood can be readily drawn; and the monkey has the outward appearance of a normal animal.

However, with parasite levels at which more than 10 per cent of the red cells are parasitized, the fatal course is not easily reversed by chemotherapeutic intervention; the animals may be myasthenic and often appear depressed; it becomes increasingly difficult to draw blood from the peripheral veins or, at times, even to obtain capillary blood for smears. These conditions continue and become progressively more pronounced until death. Thus, we have divided the determinations made in this series into 4 groups: (*1*) normal (control) values, (*2*) values obtained on animals having less than 10 per cent parasitemia, (*3*) values obtained on animals having greater than 10 per cent parasitemia, and (*4*) values obtained within the 24-hour period preceding death.

RESULTS

In general the data are presented and discussed by comparing the averages of the 4 groups (Tables I, II). Entirely similar results were obtained by calculating the changes in individual animals.

Plasma volume. Figure 1 shows the changes in plasma volume expressed as ml. per kgm. of body weight. It will be seen that the plasma volume increases throughout the course of the disease until just before death. Red cell destruction is a constant feature of active malaria; and, therefore, an increase in plasma volume is not unexpected, since the usual physiological mechanism for maintaining a constant blood volume in the presence of erythrocyte loss is plasma dilution. The terminal fall in plasma volume may reflect either (*1*) pooling of blood in regions which the dye cannot penetrate except by diffusion or (*2*) increased capillary leakage. However, none of the plasma volume alterations reveal statistical significance (Table II).

Blood volume. Although the plasma volume shows progressive enlargement until just before death from malaria, the whole blood volume is reduced early in the disease. It is obvious that

† Footnotes in Table I applicable also to Table II.

this reduction is entirely due to red cell destruction which begins with, or shortly after, inoculation. However, the reduction in whole blood volume is not, in itself, serious until the terminal stages are reached when the average reduction is 42.4 per cent. It is highly probable that such a loss may lead to circulatory failure and a fatal outcome.

Erthrocyte mass. The loss in circulating red cell volume throughout the course of fatal *P. knowlesi* infections is almost linear (Figure 1). The average terminal reduction reached the high figure of 73.9 per cent at which time the average red cell mass per kgm. was but 7.8 ml. Neither the whole blood volume nor the hematocrit (Figure 1, Table I) shows parallel alterations due to the fact that the plasma volume increases in early malaria and does not fall as precipitously as does the red cell volume in the terminal stages.

Plasma protein. While the plasma protein concentration shows a small but progressive reduction during the course of the disease (Figure 2, Table I), the total circulating protein increases until just before death. The explanation for these results lies in the observed fact that there is a gradual increase in plasma volume until the day of death. The terminal fall in total circulating protein (which is statistically significant [Table II]) indicates again that increased capillary leakage may occur near the end of the fatal course.

Arterio-venous oxygen difference. The difference between the O_2 content of arterial and venous blood reveals minor changes during early malaria (Figure 2, Table I) with a marked terminal rise. Due to the drastically reduced blood volume and prolonged circulation time at this stage, the volume flow throughout any portion of the capillary bed must be materially reduced terminally.

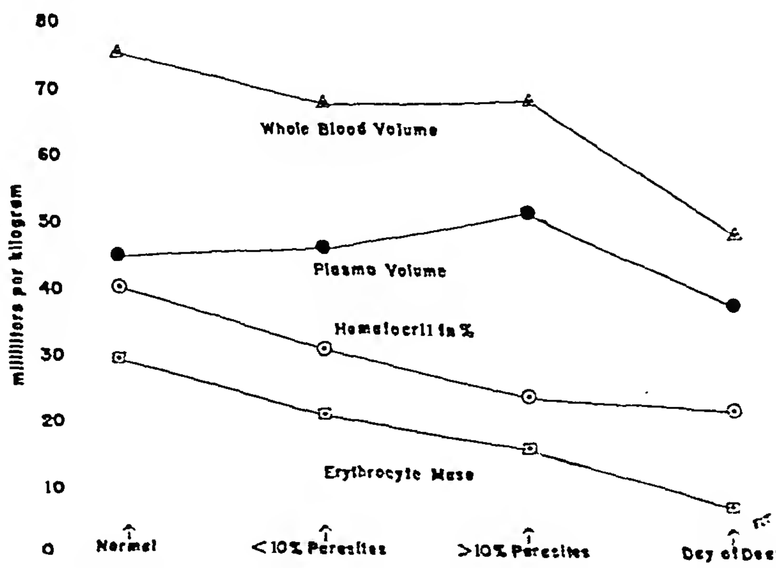

FIG. 1. CHANGES IN BLOOD AND PLASMA VOLUMES IN FATAL SIMIAN MALARIA

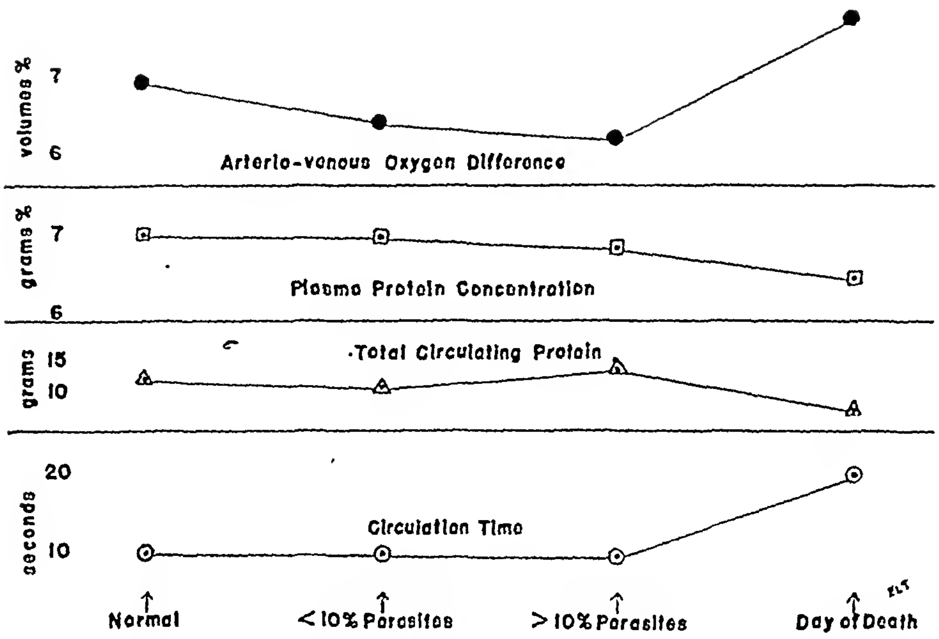

FIG. 2. AVERAGE PHYSIOLOGICAL ALTERATIONS IN FATAL SIMIAN MALARIA

Therefore, such an increase in A-V difference at this time is not unexpected.

Circulation time. During the early stages of malaria, the circulation time shows minor reductions (Figure 2, Table I). That this is a concomitant of dilution of the blood (loss of red cells and increase of plasma) and a lowered viscosity is highly probable. Terminally there may be a doubling of the circulation time. Our results indicate that although such a terminal slowing of the circulation could be due to intravascular agglutination which apparently occurs at this time (2), it could likewise be ascribed to vasoconstriction which occurs to compensate for the reduced circulatory volume.

"Extracellular" fluid volume. The volume of fluid which is available for the dilution of NaSCN ("extracellular") increases in a progressive manner throughout the fatal course of *P. knowlesi* infections in the monkey. Actually, the grouped data (Figure 3, Table I) mask some of the more startling alterations of this volume in some of the animals. Usually the *apparent* "extracellular" volume exceeded 60 per cent of the body weight

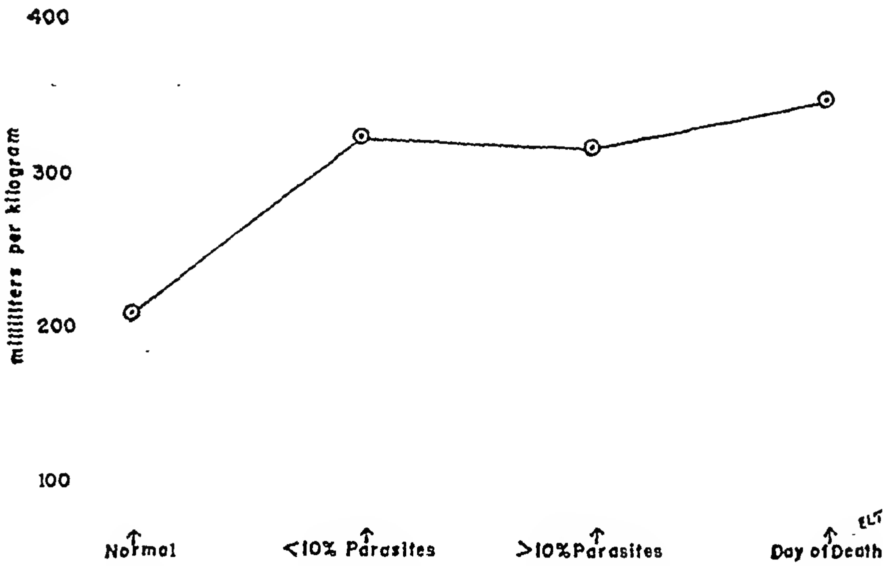

FIG. 3. "EXTRACELLULAR" FLUID VOLUME IN FATAL SIMIAN MALARIA

just preceding death of animals whose survival period and consequently the febrile period was prolonged (10 to 12 days).

DISCUSSION

Feldman and Murphy (1), who measured the blood and plasma volumes in sporozoite-induced malaria in the human being, pointed out that "the plasma volume is increased almost without exception during the active phase of *vivax* and *falciparum* infections studied." On the other hand, Knisely, *et al* (2) inferred from microscopic observations of the capillaries of living monkeys infected with *knowlesi* that "there is a progressively decreased circulating plasma volume."

From the measurements reported here, it is now possible to resolve these 2 divergent views. In early malaria (in fact, up until the day of death in simian malaria), the plasma volume is *progressively* increased. The patients studied by Feldman and Murphy, while seriously infected, were not usually in the final stages of the disease. Indeed, there were noted in 1 patient (described as being in shock) plasma and blood volume reductions of 46 and 57 per cent, respectively. This patient recovered following transfusion with whole blood and plasma. Knisely, *et al*, on the other hand, were observing the alterations in the monkey infected with an almost uniformly fatal type of malaria, and their conclusions were based primarily on observations made near the time of death.

As was observed in the human being (1), the monkey shows a marked and progressive fall in the venous hematocrit value. These observations do not support the subjective inference of Knisely that at times "the venous blood shows high red cell counts (hemoconcentration)."

Since the early reduction in circulating blood volume is due entirely to red cell destruction, it follows that the oxygen-carrying capacity of the blood will be reduced by at least a similar percentage. Indeed, since the presence of the parasite within the red cell reduces its ability to carry oxygen (by destroying hemoglobin) (9), one would expect an even greater decrease in the O_2 capacity of the arterial blood than the anemia would indicate.

The severe reduction in the number of circulating red cells and in the ability of some of the circulating cells to carry oxygen is associated, at least terminally, with a *100 per cent* increase (prolongation) of the circulation time. That tissue anoxia will result is an obvious corollary of these findings.

At the outset, the progressive *apparent* increase in the size of the "extracellular" compartment in simian malaria was difficult to explain. As previously mentioned, animals having the longest periods of survival (10 to 12 days) revealed *apparent* "extracellular" volumes which exceeded 60 per cent of the body weight. Since the plasma volume and the body weight fall terminally, it is evident that in the malarious monkey NaSCN no longer measures the "extracellular" water. One of the present authors (10) has shown that in febrile conditions SCN enters the tissue cells and becomes diluted by the entire water mass of the body.

Since the tissue cell, at elevated body temperatures, becomes permeable to the SCN ion which it normally excludes, it follows that cellular permeability to native ions might also be altered under the same or similar conditions. Pinelli (11), Velick and Scudder (12), Zwemer, Sims and Coggeshall (13), Flosi (14), and Morin, Bader, Monnier and Moreau (15) have all reported a decrease in blood sodium or chloride and/or an increase in blood potassium concentration in malaria.

Our observations indicate that such changes may occur as a result of altered cellular permeability in febrile states. That the entrance of Na and Cl into cells and the loss of K from cells might be accompanied by severe metabolic disturbances leading to a fatal outcome cannot be overlooked.

SUMMARY AND CONCLUSIONS

1. Repeated measurements of plasma, blood and "extracellular" fluid volumes, hematocrit values, plasma protein concentration, arteriovenous oxygen differences, and circulation time have been made in 16 *Macacus mulata* monkeys with fatal *P. knowlesi* infections.

2. Statistically significant alterations in some of these values appear early in the disease and

by mosquito inoculation without the development of clinical jaundice.[2]

MATERIALS AND METHODS

The patients in the blood inoculation group were given initially either the McCoy strain of *P. vivax* or the McLendon strain of *P. falciparum*. After 3 to 6 days of fever they received an antimalarial drug under study. If there was complete suppression of parasites for 2 or 3 weeks, they were then reinoculated from another donor and the second course of fever was allowed to run to a spontaneous termination. If this did not give them the required 75 hours of fever over 103°, they were inoculated with *P. malariae* or given a course of triple typhoid vaccine infusions. Thus most patients were inoculated more than once and their stay on the wards ranged from 1 to 6 months. Inoculations were performed by transferring from 0.1 to 4.0 cc. of citrated blood directly from one patient to the other, the amount depending on the parasite density of the donor's blood.

Some characteristics of the patients treated are important in evaluating the results. They were almost all referred by the Social Hygiene Clinics of the New York City Board of Health. In general they were from an economic stratum that is more prone to dietary deficiencies and alcoholism than the average civilian or soldier with naturally occurring malaria. In addition about 50 per cent had received fairly extensive arsenical treatment; only 11 per cent had received no prior antiluetic treatment.

The bromsulfalein excretion was examined routinely on admission so that observations are available on all but a few patients. The 5 mgm. per kgm. dose was used. Any retention of over 15 per cent in 30 minutes, with a 5-minute specimen designated as 100 per cent, was considered abnormal. Of 400 patients on whom the test was done before treatment only 72 per cent were normal by these criteria. By contrast, all but 1 of the 27 conscientious objectors had readings well under 15 per cent, and the 1 exception had 2 determinations of 14 and 18.

RESULTS

The only significant difference in history and preliminary work-up between patients who later developed jaundice and those who did not was in bromsulfalein retention. As shown in Table I, the former group had a significantly higher incidence of liver impairment demonstrated by that test than 100 patients picked at random from among those who did not develop jaundice. Differences were observed in the amount of previous exposure to the arsphenamines and excessive indulgence in alcohol, but these are not statistically significant. The age and sex range of the jaundiced patients was the same as that of the group as a whole. There was a somewhat higher incidence in those of the white race, but some attacks of jaundice may well have been missed in the negroes. No strain of malaria was associated more often with jaundice than any other.

Half of the 36 patients became jaundiced while they were febrile with malaria. These will be referred to hereafter as Group 1. Those occurring in the post-febrile period will be designated as Group 2. Of the 18 patients in Group 1, 6 occurred during the first bout of fever, 11 during the second and 1 during the third. In Group 2, 4 occurred after the first bout, 12 after the second and 2 after the third.

Fifty per cent of the patients in Group 1 and 88 per cent of these in Group 2 had either mild symptoms or none at all. The remainder were more severely ill with such symptoms as marked anorexia, vomiting, diarrhea, epigastric pain, pruritis, and in 1 case hematemesis and ascites. None died. Almost all had enlargement of the liver. The average duration of jaundice in Group 1 was 13 days and in Group 2, 7 days. The diagnosis of hepatitis was confirmed by tests for urinary bile and urobilinogen, icteric index or serum bilirubin and bromsulfalein excretion. In Group 1, 7 patients had no drop in hemoglobin over the 7 to 10 day period prior to the onset of jaundice, and 11 had an average drop of 1.3 grams, no more than the average patient has with the same amount of malaria.

TABLE I

Incidence of abnormal bromsulfalein retention among patients prior to blood inoculation to establish malaria

21 patients who developed jaundice compared with 100 patients picked at random who did not develop jaundice.

	Per cent bromsulfalein retention in 30 minutes				
	<16%	<21%	<31%	<41%	<51%
Patients with jaundice, *number*	12	15	18	20	21
Patients with jaundice, *per cent*	57%	71%	86%	95%	100%
Patients without jaundice, *number* and *per cent*	82	90	99	100

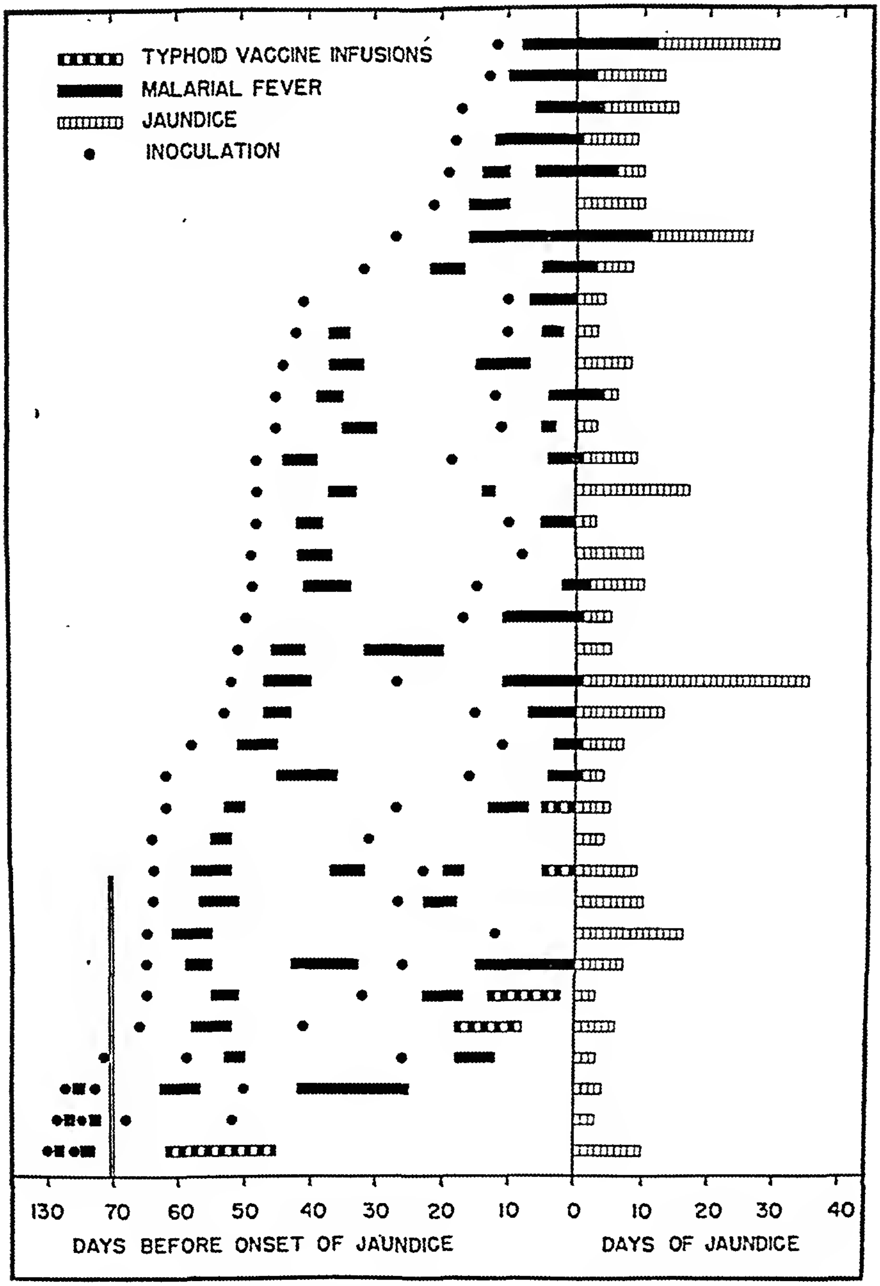

FIG. 1. SCHEMATIC REPRESENTATION OF THE TIME RELATIONSHIPS OF THE INOCULATIONS WITH BLOOD TO INDUCE MALARIA, THE DURATION OF MALARIAL AND TYPHOID VACCINE FEVER, AND THE ONSET AND DURATION OF JAUNDICE

The day of onset of the jaundice occurs at the zero line; the scale changes at the far left.

The relationship between the time of inoculation and the onset of jaundice is presented in Figure 1. These data are presented in detail to illustrate the possibility of a transfer of an icterogenic virus with the transfer of blood utilized for inoculation of patients with malaria. In Table II the figures are broken down into groups and reveal that those who developed jaundice during malaria had in general shorter "incubation periods" than those who developed their jaundice in a malaria-free

TABLE II

Number of days between inoculation and onset of jaundice (taking the maximum number of days when 2 or more inoculations were performed)

Group 1 includes those who developed jaundice while febrile with malaria, Group 2 those who developed it after their malaria had been terminated.

Days	Group 1	Group 2
0– 40	7	1
41– 55	8	6
56– 70	3	7
71–130	0	4

interval. In 28 of the patients, 78 per cent, the period between the first inoculation and onset of the jaundice was over 40 days. All patients were on the wards at least 3 weeks before the onset of jaundice.

There is additional data suggesting the possibility of transfer of an icterogenic agent in inoculation malaria. In 2 instances jaundice developed in each of 3 patients who had received their infected blood from a single donor, and there were 4 patients who donated blood to 2 others who later developed jaundice. The intervals in the former group were 12, 32 and 111 days in one instance, and 17, 26 and 42 days in the other. In the latter group the intervals were 8 and 16, 10 and 51, 44 and 118, and 53 and 66 days. The records available do not indicate how many patients received blood from these same donors and did not develop jaundice.

DISCUSSION

As far as is known, none of the drugs used in these studies to cure the malaria is hepatotoxic in the doses administered. In only 1 of the patients could hepatitis possibly be related to a drug, and that was a sulfonamide which was given to other patients who did not develop hepatitis. There is no reason to believe that the typhoid vaccine infusions caused the jaundice. Some of the cases may have been sporadic infectious hepatitis. There were always 15 to 30 patients in various stages of treatment associating closely with each other on the male ward. The cases were evenly distributed over a 2½-year period. One nurse developed typical acute hepatitis during this period without known contact outside the hospital.

Since no attempt was made to prove the transmission of a virus in any of the above reported patients, the evidence for such an etiology of some of the jaundice occurring during and after therapeutic malaria is only suggestive. But the fact that in half of the patients hepatitis occurred after the termination of malaria suggests that some of that occurring during malaria may be of the same etiology.

The incubation periods are on the whole considerably shorter than those reported for homologous serum jaundice. Incubation periods as short as 2 weeks, however, have been reported (9). Neefe *et al* (10) have reported changes in liver function tests in from 12 to 35 days after inoculation, although jaundice did not appear until considerably later. It is possible that the combination of an arsphenamine-injured liver and an intervening debilitating disease such as malaria may considerably shorten the time ordinarily required for the development of jaundice.

Of great importance with regard to this work are the recent reports by Neefe *et al* (11) and by Havens (12) that the parenteral transfer of a virus isolated from an epidemic of infectious hepatitis was followed by the same incubation period as the oral transfer, 20 to 37 days. Their data strongly suggest that there are at least 2 strains of hepatitis virus, and it is possible that strains with short as well as long incubation periods may have been responsible for our cases.

The occasional occurrence of jaundice, after arsphenamines have been resumed following malaria, may well be homologous serum jaundice rather than the toxic effect of arsphenamines on top of that of malaria as suggested by Kopp and Solomon (1). Indeed, there may be a distinct similarity between the problems of arsphenamine and malaria hepatitis in luetic patients. The former has recently been shown to be caused largely by transmission of a virus through improperly sterilized equipment (13, 14), a plausible explanation for the increased incidence of arsphenamine hepatitis during epidemics of infectious hepatitis.

Since the disease may be extremely serious, and since immune globulin has been shown to prevent infectious hepatitis if given early enough (15, 16), it might be wise to give immune globulin to each patient inoculated by transfer of infected blood. The evidence for its effectiveness in preventing post-transfusion hepatitis is not as strik-

ing, but it was successful in a study reported by Grossman *et al* (17).

The data presented suggest that care should be exercised in drawing conclusions about the effect of naturally occurring malaria on the liver from studies of blood inoculation malaria in syphilitic patients. The returned troops with relapsing malaria have, on the whole, more normal livers to start with, they are inoculated by mosquitoes rather than the transfer of human blood, and their malaria is usually treated promptly rather than allowed to run for 1 to 2 weeks.

SUMMARY

Thirty-six instances of jaundice complicated the treatment of 450 syphilitics with malarial fever induced by blood inoculation. Only half of these occurred during an actual attack of malaria.

None of 99 mosquito-inoculated patients developed jaundice.

The possibility that some of these attacks of hepatitis were caused by a specific icterogenic virus is discussed.

Evidence is presented to show that an appreciable number of patients with central nervous system syphilis have impaired hepatic function before they are given malaria.

MECHANISM AND SIGNIFICANCE OF THE THYMOL TURBIDITY TEST FOR LIVER DISEASE

By HENRY G. KUNKEL AND CHARLES L. HOAGLAND[1]

(*From the Hospital of the Rockefeller Institute for Medical Research, New York City*)

(Received for publication April 7, 1947)

An increase in the amounts of the globulin components of the serum has long been recognized in advanced states of liver disease (1, 2, 3), although the significance of the alteration has never been defined. It has been the basis of the Takata-Ara, Weltmann and the formol-gel reactions which have been used for many years in the diagnosis of liver disease. The nonspecific nature of these tests is now clear following the demonstration that positive reactions are found in any disease showing marked hyperglobulinemia (4, 5, 6). More recently, several new serum reactions, which appear to depend on small changes in the proteins of the serum, have been used for demonstrating liver disease. These include the cephalin flocculation, the colloidal gold and the thymol turbidity tests. The cephalin flocculation reaction has been studied in detail by Hanger and his coworkers (7, 8) and has been found to be a sensitive index of liver damage. The test may be positive in patients with liver disease who show normal serum protein values according to the usual methods of protein estimation and, conversely, the serum of patients with marked hyperglobulinemia may show negative cephalin flocculation reactions. The exact serum protein constituent that is altered in liver disease and is responsible for a positive cephalin flocculation test has not been clearly established; recent work by Hanger (8) appears to implicate albumin in addition to gamma globulin. The final solution to the problem is hampered by the complexity of the cephalin flocculation reaction, a fact which is also true of the colloidal gold reaction.

The technique of the thymol turbidity test is much simpler, however, and probably consists of a direct precipitation of a protein appearing in liver disease by the addition of a thymol solution. It would seem, therefore, that a study of the mechanism of this reaction and the protein component concerned would be more likely to yield clear-cut information regarding at least one of the proteins that appear in the blood stream during diseases of the liver. The present study was an attempt to elucidate the mechanism of the reaction and to define its significance in terms of clinical observations.

MATERIALS AND METHODS

The sera used in the study of the thymol turbidity reaction were selected from a group of 200 patients with infectious hepatitis and 65 patients with other liver disorders admitted to the Out Patient Department of the Hospital of the Rockefeller Institute.

Technique of performing the thymol turbidity test. The thymol reagent was prepared as described by Maclagan (9). Slight variations of this method produced unsatisfactory results. In alkaline solution thymol is somewhat unstable and turbidity of the reagent often occurs on standing. Exposure to air increases the turbidity of the solution and it was found important to keep the thymol reagent tightly stoppered. As the solution becomes increasingly cloudy, its activity decreases and it is important that only clear or very slightly turbid solutions be used. If properly prepared, the thymol reagent is satisfactory for at least one month. Although the pH of the thymol reagent was slightly lower than that originally stated by Maclagan, it proved to be satisfactory.

Three ml. of the thymol reagent were added to 0.05 ml. of serum and the degree of turbidity measured in the Coleman Jr. spectrophotometer at 650 mμ. This represented a 1/60 dilution and corresponded to that originally described by Maclagan. Figure 1 shows the turbidity of sera from cases of liver disease at various dilutions of reagent using saline dilutions as controls. It can be seen that the maximum turbidity was usually obtained at a 1/12 dilution and that differences in certain sera at the lower dilution might not be so marked at the 1/60 dilution. Although the use of lower dilutions has certain apparent advantages, all determinations discussed in this paper were performed at Maclagan's standard 1/60 dilution.

The degree of turbidity was compared with a $BaSO_4$ standard as described in a previous publication (10). This proved to be a satisfactory standard regardless of tube size or type of instrument used. The units of turbidity corresponded to those originally described by Maclagan using visual comparators.

[1] Deceased, August 2, 1946.

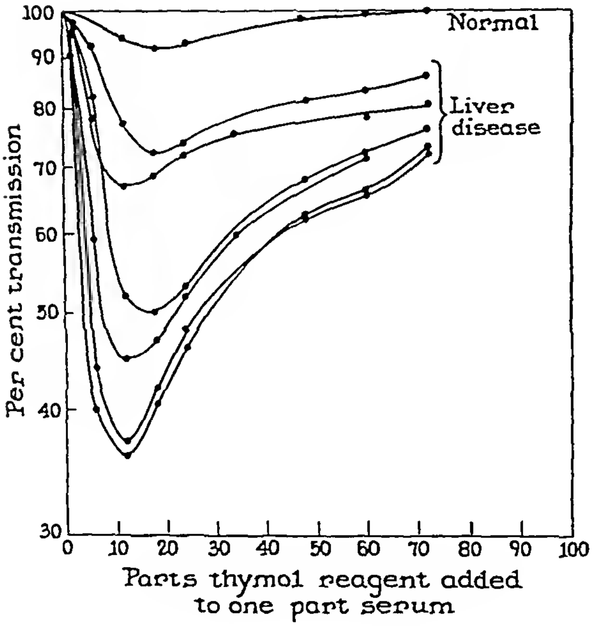

FIG. 1. TURBIDITY READINGS AS MEASURED IN THE SPECTROPHOTOMETER AT VARIOUS DILUTIONS OF SERUM WITH THYMOL REAGENT

Estimation of the degree of flocculation of the thymol serum mixture was also carried out in a number of patients. The finding of Neefe (11) that in certain patients, following an attack of infectious hepatitis, the 24-hour flocculation with thymol reagent remained positive for a slightly longer period than the usual thymol turbidity reaction, was confirmed. In general, however, the estimation of flocculation proved to be a less sensitive index than turbidity determinations, and did not furnish quantitative results.

Electrophoretic analyses were made in diethylbarbituric acid buffer ($\mu = 0.1$, pH $= 8.6$) by the method of Longsworth (12). Determinations of lipids were carried out by the gasometric lipid carbon method of Van Slyke and Folch (13). Total and free cholesterol of the plasma was determined by the method of Schoenheimer and Sperry (14). Extraction of lipids from serum was done by freezing in the presence of ether as described by McFarlane (15). A modification of Hanger's method (7) was used for the determination of the cephalin flocculation reaction. Bromsulfalein retention was estimated by the method of Rosenthal and White (16) modified for the use of the Coleman Jr. spectrophotometer. Globulin was determined electrophoretically and by fractionation with Na_2SO_4 (17). In addition, quantitative measurements of globulin were obtained by a turbidometric technique (18).

Immunological experiments were carried out by injecting rabbits with 5 to 8 mgm. of thymol protein every 2 days for 8 injections. The antiserum was absorbed with normal human serum. Precipitin tests were carried out by the technique of Swift, Wilson, and Lancefield (19).

EXPERIMENTAL

I. *The relation of the thymol turbidity reaction to the lipids in the serum*

It was demonstrated by Maclagan (9) that the precipitate resulting from the addition of thymol reagent to serum is high in cholesterol and phospholipids. Recant, Chargaff and Hanger (20) found that sera from cases of liver disease from which lipids had been extracted with ether no longer showed turbidity following the addition of thymol reagent. These observations indicated that lipids are an important factor in the thymol turbidity reaction. This work was confirmed and extended. Thymol was found to have a special effect on lipids in general. Any lipid emulsion tended to be broken up by the addition of a thymol solution. Figure 2 shows the effect of thymol in increasing the particle size of a lipid emulsion as viewed under the microscope. When such emulsions were visualized with the naked eye, an increase in turbidity accompanied the change in particle size. This turbidity was purely the result of the physical alteration in the lipid emulsion resulting from the addition of thymol. Lipemic sera from patients with liver disease, nephrosis, diabetes, and thyroid disease all showed an increase in turbidity upon the addition of the thymol reagent. This, however, was purely a physical change in the lipid emulsion, since no protein was precipitated as in the usual thymol turbidity reaction accompanying liver disease. The following example serves to illustrate this point.

Three-tenths ml. of lipemic serum from a patient with nephrosis was diluted 60 times with the thymol barbital buffer reagent. This gave an increased turbidity over

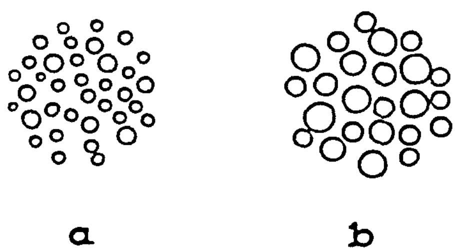

FIG. 2. COMPARISON OF THE PARTICLE SIZE OF EQUAL QUANTITIES OF A LIPID SUSPENSION IN (a) BARBITAL BUFFER, (b) BARBITAL BUFFER PLUS THYMOL, AS VIEWED UNDER THE MICROSCOPE

the serum with barbital buffer alone equivalent to 60 units. The turbid mixture was then spun for 3 hours in the centrifuge at 15,000 r.p.m. No sediment settled at the bottom of the tube, but a white layer formed at the surface leaving a clear solution underneath. Analysis of the surface layer showed that it contained 6 mgm. total lipid and 0.001 mgm. nitrogen. The material responsible for the turbidity had been brought to the surface of the solution by high speed centrifugation and was found to contain a negligible amount of protein. A similar experiment carried out on the turbid material resulting from the addition of thymol reagent to clear serum from a case of infectious hepatitis demonstrated that the cloudy material all settled to the bottom of the tube. Nitrogen analysis of the precipitate showed that it contained 0.44 mgm. of N. Whereas the turbidity of this serum had been found to be equivalent to only 30 units, the material responsible for the turbidity consisted of a large amount of protein.

It appears, therefore, that the turbidity produced by the action of the thymol reagent on lipemic sera from subjects without liver disease is due to an increase in the particle size of the protein-free lipid suspension, while the turbidity produced by the reagent in clear hepatitis serum is due to the formation of a protein-lipid-thymol complex.

Since certain sera from cases of liver disease are lipemic, it was of some importance to find a simple method of determining how much of the turbidity produced by the thymol reagent indicated a true reaction with precipitation of protein. When a thymol solution having the same pH as the usual reagent, but with a high ionic strength, was added to clear serum from a patient with liver disease giving a positive reaction, no turbidity appeared. However, when this solution was added to an artificial lipid emulsion or lipemic sera from patients with nephrosis, the turbidity produced was the same as that caused by the low ionic strength reagent. The thymol altered the state of the lipids regardless of the ionic strength of the solution. The usual protein precipitation reaction occurred only with the low ionic strength thymol reagent. In evaluating the turbidity produced in lipemic serum by Maclagan's thymol reagent, the amount of turbidity due to protein precipitation alone was obtained by using as blank in the photometer serum with the high ionic strength thymol buffer (Table I).

The presence of lipids in the serum is also an essential factor in the usual thymol turbidity reaction, as indicated by the fact that positively reacting sera after extraction with ether no longer give the reaction. The essential role of the lipids was further borne out by the finding that surface-acting agents, such as various tweens, completely inhibited the formation of any precipitate in hepatitis serum to which thymol had been added. Once formed, the thymol precipitate also dissolved readily on the addition of small amounts of tween 80.[2] In other protein precipitation reactions which depended purely on the natural solubility of the proteins involved, the presence of tween actually enhanced the precipitation. The action of the tween was undoubtedly related to its effect on the state of the lipids involved in the reaction.

Since the soluble lipids play an essential part in the thymol turbidity reaction, it seemed important to test the effect of the addition of various concentrations of lipid on the reaction. Because of the specific effect of thymol on lipid suspensions it was important to keep the lipids in their most soluble state. As a result, lipid was added in the form of clear serum giving a negative thymol turbidity reaction. Four such sera were chosen containing varying amounts of lipid. When each of these sera was added to normal serum, the thymol turbidity reaction of the combination remained negative. However, when added to serum with a high gamma globulin level giving a positive thymol reaction, the turbidity of the combination was proportional to the amount of lipid in the added serum. This effect was more strikingly brought out by first extracting the

TABLE I

[2] Polyoxyethylene sorbitan monooleate.

lipids from the serum of another patient with a high gamma globulin level in the serum. The thymol turbidity reaction was reduced from 22 to 9 units by this procedure. Table II shows the relative effectiveness of various sera in restoring a positive thymol turbidity reaction to this extracted hepatitis serum. It can be seen that the high lipid sera had a much greater effect than normal serum. The major portion of the increased turbidity was due to increased precipitation of lipid as shown by the protein and lipid analyses of the precipitates. Figure 3 demonstrates more clearly the comparative effect of various lipid concentrations on the turbidity, protein content, and lipid content of the precipitate formed with extracted hepatitis serum. The results were obtained in the same experiment illustrated in Table II. It is evident that, although there is increased precipitation of protein in the presence of higher lipid concentrations, the major portion of the increased turbidity is due to increased precipitation of lipid. In other words, the resulting turbidity reflected primarily the concentration of lipid in the added serum. The relationship was so close that it was possible to use this system as a rapid method of estimating the concentration of lipid in an unknown serum.

TABLE II

Relative effect of the addition of 0.2 ml. of sera, differing only in their lipid content, in restoring a positive thymol turbidity reaction to 0.2 ml. ether-extracted hepatitis serum

2000	4	50	3.41	5.22

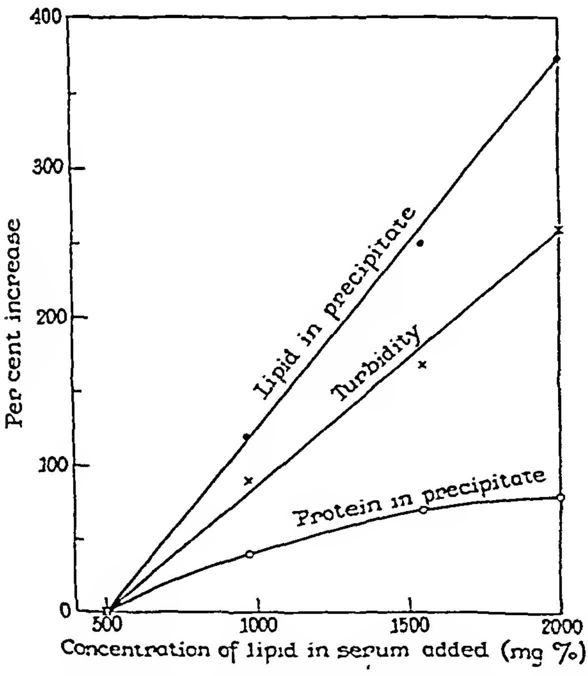

FIG. 3. EFFECT OF THE ADDITION OF SERA CONTAINING VARIABLE AMOUNTS OF LIPID ON THE TURBIDITY, LIPID CONTENT, AND PROTEIN CONTENT OF THE PRECIPITATE FORMED IN EXTRACTED HEPATITIS SERUM WITH THYMOL REAGENT

The above data demonstrated the marked influence of lipid concentration on the thymol turbidity reaction in a somewhat artificial system involving the addition of sera with variable lipid concentrations. In order to evaluate more clearly the effect of the concentration of lipids in sera on the reaction as it is usually applied, lipid analyses were carried out simultaneously on the serum of patients with liver disease and the specific precipitate resulting from the addition of thymol reagent. The amount of lipid in the precipitate varied from 20 to 50 per cent and was directly proportional to the concentration of lipid in the original serum (Figure 4). The turbidity that is usually measured in the thymol turbidity reaction depends on both the protein and lipid that are precipitated. Since the concentration of lipid in the precipitate is proportional to the concentration in the serum, it is clear that the thymol turbidity reaction actually determines in part the concentration of lipid in the serum of patients with liver disease.

Despite the fact that the level of the lipids in the serum is one of the variables that is measured in the thymol turbidity reaction, a number of patients with liver disease other than infectious hepatitis have been observed with high lipid levels in the serum but with low or negative thymol turbidity test values. Fractionation of the total lipid in these cases into the cholesterol and phospholipid partitions did not reveal any specific effect. The addition of reactive protein, or serum contain-

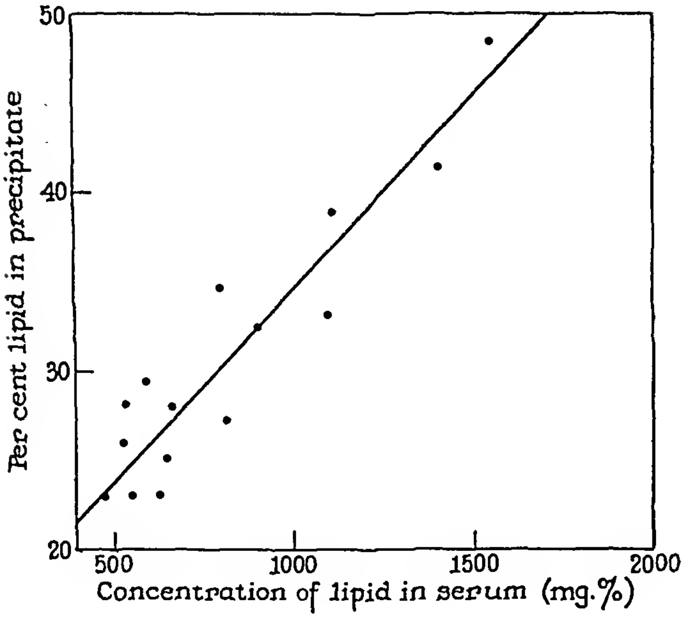

FIG. 4. THE RELATION OF THE LIPID CONTENT OF SERUM FROM PATIENTS WITH LIVER DISEASE TO THE LIPID CONTENT OF THE SPECIFIC PRECIPITATE FORMED IN THE THYMOL TURBIDITY REACTION

ing reactive protein, always produced a positive reaction in proportion to the total lipid concentration. The presence of the thymol-reacting protein was the essential factor while the level of the lipids affected only the intensity of the reaction.

II. *Identification of the protein involved in the thymol turbidity reaction*

Maclagan (9) analyzed the precipitate obtained in a positive thymol turbidity reaction and found that it consisted of approximately 40 per cent protein. He suggested that this was probably a gamma globulin because of its low solubility. Hanger and associates (20) were unable to obtain positive thymol turbidity reactions by adding gamma globulin electrophoretically separated from hepatitis sera to normal sera and various lipid fractions. They concluded that the protein involved in the reaction was probably an alpha or beta globulin and not in the gamma globulin fraction.

(*a*) *Electrophoretic analysis of the thymol precipitate.* Studies of the precipitate obtained with thymol reagent were hampered by the large amount of lipid that was present. Turbid solutions were always obtained when attempts were made to dissolve the precipitate and it was impossible to obtain an electrophoretic pattern. Extraction of the lipids from the precipitate in the cold with ether alone, ether and alcohol, or acetone alone, always resulted in denaturation of the proteins in the precipitate. When removed from serum the proteins were apparently less resistant to the action of organic solvents.

Attempts were also made to dissolve the precipitate resulting from the thymol reaction in normal serum and observe the change in the electrophoretic pattern. The high lipid concentration, however, still interfered and no conclusive results could be obtained. The difficulty was finally overcome by the use of tween 80, a strong emulsifying agent. A 1 per cent concentration of this material did not affect the electrophoretic pattern of normal serum. A clear solution suitable for electrophoretic determinations was obtained in the following manner.

Two hundred ten ml. of thymol reagent were added to 15 ml. of very reactive hepatitis serum (38 units) at 0° C. The precipitate was collected by centrifugation in the cold and suspended in 10 ml. barbital buffer containing 1 per cent tween at pH 8.5 and $\mu = 0.1$. This was then dialyzed in the cold against barbital buffer at the same pH and ionic strength. A small amount of sediment that still remained was thrown down by centrifugation and the resulting supernate was quite clear.

Figure 5 shows the electrophoretic pattern of the protein solution obtained in the above manner. The sharp peak (*b*), representing almost the entire amount of protein present, had a mobility of 1.6×10^{-5} which places it in the gamma globulin fraction but with an unusually rapid mobility. A

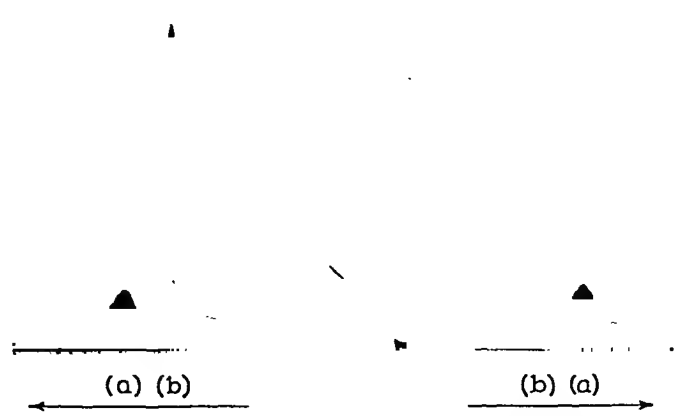

FIG. 5. ASCENDING AND DESCENDING ELECTROPHORETIC PATTERNS OF THE PROTEIN COMPONENT OF THE PRECIPITATE FORMED IN THE THYMOL TURBIDITY REACTION

Peak (*a*) $= \beta$ globulin ($\mu = 2.83 \times 10^{-5}$); peak (*b*) $= \gamma$ globulin ($\mu = 1.60 \times 10^{-5}$).

small definite beta globulin peak (*a*) is also visible. In a second experiment with material from another patient, lipid and tween were removed by subjecting the protein to repeated precipitations from large volumes of solution by lowering the salt concentration. The final preparation contained no lipid and the electrophoretic pattern showed a single peak with the mobility of a gamma globulin. Further experiments with the thymol-precipitated protein in the absence of tween indicated that when all of the lipid was removed by centrifugation at 12,000 r.p.m. at high salt concentrations, the remaining protein migrated extremely slowly. In 1 experiment the mobility was 0.5×10^{-5}. It appeared as if the more lipid that was removed, the more slowly the remaining protein migrated.

(*b*) *Effect of the addition of gamma globulin to normal serum.* The importance of the gamma globulin fraction was borne out in a series of experiments with gamma globulin separated electrophoretically from various types of sera. Considerable difficulty was encountered in adjusting the protein concentration, the ionic strength, and the pH of each fraction to exactly the same level because of the small and variable amount of gamma globulin that was obtained by electrophoretic separation. Slight variation in these fractions caused marked differences in their effect on the thymol turbidity reaction of serum and, as a result, this method of studying the protein component responsible for the reaction was not completely satisfactory. However, it was possible to demonstrate that gamma globulin fractions from certain sera demonstrating a very high thymol turbidity reaction, although negative alone, produced positive reactions with thymol reagent when added to normal serum. The gamma globulin precipitated with thymol reagent only in the presence of lipid. The amount of turbidity produced was proportional to the concentration of lipid in the serum to which the gamma globulin was added. No turbidity was produced with serum in the presence of a small amount of tween.

That the gamma globulin fraction is important in the thymol reaction as it is usually carried out was also indicated by experiments where this fraction was removed from 2 positive sera electrophoretically. The sera, after being brought to their previous state in all respects, except that the gamma globulin was absent, now gave a negative reaction.

Comparison of gamma globulin preparations from various sera in respect to their ability to induce a positive reaction in the presence of lipid was attempted (Table III). Four mgm. of gamma globulin were added to each 0.1 ml. of serum used. The gamma globulin obtained from the serum showing the pattern illustrated in Figure 6*a* was slightly more active in inducing a positive thymol reaction than was that obtained from normal serum. It also appeared to be slightly more active than was gamma globulin obtained from the serum of a patient with cirrhosis of the liver which showed an increase in the gamma globulin fraction but a negative thymol turbidity reaction. A definite and clear-cut difference in activity was obtained when the hepatitis gamma globulin was compared with gamma globulin from the serum of a patient with multiple myeloma. The latter serum had given a negative thymol turbidity reaction. Since all the gamma globulin preparations had some activity in the presence of lipid, it was impossible to draw very definite conclusions. Certainly, the activity of the gamma globulin preparations was not proportional to the activity of the sera from which they were obtained.

TABLE III

Comparative effect of equal concentrations of gamma globulin, obtained from various sources, on the thymol turbidity reaction of a high lipid serum

Source of gamma globulin	Thymol turbidity of serum	Thymol turbidity of gamma globulin on addition of serum containing 950 mgm. per cent lipid
	units	*units*

4. Normal serum	2	20
5. Cirrhosis serum	4	21
6. Multiple myeloma serum	3	8

(*c*) *The change in the electrophoretic pattern of hepatitis serum following removal of the thymol protein.* In order to obtain further information about the protein or protein complex that is precipitated with thymol reagent, electrophoretic analyses were carried out on 3 highly active hepatitis sera before and after removal of the thymol

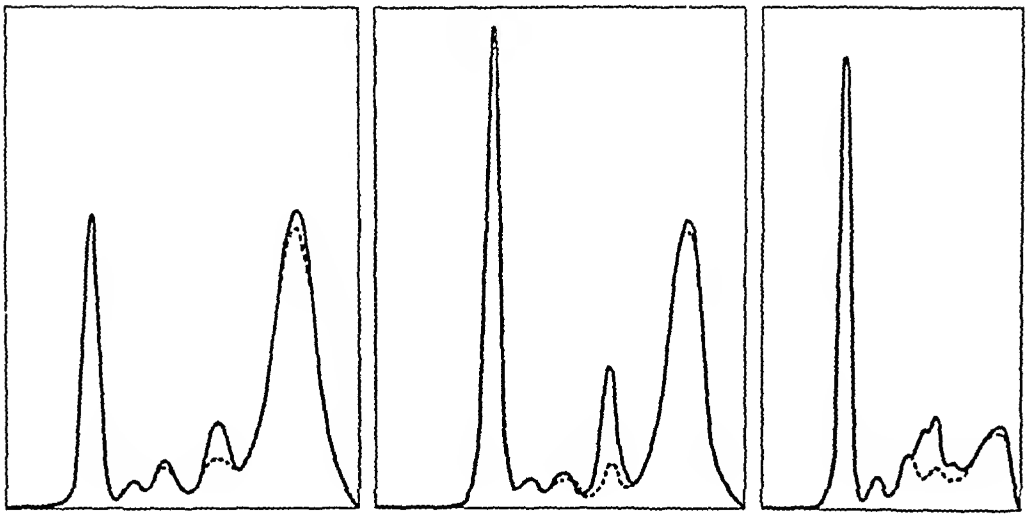

FIG. 6. ASCENDING ELECTROPHORETIC PATTERNS BEFORE AND AFTER REMOVAL OF THE THYMOL PRECIPITATE IN 3 PATIENTS DEMONSTRATING VERY HIGH VALUES FOR THE THYMOL TURBIDITY TEST

The dotted lines indicate the areas which were altered by the precipitation.

precipitate. The thymol precipitate-free serum was obtained in the following manner.

To 7 ml. of hepatitis serum, 98 ml. of thymol reagent were added. The precipitate was permitted to settle for 30 minutes and then removed by centrifugation. The clear supernatant solution was dialyzed against saline until all traces of thymol were removed. The volume of solution was brought down by evaporation in the dialysis bag placed in front of an electric fan. This procedure was continued until the protein content of the solution was equal to that in the original serum minus the quantity in the thymol precipitate. Electrophoretic analyses were then carried out after the usual adjustment to a pH of 8.6 and $\mu = 0.1$ by dialysis against barbital buffer.

By superimposing the tracings obtained before and after removal of the thymol precipitate (Figure 6), the differences in the electrophoretic patterns of the 3 sera are clearly visible. The predominant alteration was in the beta globulin fraction. The question arises as to whether the change in this fraction is due solely to the removal of lipid from the serum as a result of the thymol precipitation. A decrease in the beta globulin is known to occur with extraction of lipids from the serum by means of organic solvents. Calculation by planimetry of the protein lost from the gamma globulin peak showed some variation in the ascending and descending patterns of the same serum. In addition, the amount of protein lost by the precipitation was small in comparison with the total protein, less than 8 per cent in all 3 cases. It was, therefore, difficult to obtain exact evidence as to how much of the protein precipitated came from the gamma globulin fraction. The figures obtained ranged between 25 and 45 per cent with an average of 37 per cent for the ascending and descending patterns of the 3 sera. These results indicated a portion of the precipitated protein came from the gamma globulin fraction but that the largest portion came from the beta fraction.

(*d*) *Immunological results.* In order to find out more definitely whether the globulin precipitated in the thymol turbidity reaction is an abnormal protein or just an increased amount of normal protein in the serum, antibodies to the protein illustrated in Figure 5 were obtained in rabbits. The antiserum reacted strongly with normal serum, and no definite difference could be obtained with sera containing large amounts of gamma globulin or sera giving a very positive thymol turbidity reaction. Absorption of the antiserum with normal serum did not aid in demonstrating a difference between normal and hepatitis serum.

(*e*) *Effect of albumin on the thymol turbidity reaction.* In view of the known effect of albumin in increasing the solubility of proteins in general and the specific effect of albumin on the cephalin flocculation reaction (8), studies were carried out to determine its effect on the thymol turbidity reaction. Figure 7 demonstrates the fall in the values

for the thymol turbidity test in the serum of a patient with hepatitis upon the addition of increasing amounts of concentrated human albumin. The albumin concentration of the serum had to be almost doubled before much change occurred.

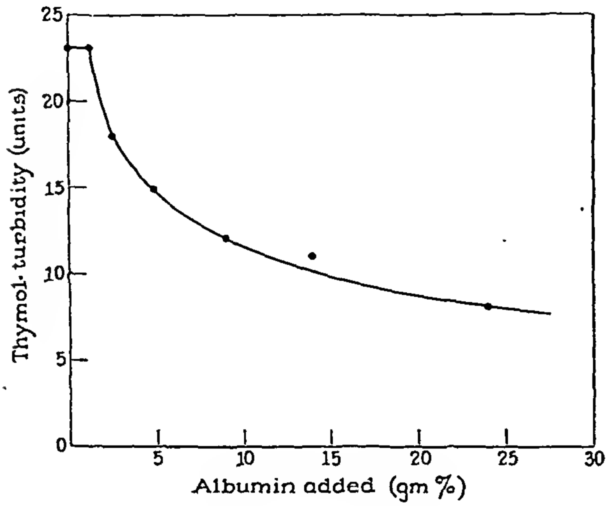

FIG. 7. THE EFFECT OF THE ADDITION OF VARIOUS AMOUNTS OF HUMAN ALBUMIN ON THE THYMOL TURBIDITY REACTION IN THE SERUM OF A PATIENT WITH INFECTIOUS HEPATITIS

In vivo studies with concentrated solutions of human serum albumin in patients with diseases of the liver have shown a definite decrease in the intensity of the thymol turbidity reaction of the serum following intensive therapy with this material. The decrease in the thymol turbidity reaction could be accounted for partly on the basis of an increase in plasma volume and on the *in vitro* effect of albumin described in the previous paragraph. However, in certain patients the fall was too great to be explained in such a manner. An example of such an effect was seen in the case of a 12-year-old boy with very severe acute infectious hepatitis accompanied by edema and ascites. The administration of three 25-gram units of albumin produced a fall in the thymol turbidity reaction from 27 to 7 units with an increase of only 1 gram per cent in the serum albumin level. The change in plasma volume in this patient was approximately 10 per cent. The cephalin flocculation reaction showed no change during this period. The thymol turbidity reaction returned to its original level within 6 days following cessation of therapy. Apparently, in the body, albumin may have a specific effect on the reaction not encountered in the *in vitro* experiment. The level of albumin in the body, therefore, is another factor influencing the intensity of the thymol turbidity reaction.

III. *Clinical observations on the effect of the protein and lipid components of the serum on the thymol turbidity reaction during the course of acute infectious hepatitis.*

In order to demonstrate further the influence of the lipid level of the serum on the reaction under study, lipid determinations were carried out on 2 groups of patients during the early icteric phase of acute infectious hepatitis (Table IV). The

TABLE IV

Average lipid concentration in the serum of patients with acute infectious hepatitis showing high thymol turbidity test values compared with those showing low values

Group	No. of patients	Thymol turbidity test values	Average total lipid concentration

B	6	below 15	610

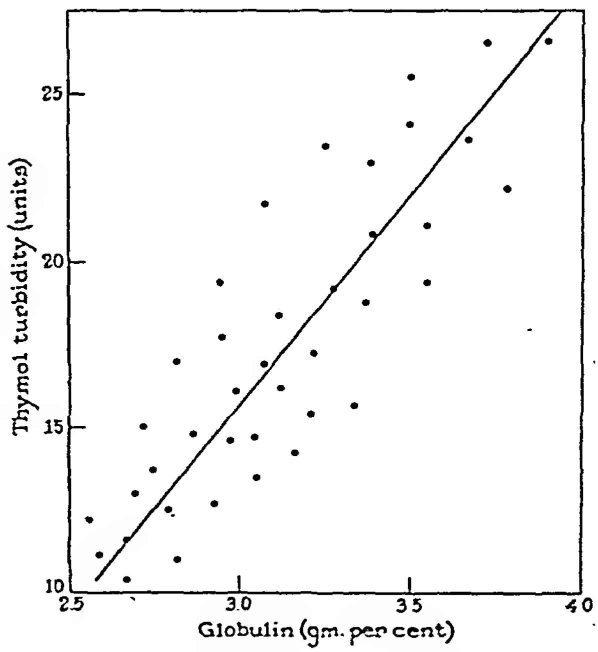

FIG. 8. RELATION BETWEEN THE ELEVATION OF THE THYMOL TURBIDITY TEST AND THE GLOBULIN LEVEL OF THE SERUM DURING THE CONVALESCENT PERIOD OF ACUTE INFECTIOUS HEPATITIS

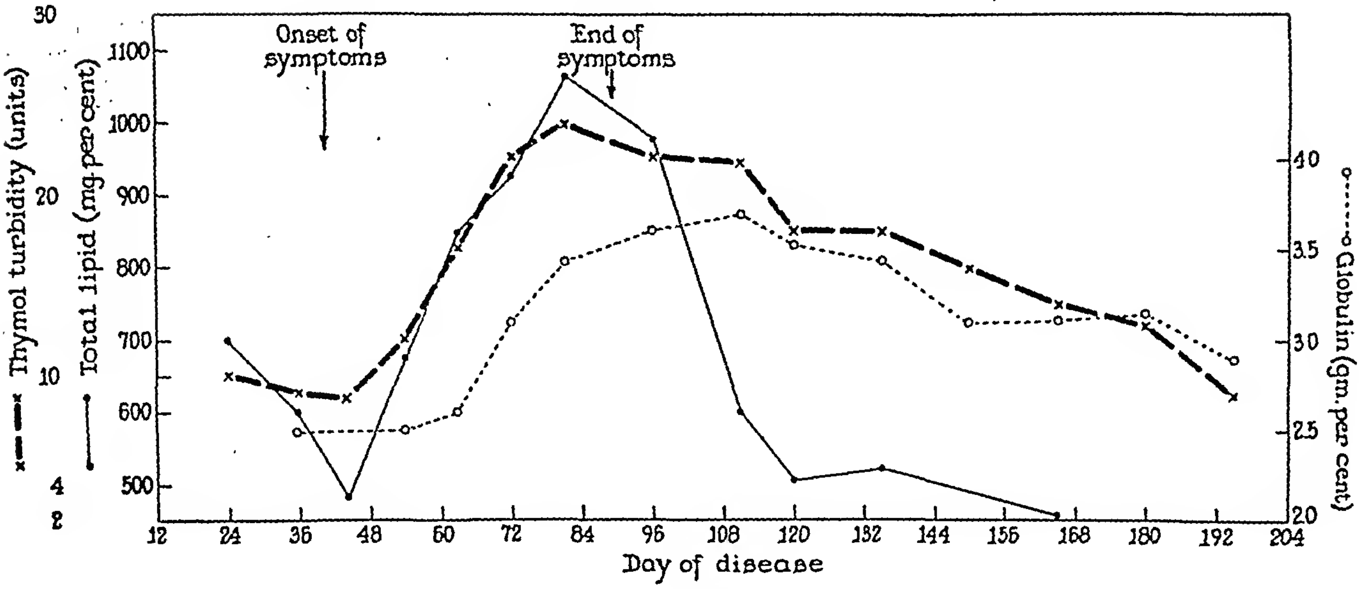

FIG. 9. ILLUSTRATION OF THE CLOSE PARALLELISM BETWEEN THYMOL TURBIDITY AND LIPID DETERMINATIONS INITIALLY, AND BETWEEN THYMOL TURBIDITY AND TOTAL GLOBULIN DETERMINATIONS DURING THE LATER PERIOD IN A RELAPSE OF INFECTIOUS HEPATITIS

severity of the illness in the 2 groups was approximately equal and they differed only in the intensity of the thymol turbidity reaction. None of the patients showed more than slight elevation of the globulin level. It can be seen that the average lipid concentration in the sera of patients with high values for the thymol turbidity test was much greater than in the group showing low values.

During the convalescent period of infectious hepatitis the influence of the lipid level became less pronounced and values for the thymol turbidity test paralleled the globulin level of the serum to a close degree. Figure 8 demonstrates this relation in a group of patients during convalescence at a time when the lipid changes were minimal.

The comparative influence of the protein and lipid components on the thymol turbidity reaction during the course of infectious hepatitis may also be seen from Figure 9. This chart illustrates the close parallelism of values obtained by simultaneous determinations of the thymol turbidity reaction and plasma lipids in demonstrating a delayed rise during the course of a recurrence of acute infectious hepatitis. The total globulin level showed an even more delayed elevation and during the late convalescent period the thymol turbidity reaction followed the pattern of the globulins very closely. Electrophoretic determinations demonstrated that the rise in total globulin was almost entirely due to an increase in the gamma globulin fraction.

DISCUSSION

The experiments that have been described make it clear that there are 2 main components in serum that are important in the thymol turbidity reaction: (*a*) the protein component, (*b*) the lipid component. Electrophoretic analyses have indicated that these 2 components are not separate but are intimately related. The entire question revolves about the difficult problem of loose protein-lipid combinations that migrate in the beta globulin fraction of serum. The ease with which these combinations are broken makes it difficult to study the lipid-protein complexes individually. The observations reported have shown a slower electrophoretic migration of the protein as the lipid is removed and suggest the possibility that some beta globulins may represent light combinations of lipid and gamma globulin.

In view of the specific effect of thymol on lipids in general, it seems logical to suppose that dilution of serum with a thymol solution would tend to throw lipid-protein complexes out of solution. The protein is carried along by the effect of thymol in decreasing the solubility of the lipids. In addition, the low ionic strength buffer used in the reagent will sometimes precipitate gamma globulin

from hepatitis serum (18) in the absence of thymol. Such a buffer solution has been used by Wolff for detecting the globulin elevation in malaria serum (21). The effect of the thymol in increasing the precipitate appears to be attributable to the action of thymol in decreasing the emulsification of lipids. The inhibitory effect of emulsifying agents on the thymol turbidity reaction also indicated that the protein precipitation was enhanced by the effect of thymol on the lipids in the serum. The reaction, therefore, probably results from a combination of the effect of thymol in decreasing the dispersion of the lipid component, and the effect of dilution with low ionic-strength buffer in decreasing the solubility of the globulin component, in such a way as to precipitate the protein-lipid combination.

The fact that the lipids of the serum play a greater role in the thymol turbidity reaction than just forming a part of the protein-lipid-beta globulin complex essential to the reaction, is indicated by the observations which demonstrated that the per cent lipid in the thymol precipitate is proportional to the total lipid in the serum of patients with infectious hepatitis. In addition, the experiments with mixtures of 2 different sera showed that a high lipid serum, although negative by itself, markedly affected the intensity of the reaction of the combination.

The effect of gamma globulin in acting with normal serum to give a positive thymol turbidity reaction suggests a similarity to the cephalin flocculation reaction where such an effect is also seen (8). One of the main points of dissimilarity between the 2 reactions that has been cited (20) is that extraction of the lipids from hepatitis serum does not affect the cephalin flocculation reaction as it does the thymol reaction. This, however, cannot be considered a fundamental difference because, in the cephalin flocculation reaction, the cephalin-cholesterol reagent used supplies ample lipid to an extracted serum. The thymol alters the state of the lipids of the serum so that a lipid globulin complex precipitates from the serum of certain patients with liver involvement. In the cephalin flocculation reaction, a lipid suspension is added to the serum so that a lipid globulin complex precipitates. The difference in the 2 tests is mainly in the manner in which the lipid globulin precipitation is brought about. Clinically, the 2 tests are related, although occasional marked differences do occur (11, 22 to 24). One of the main discrepancies is seen in the earlier development of a positive cephalin flocculation reaction during the pre-icteric stage of acute infectious hepatitis. A possible explanation may lie in the fact that the lipids show a delayed rise in this disease, and, therefore, the effect of increased lipids on the thymol reaction would not be present.

An increased concentration of gamma globulin was found electrophoretically in all sera showing a positive thymol turbidity reaction. Most of the positive sera but not all also showed increased amounts of beta globulin. There is difficulty in explaining negative reactions in certain patients with cirrhosis of the liver who have markedly increased gamma globulin levels, high beta globulin concentrations, high total lipid values and, in addition, low plasma albumin. This should be the ideal situation for a very positive thymol turbidity reaction. The evidence for a qualitative difference in the increased globulin is not sufficiently conclusive to explain such a case entirely, especially in view of the negative results obtained in immunization experiments. Similar discrepancies have been noted in the cephalin flocculation reaction and Hanger and his associates (8) have obtained evidence that albumin plays an important role. This problem requires further study.

In the course of studies on patients with various types of liver disease associated with marked hypergammaglobulinemia, it was noted that most of them had equally high thymol turbidity values: approximately 35 units. This was also true of sera from patients with kala azar and schistosomiasis with marked hypergammaglobulinemia. This represented a protein precipitation of approximately 0.8 gram, a very small portion of the gamma globulin of these sera. This was not true of patients with multiple myeloma. The gamma globulin elevation in this disease appears to be very different. A negative thymol turbidity reaction was always obtained. It appeared as if there was a maximal amount of protein that could be precipitated. A possible explanation for this phenomenon may reside in the fact that all these sera showed approximately the same amount of lipid and, therefore, only a limited amount of lipid was

available to precipitate with globulin in the presence of thymol reagent. More protein readily precipitated if additional lipid was added.

The close relation between the level of the lipids in serum and the intensity of the thymol turbidity reaction must be kept in mind in evaluating observations by this test because of the frequent occurrence of elevation of the plasma lipids in liver disease. The dependence of the test on 2 variable factors, the protein and lipid components, is somewhat of a disadvantage to a clear analysis of the significance of the reaction. This may be the reason for the lack of correlation between the intensity of the reaction and the severity of illness observed in a clinical study of infectious hepatitis (22).

Serial determinations of the thymol turbidity test during the course of infectious hepatitis have revealed that values for the test show a delayed rise following the onset of the disease and a prolonged elevation during convalescence (25). The relative effect of the lipid and globulin components of the reaction upon this pattern was demonstrated. The values for the thymol turbidity test closely paralleled the plasma lipids during the acute phase of the disease and the total globulin level during convalescence. The prolonged high values for the thymol turbidity test following infectious hepatitis were due to persistent elevation of the serum globulins. These observations were substantiated by electrophoretic patterns taken during the course of this disease. During the early period of elevation of values for the thymol turbidity test the dominant abnormality was an increase in the electrophoretic beta globulin. This was a reflection of the elevated plasma lipids. Later the predominant aberration was an increase in the gamma globulin, which remained elevated as long as the thymol turbidity reaction remained positive. Thus, it is apparent that the thymol turbidity test has a different significance during different stages of a single disease such as acute infectious hepatitis.

Determination of the lipid changes alone is not a sensitive index of acute liver damage, and there is no simple specific method of determining the small increases in globulin following such damage. The thymol turbidity test in reflecting the combination of these aberrations is a more sensitive index of liver injury than either one alone. Since the essential factor in the mechanism of the reaction is the increase in the globulin component following acute liver injury, investigations of the significance of the reaction really call for an understanding of the corresponding hyperglobulinemia.

The serum globulins are known to show a delayed rise in several diseases; this has been considered to be a reflection of the development of antibodies. Recent studies on typhus (26), however, have demonstrated that complement fixation tests and the Weil-Felix reaction did not parallel the alteration in globulin. The explanation for the change in liver disease is also very obscure. Liver biopsies obtained from the patients with marked hyperglobulinemia have revealed marked evidence of regeneration of liver tissue, suggesting that globulin elevation may be correlated with the healing process.

SUMMARY

1. The turbidity produced by the thymol reagent of Maclagan in the serum of patients with infectious hepatitis is shown to depend on the presence both of lipids and of abnormal lipid protein complexes migrating in the beta globulin fraction of the serum. The gamma globulin fraction of serum also plays an important role in the reaction. The relative importance of the different components in the reaction varies with different sera. Development of the turbidity is prevented if the lipids are kept in solution by the addition of a tween or are extracted with ether, or if the gamma globulin is removed.

2. In lipemic sera the thymol reagent causes a nonspecific increase in the turbidity due to increase in particle size of the lipid globules. Correction for this effect can be made by using a photometric blank prepared from serum and a thymol reagent containing such a high buffer concentration that precipitation of the globulin component is prevented.

3. Immunological studies did not reveal evidence that the protein concerned in the reaction was abnormal.

4. A possible similarity between the mechanism of the thymol turbidity and cephalin flocculation reactions was discussed.

5. In patients with acute infectious hepatitis values for the thymol turbidity test were found to parallel alterations in serum lipids initially and alterations in gamma globulin during late convalescence.

THE EFFECTS OF TEMPORARY CESSATION OF RENAL BLOOD FLOW IN RATS [1]

By SIMON KOLETSKY AND GORDON E. GUSTAFSON

(From the Institute of Pathology and Department of Surgery, Western Reserve University School of Medicine, Cleveland, Ohio)

(Received for publication April 23, 1947)

Litten (1) observed in 1881 that temporary occlusion of the renal artery in dog and rabbit for 1½ to 2 hours was followed by tubular necrosis. In 1926 McEnery, Meyer and Ivy (2) clamped the blood vessels of both kidneys in dogs for periods of 30 minutes to 1 hour. This led to an increase in BUN [2] and some animals died in uremia. Recently, Emmel (3) described the mitochondrial and pH changes in the rat's kidney following interruption and restoration of the renal circulation. Scarff and Keele (4) removed the right kidney of rabbits and then clamped the left renal pedicle for periods up to 120 minutes. After release the BUN rose rapidly until death or reached a peak and declined with recovery. Outcome did not always depend on time of occlusion. Van Slyke *et al* (5) found that in the dog, if one kidney was removed and the renal artery of the other clamped for 3 hours, the animal would recover following an elevation of BUN. With clamping of 4 hours, only half of the dogs recovered and at 6 hours the procedure was uniformly fatal with uremic death in 4 to 8 days. Thus renal occlusion of more than 4 hours was considered irreversible. Selkurt (6) studied the effect of temporary clamping of the left renal artery of the dog on subsequent left renal clearances. Ischemia of 20 minutes' duration practically eliminated creatinine and para-amino-hippuric acid clearances during observations extending for 136 minutes after release of clamp.

In the following experiments a study was made of the effects of temporary complete renal ischemia in rats.

METHODS

Adult white male rats, weighing about 200 grams each, were anesthetized with intraperitoneal sodium pentobarbital given in dosage of 25 to 35 mgm. per kgm. of body weight (0.3 to 0.4 ml. of a 2 per cent solution). With aseptic technique the kidneys were then exposed by lumbar incisions extending through the oblique abdominal muscles, the renal pedicles isolated, and the renal artery and vein occluded by means of bulldog clamps. The latter were applied on right and left sides usually within an interval of 20 seconds. Ureters were not occluded. Except for separation of adrenal from the kidney, no dissection of peri-renal fat was made. In all rats 0.5 ml. heparin was injected into the tail vein about 10 minutes before clamping to retard intrarenal thrombosis during the period of vascular occlusion. The heparin did not cause excessive bleeding. Food and water were withheld for about 10 hours prior to anesthesia, and were given *ad libitum* following the operation.

Complete renal ischemia was maintained bilaterally for exact periods of time, *i.e.*, 30 minutes, 1 hour, 90 minutes, and 2 hours. The kidneys were generally dark purple at the end of these periods, but all became uniformly pink either within a matter of seconds or a few minutes after removal of the clamps. A group of 15 rats was studied at each time interval.

Renal function was followed by determination of BUN, made according to the method of Ormsby (7) with 0.1 or 0.2 ml. of blood from the tail. A control level was obtained prior to operation and then values were determined at fixed intervals following removal of the clamps, *i.e.*, 6 hours, 24 hours, 2, 3, and 4 days, and in some instances 6 and 8 days. A sample of heart's blood was taken for BUN in rats which died in uremia.

The kidneys of all rats were removed for gross and microscopic study, either at the time of death or when the animals were sacrificed, usually from 4 to 8 days after the period of complete renal ischemia. A few rats in the 90-minute or 2-hour group showed renal infarction at autopsy and these were discarded and replaced. There was no observable post-operative infection.

Additional experiments indicated that the method used to produce complete renal ischemia was effective. In 5 rats coronal section of the kidneys after application of the clamps was not followed by bleeding from the cut surface. Profuse hemorrhage occurred when the clamps were released. Ten rats were sacrificed after periods of complete renal ischemia ranging from 30 minutes to 2 hours. In 2 of these animals 1 kidney was left unclamped to serve as a control. Immediately after sacrifice, with the clamps still in place, the thoracic aorta was cannulated and perfused at an average pressure of 150 mm.

[1] Aided by a grant from the Elisabeth Severance Prentiss Foundation.

[2] BUN denotes blood urea nitrogen.

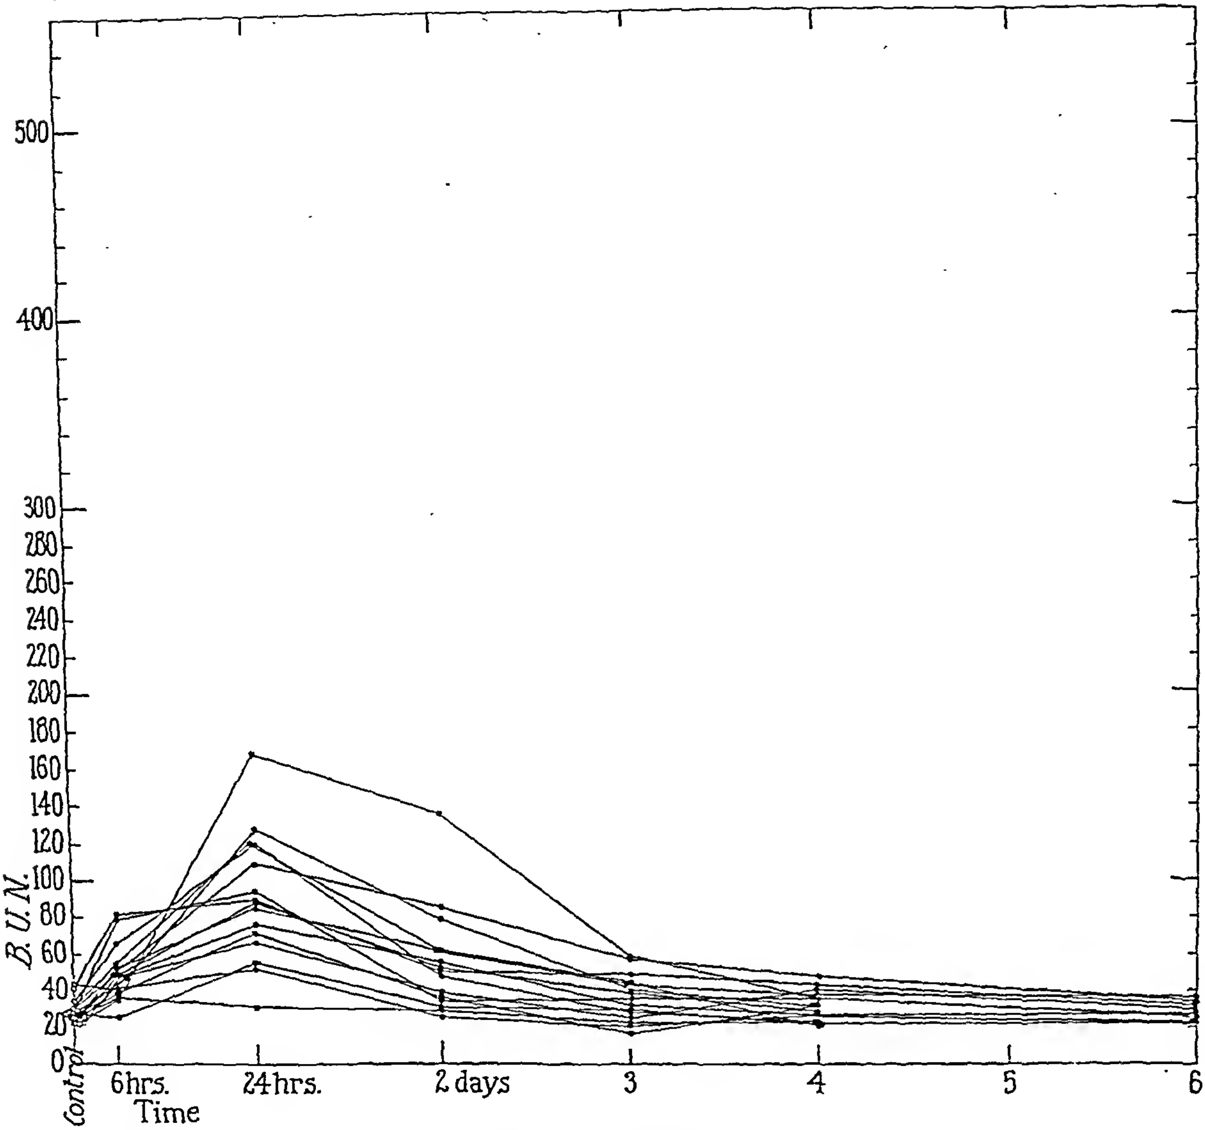

FIG. 1. BLOOD UREA NITROGEN FOLLOWING COMPLETE RENAL ISCHEMIA FOR 30 MINUTES

Hg with warm physiological saline followed by Higgin's india ink diluted 1 to 10 with saline. No gross coloration of the clamped kidneys was obtained. Microscopically, staining with india ink was practically negligible although pigment was observed occasionally in capillaries beneath pelvic mucosa and rarely in a few capillaries within the medulla.

RESULTS

After removal of the clamps, there was a progressive rise in BUN either until death or until a peak was reached, followed by a gradual decline and survival (Figures 1 to 4[3]). The animals which died showed typical manifestations of uremia, *i.e.*, weakness, apathy, somnolence, and diarrhea. The mortality among the 4 groups of rats is recorded in Table I.

[3] Values for BUN are in mgm. per 100 ml. of blood. For convenience the time of death is given to the nearest day.

TABLE I

Mortality in 60 rats following complete renal ischemia

Number of rats	Duration of complete renal ischemia	Mortality
		per cent
15	30 minutes	0
15	1 hour	13
15	90 minutes	73
15	2 hours	100

Fifteen rats with complete renal ischemia for 30 minutes. There was no mortality in this group. In 14 of the 15 rats the BUN rose to a maximum 24 hours after return of renal circulation, the values ranging from 52 to 168, with a mean of 94. In 1 rat with a control BUN of 25, a rise to only 37 was obtained at 6 hours. In every instance the BUN reverted to normal by the end of 4 or 6 days.

Fifteen rats with complete renal ischemia for 1 hour. Only 2 of the 15 rats in this group died, a mortality of 13 per cent. In the fatal cases death occurred 3 days after release of the clamps and the terminal BUN values were 312 and 400, respectively.

Thirteen rats survived the renal ischemia. The maximum rise in BUN (105 to 256) usually occurred at 1 or 2 days. By the end of 4 or 6 days the values in 6 animals had declined to normal, but were still slightly elevated in the remaining 7, *i.e.*, 40 to 82.

Fifteen rats with complete renal ischemia for 90 minutes. Eleven of the rats died in uremia, a mortality of 73 per cent. Death occurred from 2 to 6 days after the renal circulation was re-

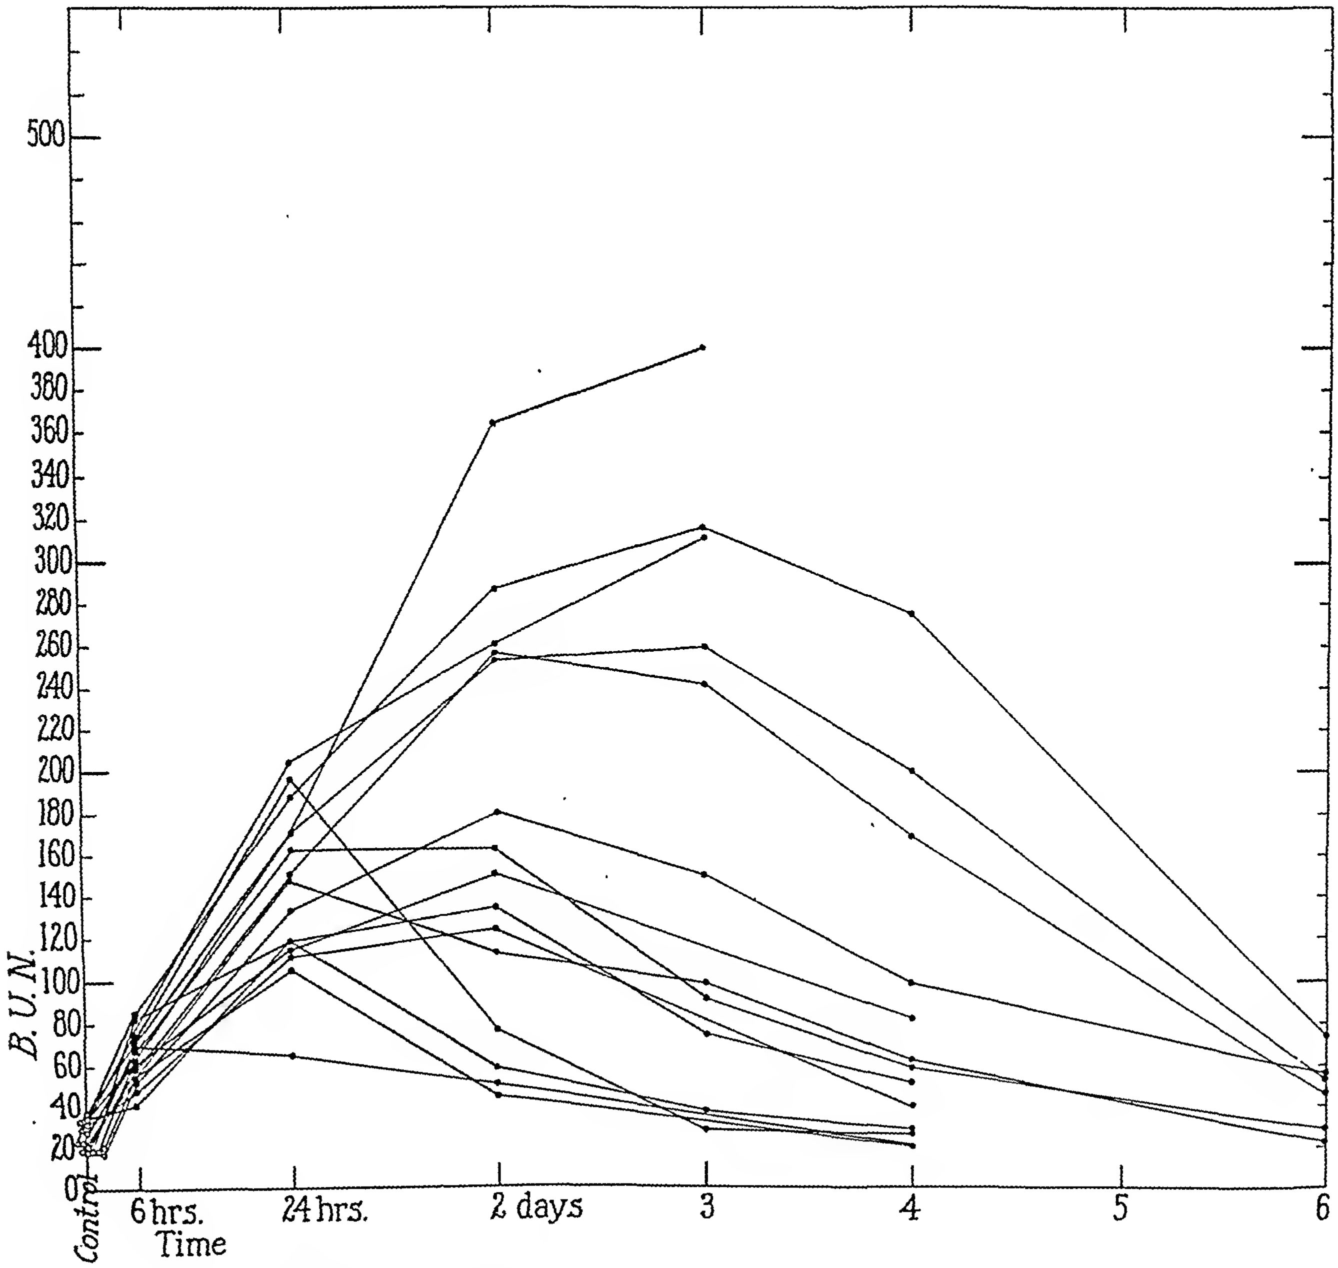

Fig. 2. Blood Urea Nitrogen following Complete Renal Ischemia for 1 Hour

ored and the terminal BUN ranged from 244 560.

Four animals in this group survived the renal chemia after attaining a BUN ranging from 0 to 260. At the time of sacrifice on the eighth y, the blood level was still slightly elevated in rats (Figure 3).

Fifteen rats with complete renal ischemia for hours. All rats in this group showed a pro-ressive rise in BUN and died in uremia from to 4 days after renewal of renal circulation Figure 4).

Morphology

The kidneys of most rats in the 30-minute group and of some in the 1-hour group showed no significant gross abnormality. In the remaining animals the kidneys were generally normal in size or slightly enlarged and frequently revealed bulging on section. The most distinctive change was the presence of a homogeneous cream-colored zone involving the entire inner portion of cortex. This contrasted with the outer cortex which was light red or brown. The medulla was pale pink and not remarkable.

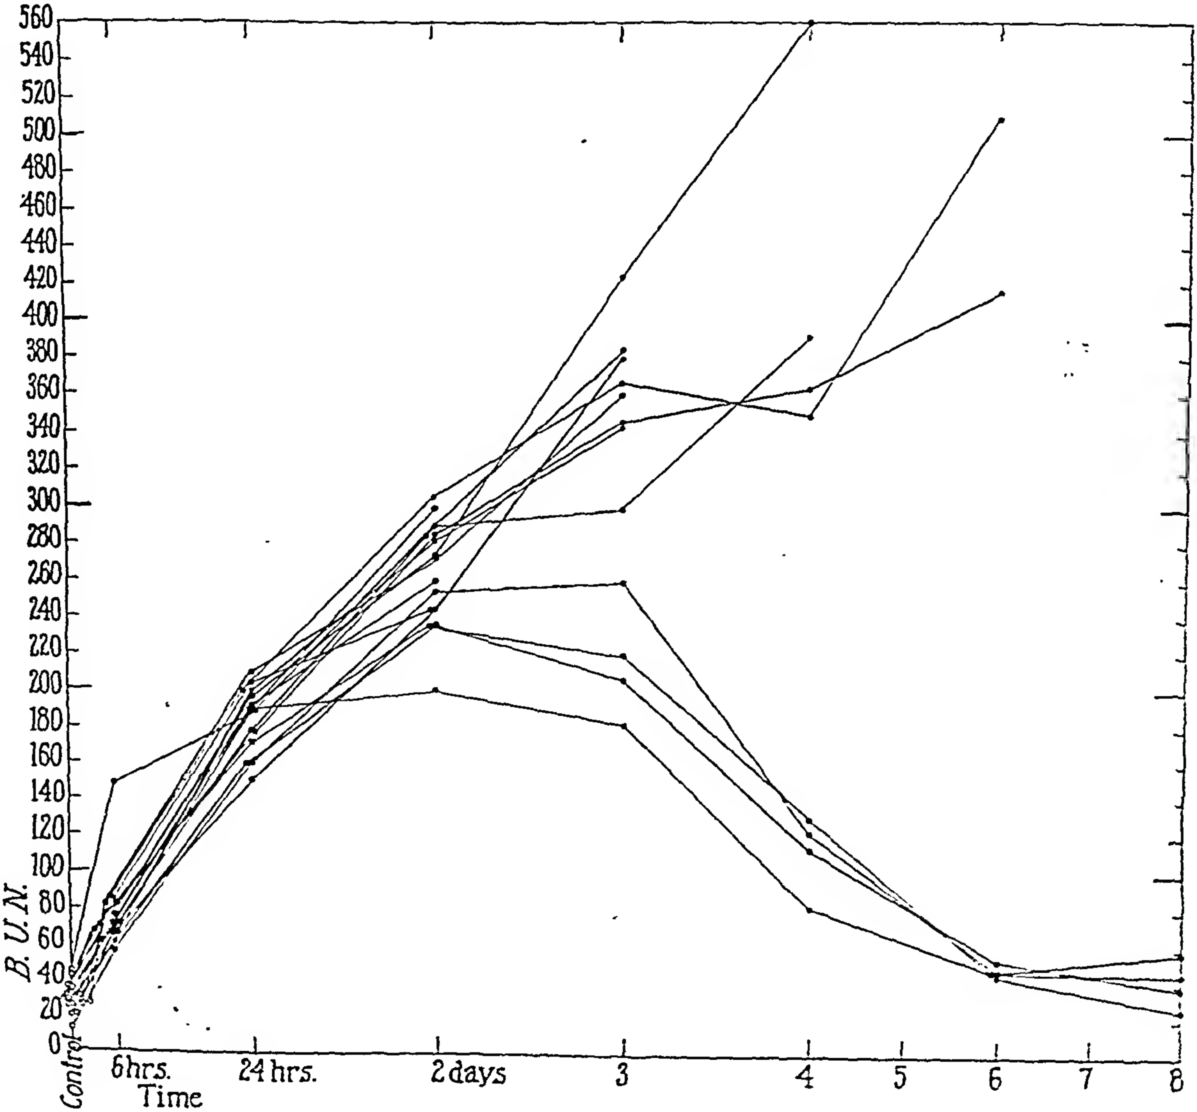

FIG. 3. BLOOD UREA NITROGEN FOLLOWING COMPLETE RENAL ISCHEMIA FOR 90 MINUTES

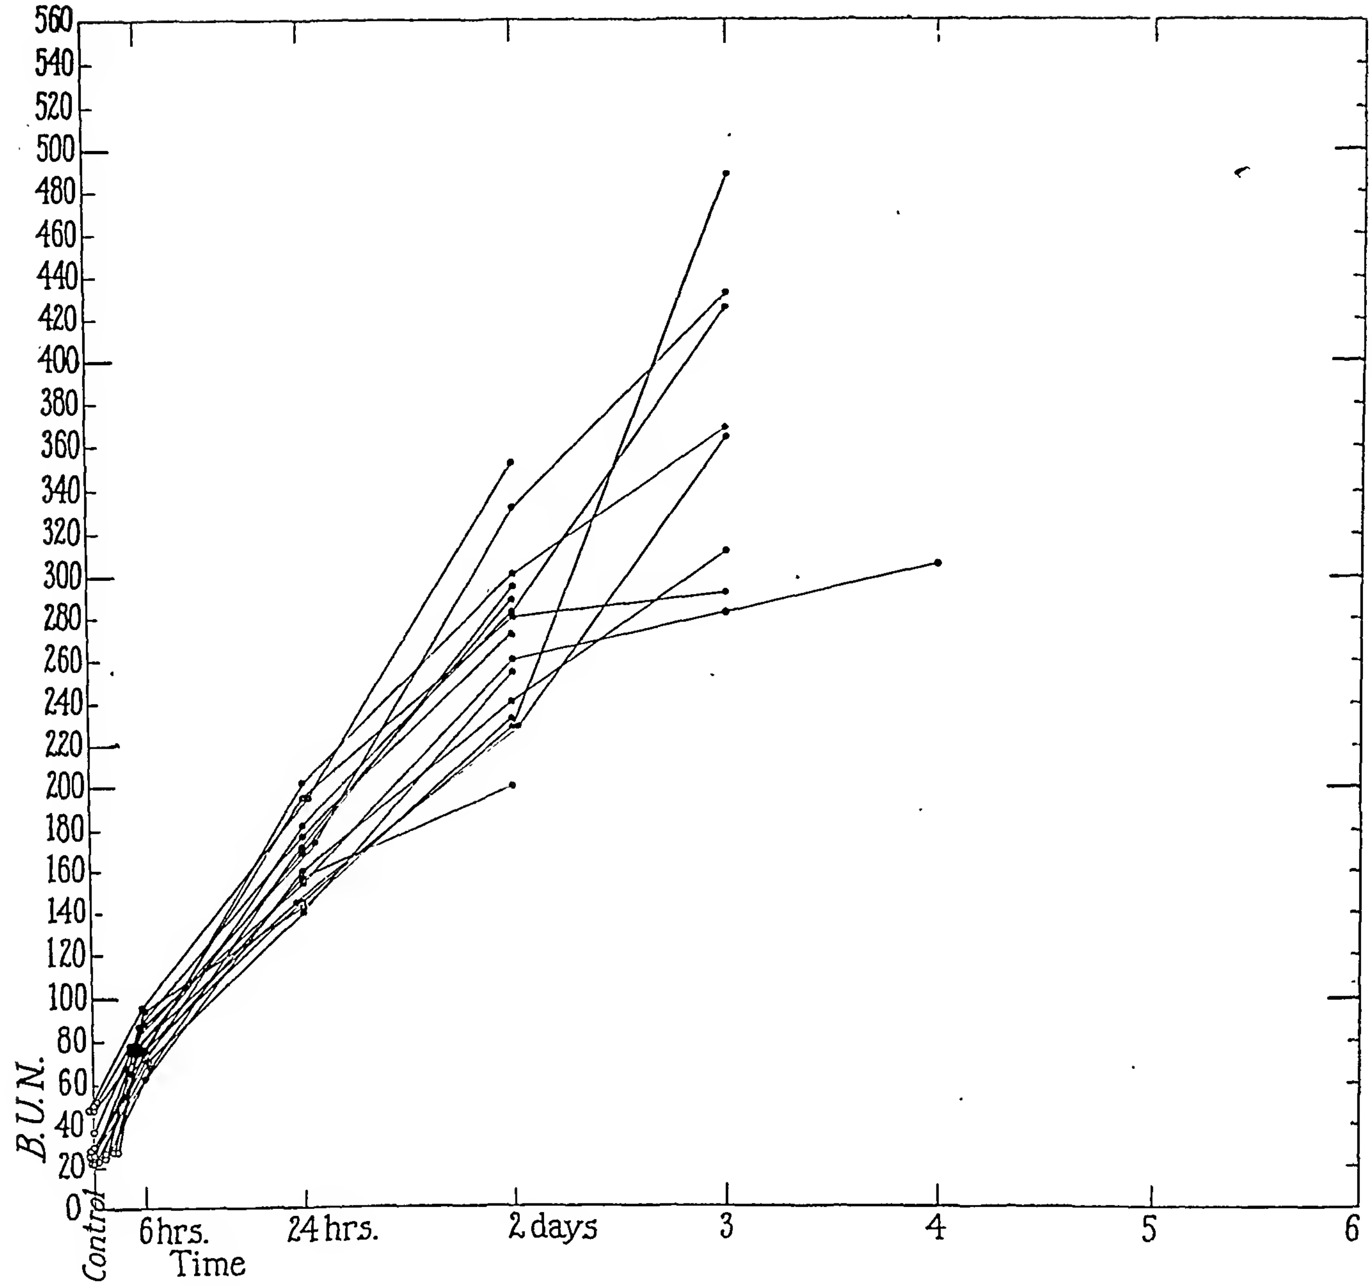

FIG. 4. BLOOD UREA NITROGEN FOLLOWING COMPLETE RENAL ISCHEMIA FOR 2 HOURS

Microscopically there was necrosis of tubules, involving principally proximal convoluted tubules in their distal or descending segments. The lesion was usually slight in rats with a 30-minute period of complete renal ischemia, more severe in degree and distribution in rats with ischemia of 1 hour's duration, and massive in animals which died in uremia, *i.e.*, chiefly those in the 90-minute and 2-hour groups.

The necrotic tubules showed loss of nuclei and the lumens were occluded by coarse acidophilic débris derived from desquamated cells. Loops of Henle and distal convoluted tubules contained acidophilic hyaline casts, often with interspersed pyknotic nuclear fragments, but the epithelium was preserved. The lumens of the collecting tubules were filled with amorphous pink staining casts. In general the glomeruli showed no significant morphologic change although some were reduced in size. No lesion of blood vessels was found. In the vicinity of necrotic tubules there was a slight focal interstitial exudate of lymphocytes and a few polymorphonuclear leucocytes.

In the more severely injured kidneys, the desquamated material within the necrotic tubules was frequently the seat of superimposed calcific de-

posit. This was negligible or absent in all rats with renal ischemia for 30 minutes and in most rats with ischemia of 1 hour's duration. The calcific material was in granular basophilic form in the early stage and later appeared as large, coarse, discrete or confluent masses attached to the lining of the tubules, often filling the lumens, and completely replacing the necrotic débris.

Regeneration of necrotic tubules was indicated by formation of new lining epithelial cells with vesicular nuclei and frequent mitoses. When sacrificed, all rats in the 30-minute group and most of those in the 1-hour group showed almost complete removal of necrotic material. The tubular lumens were generally dilated and lined by intact flat epithelium. There was marked reduction in the number of casts. Rats which died in uremia usually showed only slight or negligible repair. In 7 surviving rats, *i.e.*, 4 in the 1-hour group and 3 with 90-minute renal ischemia, regeneration was incomplete since numerous tubules contained calcific masses in place of the necrotic débris. A similar change was also observed in several rats among the 90-minute and 2-hour groups which died in uremia.

DISCUSSION

Rats readily survived a 30-minute period of complete renal ischemia and usually survived a 1-hour period. The mortality was high (73 per cent) at 90 minutes and reached 100 per cent at 2 hours. Animals which died showed progressive elevation of BUN and death occurred in uremia from 2 to 6 days after renal blood flow was restored. In rats which survived, the BUN rose to a maximum from 6 hours to 3 days after release of the constricting clamps, depending on duration of the ischemia, and then returned to normal or slightly elevated values within the next few days.

Only 2 hours of complete renal ischemia were required to produce death consistently as compared to 4 hours or more in the dogs studied by Van Slyke *et al* (5). Presumably this is due to a difference in species. Difference in experimental procedure, *i.e.*, simultaneous bilateral occlusion of renal vessels as against Van Slyke's technique of resecting one kidney and clamping the renal artery of the other, is evidently not significant. Following resection of the right kidney, we clamped the left renal artery and vein in 6 rats and the left renal artery alone in 6 additional rats. All 12 animals died in uremia from 1 to 3 days after a 2-hour period of vascular occlusion.

In our experiments, cessation of blood flow to the kidneys was produced by clamps which completely occluded main renal artery and vein. During the period of occlusion there was apparently no significant collateral circulation to the kidneys. Release of clamps was followed by almost immediate return of circulation and the subsequent presence of intact blood supply to the kidneys was confirmed morphologically by the absence of thrombosis or infarction. In all animals the renal lesion was uniform in both kidneys.

There was fairly good correlation between duration of renal ischemia and the resulting morphological injury to the kidneys after renewal of blood flow. With the longer periods of vascular occlusion, tubular necrosis of the kidneys was usually more diffuse and wider in distribution in the individual nephrons. Also, in rats which survived, the mean rise in BUN was more pronounced and sustained and was followed by a slower decline.

The principal change was necrosis of proximal convoluted tubules, especially the distal or descending segments. The reason for this localization is not known. The lumens of the tubules were blocked by coarse anuclear acidophilic masses, representing necrotic desquamated epithelial cells. Significant damage to epithelium of loops of Henle, to distal convoluted and collecting tubules, as well as to glomeruli, was not morphologically evident.

These observations are in contrast with the kidneys of human crush syndrome (8) or the experimental lesion in the rat (9), which show lower nephron nephrosis with involvement of the ascending loops of Henle and the distal convoluted tubules. The latter are often necrotic whereas the proximal tubules reveal only moderate degenerative change in the nature of cloudy swelling. The lesion also differs from that of rats with fatal tourniquet shock in which there is degenerative change, mainly of the proximal convoluted tubules, but no necrosis and only slight

cast formation (10). However, because of the short survival time of such rats, from a few to several hours, the renal lesions are not strictly comparable with those due to complete ischemia.

In this study the damage to the kidneys was due primarily to the temporary period of complete anoxia during which the cells presumably underwent profound chemical alteration. However, return of circulation was required to bring about the development of cellular necrosis.

In rats with a 30-minute period of complete ischemia, the renal lesion was relatively slight and was followed by complete regeneration. This was also true of most rats in the 1-hour group even though kidney damage was more extensive. After 4 to 8 days the tubules were cleared of necrotic material and presented dilated lumens lined by newly formed flat epithelium. However, in 4 animals of the 1-hour group and in 3 surviving rats with 90-minute renal ischemia, even though the majority of tubules were effectively restored, some revealed failure of regeneration associated with massive calcific deposit. Such tubular injury perhaps explains the failure of the BUN in these animals to return to normal at the time of sacrifice. Most rats which died in uremia showed only slight or negligible regeneration. This does not necessarily indicate an intrinsically irreversible lesion since death occurred before repair could be effective.

SUMMARY

1. Rats readily survived a 30-minute period of complete renal ischemia and usually survived a 1-hour period. The mortality at 90 minutes was 73 per cent and at 2 hours the procedure was uniformly fatal.

2. After circulation was restored, the blood urea nitrogen rose rapidly until death, or reached a maximum level and then declined with survival of the animal.

3. The principal morphologic change was necrosis of the descending segments of the proximal convoluted tubules.

4. The renal lesion was not similar to that observed in human or experimental crush syndrome or in rats with fatal tourniquet shock.

SEROLOGICAL RESPONSE TO INTRANASAL ADMINISTRATION OF INACTIVE INFLUENZA VIRUS IN CHILDREN [1]

By J. J. QUILLIGAN, JR., and THOMAS FRANCIS, JR.

(From the Department of Epidemialagy and the Virus Labaratory, School af Public Health, and the Department of Pediatrics, Medical School, University af Michigan, Ann Arbar)

(Received for publication April 25, 1947)

The published reports on antibody response of human individuals to the inhalation of influenza virus have been most concerned with the effect of active or "attenuated" virus (1 to 9). In some instances experimental disease was induced to test the efficacy of previous vaccination or to note the effects of inhalation of active virus on the production of antibodies against influenza. Burnet (7) reported that 68 to 80 per cent of a group he studied did not show significant changes in antibody titer when they inhaled an "attenuated" influenza virus preparation. It has been demonstrated (6 to 9) that inhalation of active influenza virus can give a modified form of the disease and result in good antibody responses. It has also been shown (1c, 2 to 5) that subcutaneously injected influenza vaccine results in protection against experimentally induced disease. Recently Henle, Henle, Stokes and Maris (10), using serologically determined antibody response as a basis for comparison, concluded that inhalation of active or inactive virus, mostly unconcentrated, was not as effective as subcutaneously injected vaccine.

The present study was conducted to determine the antigenic effect of inactive virus in concentrated form given intranasally, by a single or multiple spray. This effect was compared to that obtained with subcutaneous vaccination.

MATERIAL AND METHODS

Virus preparation

The inactive virus preparation was prepared by a commercial biological laboratory from infected allantoic fluid, centrifuged 2 times in a Sharples centrifuge and furnished to the Influenza Commission by W. M. Stanley. The virus was inactivated with formalin in a final concentration of 1:2,000, and phenyl mercuric nitrate to a concentration of 1:100,000 was added. The material originally comprised equal parts of Type A influenza virus (½ PR8 strain [11] and ½ Weiss strain [12]) and the Lee strain (13) of Type B influenza virus. It was estimated to contain 10 mgm. of protein per ml. and was received in this laboratory on September 11, 1944. The material was diluted just prior to use on September 30, 1945. When tested serologically on March 13, 1946, a 1:5 dilution in physiological saline gave a hemagglutinating titer of 51,200 and a 1:40 dilution gave a titer of 5,120 (14).

Subjects

The children were from 3 cottages of 50 boys each at the Wayne County Training School, Northville, Michigan. The range in age was from 8 to 14 years. Most of the children used were smaller than average in size and of lower than average mental level. The only selection made within the group was the elimination of any children with allergic tendencies.

A total of 80 children was divided into 4 groups. Twenty children from Cottage 1 were used in Group I; 20 children from Cottage 9 constituted Group II; and 20 children from Cottage 6 made up Group III. The fourth group contained 10 children from Cottage 1 and 10 children from Cottage 9. In the course of the study one child was lost from each group except Group I.

In each cottage there were children who were unvaccinated and who did not receive any control fluid. In Cottage 1 this group consisted of 20 children; in Cottage 9, 20 children; and in Cottage 6, 30 children.

In the vaccinated group there were 11 children who had received a combined influenza virus, Types A and B, vaccine in January, 1944. Five of them were in Group I; 3 in Group II; and 3 in Group III. None of the children in the control group had been given any previous vaccination against influenza viruses.

Administration of inactive virus preparation

A 1:5 dilution in physiological salt solution was employed for the intranasal sprays. The atomizer was obtained from the Vaponephrin Company, Upper Darby, Pennsylvania; with 10 lbs. pressure of nitrogen gas it delivered approximately 0.25 ml. per 2 minutes. Each individual was sprayed for 1 minute in each nostril. The adapter was washed with antiseptic solution before use

[1] This study was aided through the Commission on Influenza, Board for the Investigation and Control of Influenza and Other Epidemic Diseases in the Army, Preventive Medicine Service, Office of the Surgeon General, United States Army.

by another subject. Precautions were taken to minimize the inhalation of the sprayed material by any other than the selected subjects. Each child was brought individually into the spray room which was located on the upper floor of Cottage 1. The room was unused except for spraying throughout the study period.

For subcutaneous administration 1.0 ml. of a 1:40 dilution of the inactive virus was given in the left arm. A clean sterile needle was used for each individual.

Group I received intranasal inhalations of the 1:5 dilution of inactive virus on October 1, 2, 3, 4, and 5, 1945. Group II received 1 intranasal inhalation of the 1:5 dilution on October 2, 1945. Group III was given 1.0 ml. of the 1:40 dilution subcutaneously on October 3, 1945. Group IV received 1 intranasal inhalation of sterile normal allantoic fluid on October 1, 1945. These last inhalations were given in a cottage well removed from that in which the spraying of the inactive virus preparation was carried out.

Oral temperatures were taken on October 1, 2, 3, 4, and 5, 1945, in Groups I, II and IV. Signs and symptoms of reactions were recorded daily in all groups. Group III had oral temperatures recorded on October 3, 4, and 5; on the latter 2 days the site of subcutaneous inoculation was examined and the children observed for systemic signs and symptoms.

Serological studies

Blood was drawn from each individual immediately before vaccination, 2 weeks after vaccination, and 5 months after vaccination. The second blood specimens were obtained from those receiving 5 intranasal inhalations 2 weeks after the third dose. Agglutination-inhibition titrations of chicken red blood cells were done according to Salk's modification (14) of Hirst's method (15). The sera from a given individual were all tested at the same time. Agglutination-inhibition was measured against the PR8 and Weiss strains of Type A virus, and the Lee strain of Type B virus. The same virus preparations were used for all tests. The chicken red blood cells were taken from animals whose cells had been checked repeatedly and found to be satisfactory.

RESULTS

Response to influenza virus, Type A

The sera from the 4 study groups exhibited varying degrees of agglutination-inhibition with the PR8 strain of Type A influenza virus. A comparison of the serological findings in the 3 vaccinated groups and the control group is presented in Figures 1, 2 and 3. The modified arithmetic means are summarized for all groups in Table I.[2]

The 20 individuals in *Group I,* who received 5 intranasal inhalations, had an initial mean titer against the PR8 strain of 224; 2 weeks later this rose to a mean of 745 and represented an increase of 3.3 times the initial value. Five months later it had dropped to 563. The distribution of these sera indicates that 2 weeks after vaccination, 12 had a 4-fold or greater increase in titer against

* Number of individuals with 2-fold or less increase in titers.

† Number of individuals with 4-fold or greater increase in titers.

[2] All titers are expressed as the reciprocal of the highest final dilution of serum giving inhibition of agglutination. The mean titration figures for each group of sera were arrived at in the following manner. The numbers 1, 2, 3, etc., were assigned to the dilutions of sera (*e.g.,* $1 = <32$; $2 = 32$; $3 = 64$; *et seq.*). The number of individuals having a certain titer was then multiplied by the number assigned to that titer (*e.g.,* $32 = 2$; therefore $2 \times 3 = 6$). The totals for each designated number were then added and this result divided by the number of sera in the group. This was then reconverted to the titer it represented and any fraction was multipled by the titer the whole number represented (*e.g.,* 2.35 is equivalent to $32 + [32 \times 0.35]$).

the PR8 strain, and 8 had a 2-fold increase or less, when compared to the titers before the virus preparation was administered (Table II).

The sera from the 19 children in *Group II* when measured against the PR8 strain gave an initial mean titer of 148 with a rise to 443, an increase of approximately 3 times the initial titer, 2 weeks after the single inhaled dose. As indicated in Table II, 7 sera had 4-fold or greater increases in titer and 12 had 2-fold or less. The mean value 5 months later had dropped to 297.

When titrated with the PR8 strain, the sera of the 19 subcutaneously vaccinated children in *Group III* had an initial mean titer of 310; 2 weeks after vaccination, 1,363; and 5 months later, 701. Of the 19 sera tested, 14 had a 4-fold or greater increase in titer 2 weeks after vaccination, and 5 had a 2-fold increase or less. The 5

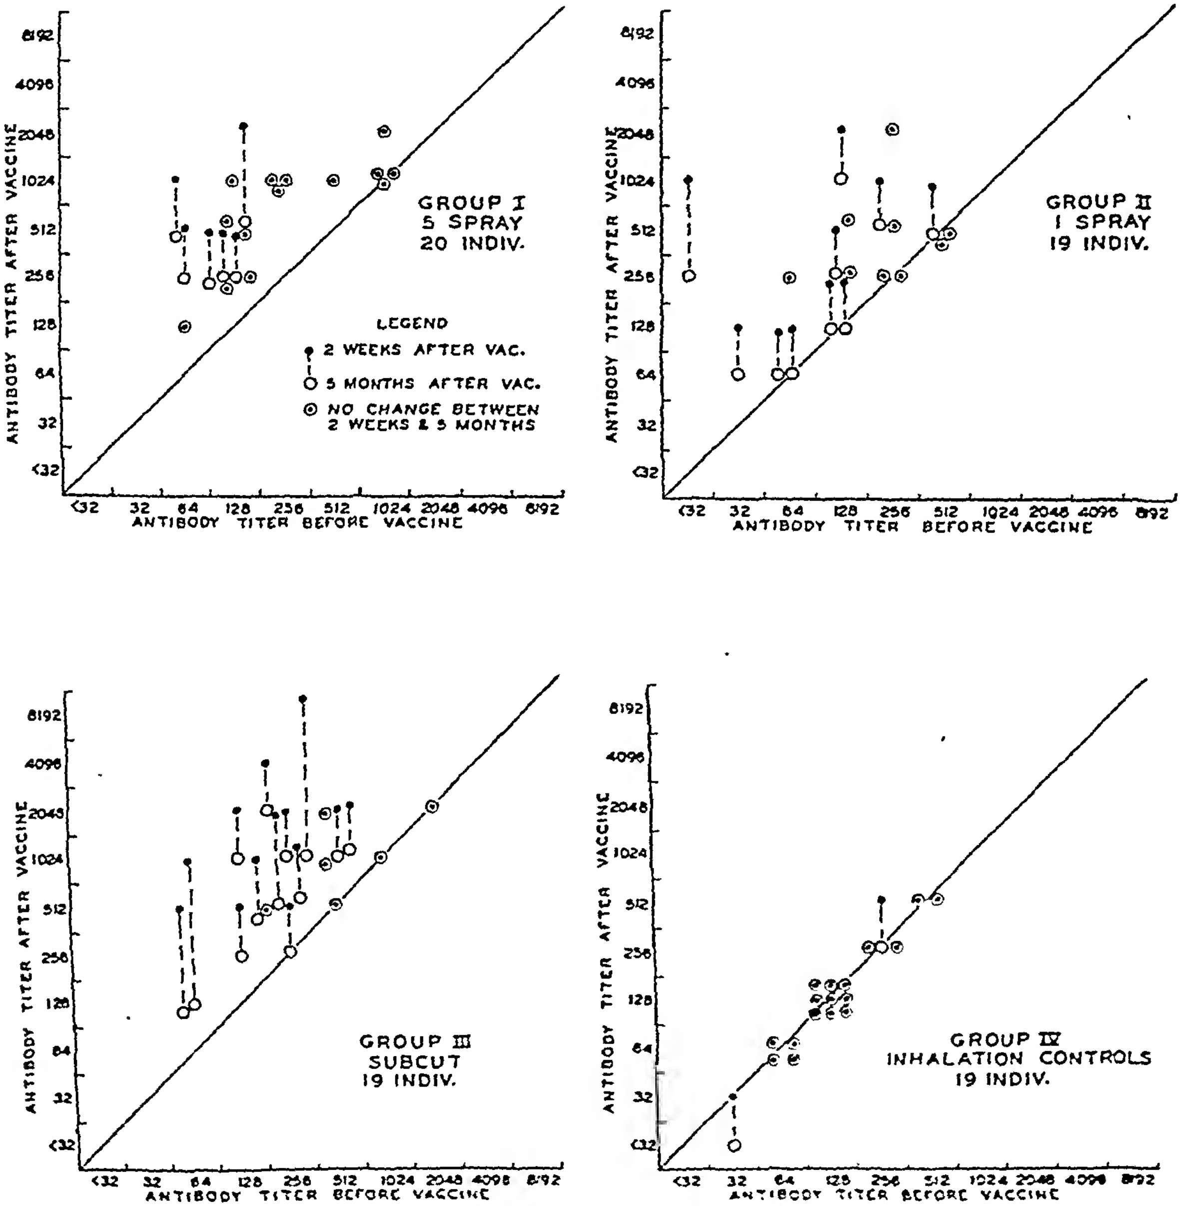

FIG. 1. CHANGE IN ANTIBODY TITER MEASURED AGAINST THE PR8 STRAIN 2 WEEKS AND 5 MONTHS AFTER VACCINE WAS ADMINISTERED

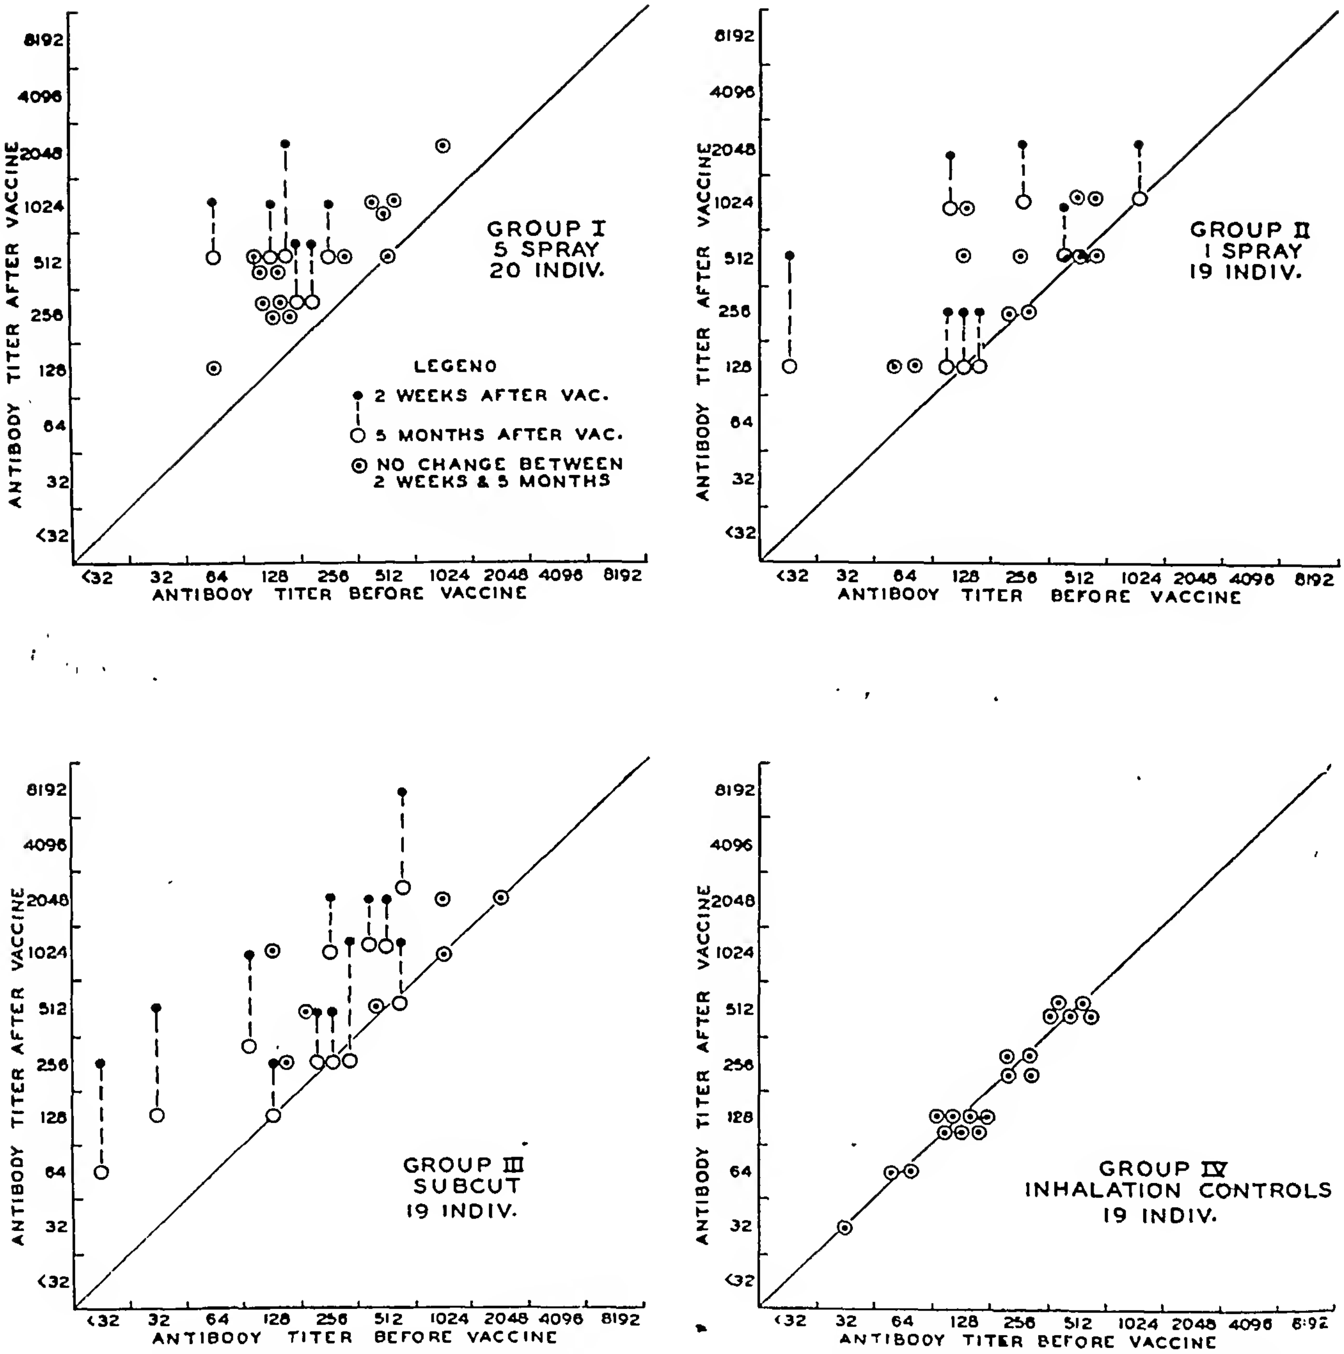

FIG. 2. CHANGE IN ANTIBODY TITER MEASURED AGAINST THE WEISS STRAIN 2 WEEKS AND 5 MONTHS AFTER VACCINE WAS ADMINISTERED

who showed the increases of 2-fold or less all had initial titers of 256 or higher. Five months after vaccination the sera showed a sharp drop with 9 falling 2-fold, 1 falling 4-fold, 2 falling 8-fold; and 6 had no change in titer (Figure 1).

The subjects who received the single inhalation of normal allantoic fluid in *Group IV* showed no appreciable change in titers when measured against the PR8 strain of influenza virus. However, it is worth noting that the sera of 2 individuals showing changes in titer were decreases against the PR8 strain; and later it will be shown that the control group when measured against the Lee strain of Type B virus showed marked rises in titer.

The serological responses of the 4 groups were similar to the above patterns when measured against the Weiss strain of Type A influenza virus (Figure 2). The differences are most noticeable in Group III, where the PR8 titers were

greater than the Weiss titers, and 5 months after vaccination less of a drop occurred with the former. The difficulty in interpreting antibody response to various strains of influenza virus has been commented on by others. Burnet and Lush (16) have assumed that any measurement of specific antibody will always include some non-specific antibody. This was shown to be true by Hirst (17). More recent evidence lends weight to the supposition that the agglutination-inhibition mechanism is a complex one and that too exact interpretation of results may lead to erroneus conclusions (18). In any event, a study of Table I and the spot charts does show a consistent picture of high initial antibody titers to both strains of Type A virus. Whether this represents previous specific experience on the part of the subjects with these Type A virus strains or is related to peculiarities of the PR8 and Weiss preparations, to non-specific characteristics of the sera used in the tests, or to combinations of these influences, one cannot surely state. Certainly, in view of the Type A epidemic in 1943 (12), the

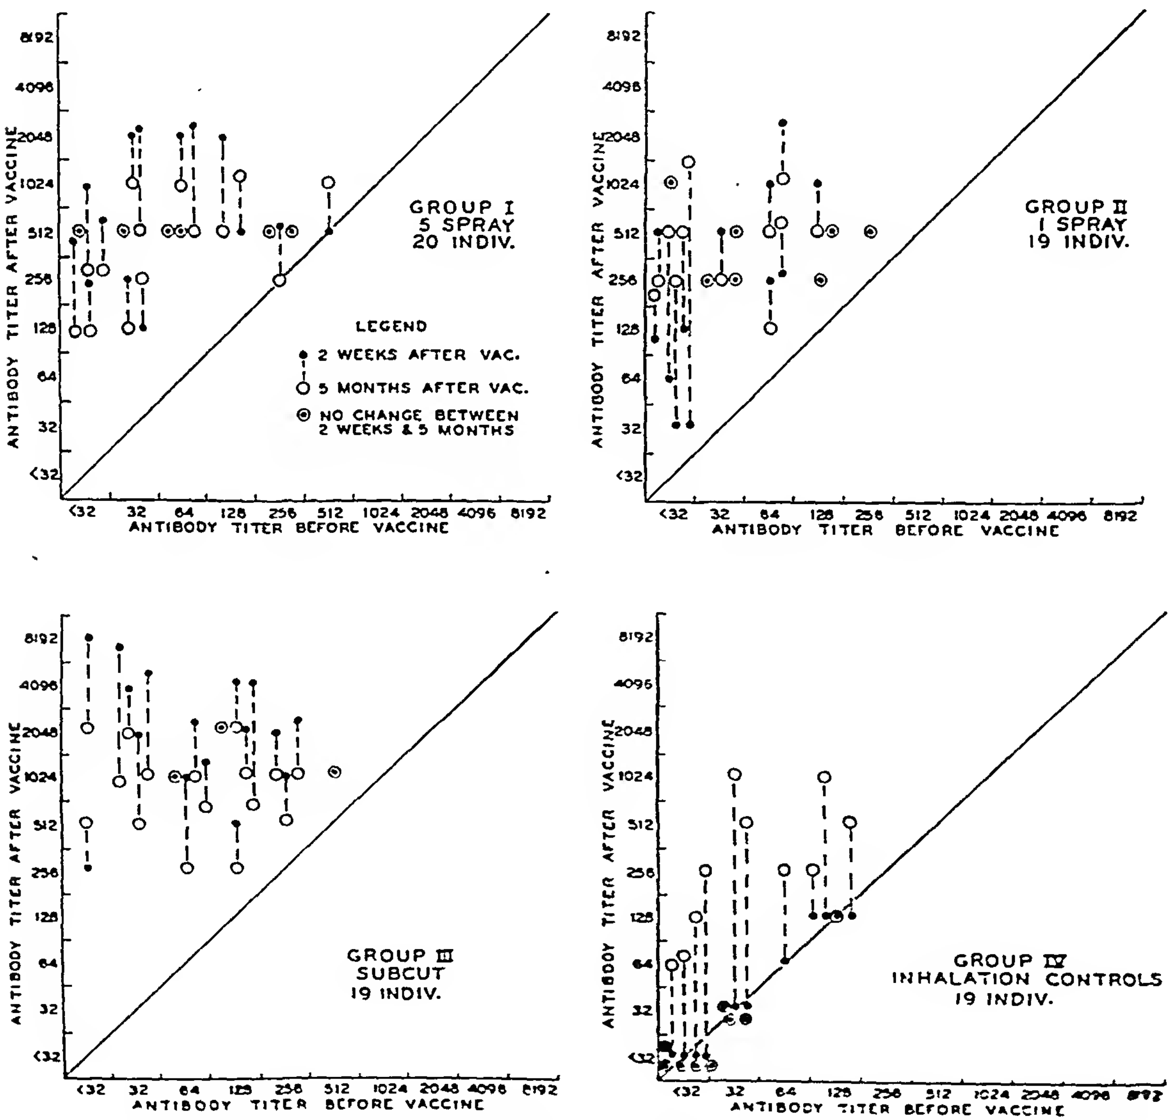

FIG. 3. CHANGE IN ANTIBODY TITER MEASURED AGAINST THE LEE STRAIN 2 WEEKS AND 5 MONTHS AFTER VACCINE WAS ADMINISTERED

possibility of previous contact with A strains is a strong one.

Responses to the Lee strain of Type B influenza virus

When the 4 groups of sera were tested against the Lee strain of Type B virus, a marked difference in antibody response, when compared with A, was apparent (Figure 3). The mean values listed in Table I show much lower initial titers for all 3 groups against the B strain. Possibly this is an indication of less experience with the Type B strains, resulting in a fuller response to the antigenic stimulus.

In *Group I,* after 5 daily sprays, the initial mean value was 58; this rose to 691 2 weeks after vaccination, representing an increase of 12 times the initial titer. Five months later the mean was 435. Table II lists the distribution when the sera taken 2 weeks after vaccination were compared with the initial values. Sixteen of the 20 in the group had a 4-fold or greater increase in titer and 4 showed a 2-fold increase. The sera taken 5 months after vaccination did not show the same drop in titers that was noted with the A strains. Although 11 sera did have decreases in titer, 3 sera had 2-fold rises in titer. In the interval between the bloods drawn 2 weeks and 5 months after vaccination, an epidemic of influenza B was noted. This will be discussed in more detail later.

The *Group II* sera, from the individuals receiving the single spray of inactive virus preparation, had similar responses when measured against the Lee strain of Type B influenza virus. The mean titers for the 3 sets of sera in this group were: initial, 40; 2 weeks after vaccination, 294; 5 months after vaccination, 430. The sera taken 2 weeks after vaccination, when compared to the pre-vaccination sera, showed 15 with a 4-fold or greater increase in titer and 4 with a 2-fold increase. A comparison with the sera taken 5 months later gave 6 with a drop in titer and an equal number with 2-fold or greater increase in titer. The spot charts in Figure 3 show this change. The same situation existed as in Group I; namely, an epidemic of Type B influenza that involved enough members of this group to cause a definite increase in a number of the agglutination-inhibition titers against the Lee strain of Type B influenza virus.

Group III, after the subcutaneous dose, showed the most striking responses against the Lee strain. The mean titers were: initial, 84; 2 weeks after vaccination, 1,935; 5 months after vaccination, 891. The increase 2 weeks after vaccination was approximately 23 times the initial mean titer and 5 months later it was 10 times the initial titer. The distribution of the 19 sera in this group is shown in Table II and indicates that 18 of the bloods taken 2 weeks after vaccination exhibited 4-fold or greater responses and one had a 2-fold increase when compared to the pre-vaccination levels. Of the sera taken 5 months after vaccination 9 had 2-fold decreases in titer and 6 had 4-fold or greater decreases in titer. In this same set of sera there were 3 with no change in titer and 1 serum with a 2-fold increase in titer.

Group IV, the sera from the inhalation controls, when titrated against the Lee strain of Type B influenza virus, showed no change between the initial titers and those of 2 weeks later. It has been previously stated that an outbreak of Type B influenza occurred in the institution in the interval between the 2-week bleedings and the 5-month bleedings. During this period the members of the various groups were under close clinical observation. When the 19 sera taken 5 months after vaccination were titrated against the Lee strain, 10 had increases in titer ranging from 2-fold to 32-fold (Figure 3). All but 1 of the 10 were 4-fold or greater increases in titer.

The levels of antibody which will be attained by human individuals in response to influenza vaccination may vary widely. Results of small groups of subjects cannot be too freely evaluated. The above data can only indicate broad, general trends of antibody response. Even the fact that the response to the strain of Type B virus was numerically better than A must be accepted with reservation. Other studies have indicated that the Lee strain, measured in terms of protection against natural and experimental disease, induces a stauncher degree of protection than certain A strains of influenza virus (4, 5, 19). The low initial titers to the Lee strain were associated with more striking increases in titer 2 weeks after vaccination and, conversely, the higher original

titers to the A strains minimized the increments in titer after vaccination. The figures listed in Table I indicate that the mean-fold increase was greater against the Lee strain than either PR8 or Weiss. However, the mean titers of the 2-week bleedings were not so sharply differentiated except in Group III. If generalizations are to be made one can point out that the mean-fold increase in titer to B was better than that to A although the differences between titers were not consistent; that subcutaneous vaccination appeared to be more effective than intranasal although rather uniform responses were obtained with the latter. It is of interest to note that the group receiving the 5 sprays had a total of 1.25 ml. of a 1:5 dilution of vaccine whereas the subcutaneous group received 1 ml. of the 1:40 dilution of vaccine, strongly suggesting that subcutaneously injected vaccine was more efficiently utilized. These studies with concentrated inactive material support the impression obtained from the results of Henle *et al* (10).

The subcutaneous vaccinations resulted in excellent antibody production against the Lee strain but in a lesser response to the A strains. Numerically the antibody titers in the subcutaneous group were higher than in previous experiments with adults (3, 5, 19). Proof of whether this represents chance or that children in this age group do respond better and more consistently, would require studies with large groups of children.

As already mentioned, some of the subjects in the vaccinated groups had received a combined A and B influenza virus vaccine in January, 1944. Their initial anti-A titers were not significantly different from the remainder of the groups so they could not be considered the cause of the higher initial titers to Type A. For the Lee strain the initial titers of those who received vaccine in 1944 were 2 times greater than the rest of the group. However, the number within each group was small enough to show only a minimal influence on the height of the mean initial titer for each study group.

Reactions

The reactions to the intranasal inhalation of the combined inactivated viruses were minimal. In the group who received the 5 daily sprays, 6 children had oral temperatures between 100.0° and 100.8° F. on the third day. Two children, after the first spray, complained of a slight sensation of fullness in the head. Two children on the fourth day had temperatures between 100.0° and 100.2° F. The single inhalation group and the control inhalation group had no reactions. Twelve of the children in Group III complained of local reactions 24 hours after the subcutaneous inoculation. Of the 12 children, 3 had slight erythema; 7 had tenderness, heat and erythema; and 2 had tenderness, heat, redness and swelling at the site of injection with axillary nodes palpable on the affected side. There were 3 children in this group with temperatures between 100.4° and 100.8° F.; and 1 child, who had a severe local reaction, complained of dizziness and slight headache.

CLINICAL OBSERVATIONS

From December, 1945, through January, 1946

Following the vaccinations done in October, 1945, periodic observations were made to determine influenza virus infection in the institution. On November 10, 1945, Type B influenza virus was isolated in Michigan (19) and on December 13, 1945, several children at the Training School reported to the sick ward with an acute illness characterized by fever, chills, prostration, headache and sore throat. The number of case throughout the school reached a peak on Dece ber 18 and fell off gradually until only occasi cases were occurring from December 18 th January 30, 1946. From throat washing of the children admitted to the sick December 18, Type B influenza virus w ered. The children from the 3 co housed the 4 groups were followed c the interval of time covering the ou of the 58 children in the 3 va developed clinical evidence of d nine of the 89 unvaccinated 3 cottages developed clinical e This includes 4 children fro trol group.

From 69[2] cases the cli

[2] This number of indivi other cottages than those

their frequency were: sore throat, temperature elevation, rhinorrhea, headache, chills and cough. Less prominent findings were excessive lacrimation (frequently associated with the complaint of burning eyes), malaise and sneezing. The sick children showed few abnormal physical findings. Prostration and lethargy during the first 12 to 24 hours was common. Moderate injection of the pharynx and a thin watery discharge appearing on the second day and rarely becoming purulent was often noted. Prompt recovery was the rule. Two children with perforated ear drums and associated chronic otitis media developed purulent aural discharges following the primary infection. They were the only complicated cases.

The total number of cases involving the children in the 4 study groups was 12: 4 of these were from the control group; 4 were from the group receiving the single inhalation; 3 were from the group receiving the 5 daily inhalations; and 1 was from the subcutaneously vaccinated group. However, when the sera from the above groups were tested 5 months after receiving the inactive virus preparation there were some individuals who showed rises in titer above the 2-week level without any clinical evidence of disease; other children who did have clinical evidence of influenza-like disease showed no rise in antibody titer in convalescence or again 5 months after the vaccination study was started. This is most noticeable in Group IV, the 19 inhalation controls, where the antibody response to infection was not masked by the effect of the inactive virus preparation. Only 1 of the 4 subjects in this group who developed clinical signs of influenza-like disease had a rise in titer against the Lee strain. The other 3 children had no rise in titer and in every determination the titers of these 3 were 32 or under when measured against the Lee strain.[4] There were no changes in the titers of the A strains in these sera. In this same group of 19 children the titers of the sera taken 5 months after vaccination showed 10 individuals with rises in titer, one of them being the child described above. The other 9 had no record of illness. The phenomenon of sub-clinical infection, as exemplified by the 9 individuals without evidence of infection and yet having rises in antibody titer in the sera taken 5 months after vaccination, is well recognized. However, the 3 individuals with evidence of disease but without rises in agglutination-inhibition antibodies are more difficult to evaluate. The use of antibody response, as currently measured, is not feasible for the diagnosis of influenza in vaccinated populations; with such a premise, then, clinical findings must be accepted for unvaccinated subjects as well. There did not seem to be any correlation between initial titer and sub-clinical infection (20).

It can be seen from Figure 3 that some rises in titer occurred during the same interval in the other groups. The subcutaneously injected group had 1 subject with a 2-fold rise in titer who showed no evidence of disease and 1 subject, whose titer was 2048, did show clinical evidence of influenza. The 5-spray group had 3 children with 2-fold rises in titer; only 1 showed evidence of disease and 2 others in this group with influenza did not have rises in titer; however, their titers were 256 and 1,024. The single inhalation group had 6 subjects with rises in titer; 2 with 2-fold rise; 1 with 4-fold rise; 2 with 8-fold rise; and 1 with 32-fold rise. Of the 6 there were 4 with clinical evidence of disease. Such figures further indicate the difficulty in interpreting clinical disease in terms of antibody response when vaccinations are carried out. Obviously, the use of the serological test is of little help. The possibility that the rises in titer seen in sera 5 months after vaccination were a continuation of the effect of vaccination is quite remote. There were no rises in titer against the A strains. Also, enough of the children who became ill had additional sera taken during the period between the 2-week and 5-month bleedings to indicate that there was a fairly consistent drop in antibody titer associated with the vaccinations. In most instances the titers 2 weeks after illness were higher and then fell to lower levels 5 months after the inactive virus preparation was administered. No significant evaluation of the effects of administration of the virus materials upon the incidence of infection with influenza virus can be made from these observations nor was the study intended for that purpose. Nevertheless, a difference in the frequency of respiratory illness among the vaccinated and unvaccinated groups was seen.

[4] These sera were tested against a strain of Type B virus isolated during the epidemic. The results showed no rise in antibodies against the current strain.

The presence of clinically undetected influenza B infection was demonstrated by the surprisingly large number of antibody rises to Type B virus in sera obtained 5 months after vaccination while A titers were continuing to fall.

SUMMARY

The data reported here indicate that a single intranasal inhalation of an inactivated influenza virus preparation resulted in good antibody responses and that the use of 5 daily sprays gave slightly higher levels of antibody. A comparison of the effect of the 2 different doses of intranasal vaccine on the sera taken 5 months after vaccination suggests that the larger dose gave a more persistent elevation in antibody titer.

The vaccine given intranasally on 5 successive days contained approximately 8 times as much inactive virus preparation as the subcutaneous material. However, a comparison of the antibody responses indicates that subcutaneously administered vaccine gives higher and more persistent levels with smaller doses. Clinical observations were made during an epidemic of influenza B in the institution.

ACKNOWLEDGMENTS

The authors wish to express their gratitude for the pleasant, cooperative efforts of Mrs. B. Brannon, Doctor R. H. Haskell, and the staff of the Wayne County Training School, and also to Miss Elva Minuse and Miss Hilda Kurtz of the Virus Laboratory.

THE VOLUME OF DISTRIBUTION OF MANNITOL AS A MEASURE OF THE VOLUME OF EXTRACELLULAR FLUID, WITH A STUDY OF THE MANNITOL METHOD[1]

By J. RUSSELL ELKINTON

(*From the Department of Internal Medicine, Yale University School of Medicine, New Haven*)

(Received for publication May 5, 1947)

The clearance of mannitol has been advocated by Smith and his coworkers as a measure of glomerular filtration rate (1). Newman, Bordley and Winternitz (2) modified Smith's procedure by calculating the clearance of mannitol from the rate of fall of concentration in serum after a single injection of the substance and suggested that the rate of glomerular filtration is more logically related to the volume of extracellular fluid than to body surface area. They also presented evidence that the volume of distribution of mannitol is of approximately the same magnitude as this fluid compartment.

The thesis of Newman, Bordley and Winternitz that the clearance of mannitol can be calculated from the fall in serum concentration alone is valid only if mannitol reaches a constant volume of distribution in the body. The determination of the volume of distribution rests on the following assumptions: (*1*) that mannitol is neither formed nor destroyed in the body, (*2*) that it is distributed uniformly throughout some portion of the body water, (*3*) that its concentration in water of serum is a fair sample of its concentration throughout this portion, and (*4*) that it is excreted solely in the urine (3). It is the purpose of this investigation to determine whether the apparent volume of distribution of mannitol meets the above basic assumptions, and to study the relation of this volume to that of extracellular fluid.

Such a study requires a precise knowledge of the errors involved in the determination of mannitol. For this reason the method of determination and its accuracy were investigated in this laboratory and certain modifications introduced to minimize the error.

[1] Aided by a grant from the Fluid Research Fund of Yale University.

METHODS

The method of determination of mannitol used was that introduced by Smith, Finkelstein, and Smith (1), with modifications as indicated below. The method involves the oxidation of glucose-free filtrate with the reduction of a known excess of KIO_4, and quantitation of the remaining KIO_4 by iodometric titration with $Na_2S_2O_3$.

Reagents.

- Acid cadmium sulfate: 34.68 grams $3CdSO_4.8H_2O$ and 169.10 ml. 1 *N* H_2SO_4 made up to 1000 ml. H_2O.
- Sodium hydroxide 1.1 *N*.
- Baker's starch-free yeast: approximately 20 per cent suspension.
- Mannitol[2] standard solution: 100 mgm. per 100 ml.
- Acid potassium periodate: 0.60 gram KIO_4 and 20 ml. conc. H_2SO_4 made up to 1000 ml. H_2O.[3]
- Concentrated KI: approximately 50 per cent solution.
- Amylose: 1 per cent solution.
- Sodium thiosulfate: 0.005 *N* $Na_2S_2O_3$ made from 0.1 *N* stock solution.

Analysis in serum. The sample of serum is rendered glucose-free by fermentation with freshly washed starch-free baker's yeast in approximately 20 per cent suspension. To 2 ml. of serum in a 150 × 20 mm. pyrex tube are added 6 ml. of the yeast suspension which is thoroughly shaken before the withdrawal of each aliquot. The tubes are stoppered, shaken 3 times during 15 minutes and centrifuged. The exact extracellular fluid content of the yeast suspension is determined by centrifugation in a Wintrobe hematocrit tube. In 19 comparisons of the extracellular fluid content of the yeast suspension before and after yeasting a large number of serum and urine ali-

[2] The mannitol was supplied through the courtesy of Sharp and Dohme, Inc.

[3] Since this study was done Barker and Clark (15) have reported that free para-aminohippuric acid (PAH) reduces acid KIO_4 and so introduces an error in the determination of mannitol when present in the same biological media. These workers obviated the error by acetylating the PAH and acidifying the KIO_4 solution with acetic instead of sulfuric acid. While such an error does not affect the study reported here, it must be considered when clearances of mannitol and PAH are measured simultaneously.

quots, the mean difference was insignificant, being only 0.14 per cent with a maximum difference of 0.3 per cent. Filtrates of serum containing concentrations of mannitol of 50 mgm. per cent or less (including serum and reagent blanks) are fortified by the addition of a 2-ml. aliquot of 100 mgm. per cent aqueous solution of mannitol added to the 2 ml. of serum and 6 ml. of yeast. Filtrates of serum containing concentrations of 150 to 175 mgm. per cent and 175 to 200 mgm. per cent similarly are diluted with 2 ml. and 4 ml. of water, respectively. Failure to fortify or dilute resulted in increase of error: in 6 unfortified known solutions of mannitol in serum the average deviation was found to be +3.3 mgm. per cent, and in 3 undiluted solutions it was −5.0 mgm. per cent.

Four ml. of the supernatant yeasted serum are pipetted directly from the centrifuge tube into a similar tube containing 6 ml. of cadmium sulfate. To this are added 2 ml. of 1.1 *N* NaOH, the tubes are stoppered, shaken several times during 10 minutes, and centrifuged. The supernatant fluid is filtered through washed absorbent cotton (plugged in the neck of a glass funnel). Duplicate 2-ml. aliquots of the cadmium filtrate are pipetted into a pyrex tube (200 × 25 mm.) containing exactly 5 ml. of KIO_4 measured from an automatic pipette. Glass tears are placed in the tubes which are then heated in a boiling water bath for exactly 20 minutes. At the end of this time the tubes in the racks are transferred directly to a bath of ice water (5° C.) in which they are kept until titrated. Cooling in a water bath at room temperature (25° C.) definitely permits continued oxidation-reduction and results in false high values for mannitol if an hour or more elapses before titration: in 13 known solutions of serum cooled at room temperature the average deviation was +4.3 mgm. per cent.

The tubes and glass tears are washed down with water. Immediately before starting the titration about 1 ml. of approximately 50 per cent KI is added to each tube. This KI must be made up freshly each day. The partially reduced KIO_4, stirred with CO_2 bubbles, is titrated by means of a Bang burette equipped with a B-D needle tip for immersion titration, with 0.005 *N* $Na_2S_2O_3$ prepared freshly each day from a factored stock solution of 0.1 *N* $Na_2S_2O_3$. This burette must never be washed with dichromate cleaning solution. Traces of dichromate remaining after the routine 5 or 6 rinsings reacted with the $Na_2S_2O_3$ and were the largest single source of error between duplicate titrations. Approximately 0.5 ml. of 1 per cent amylose solution is added when the titration is within 0.25 ml. to 0.15 ml. of the endpoint. The endpoint can be read to 0.005 ml.

To calculate the concentration of mannitol it is first necessary to determine the amount present in the solution titrated. This value which is V in Equation 1 below, varies according to whether or not 2 ml. of standard solution of mannitol or 2 or 4 ml. of water are added to the yeasting solution and also according to the extracellular fluid content (h) of the 6-ml. aliquot of the particular yeast suspension used:

(*a*) $V = 1.33$ per $(2 + 6h)$
(*b*) $V = 1.33$ per $(4 + 6h)$
(*c*) $V = 1.33$ per $(6 + 6h)$

Each 1 ml. of 0.005 *N* $Na_2S_2O_3$ titrated by difference is equivalent to 0.092 mgm. of mannitol in the solution titrated. The concentration of mannitol (M) in mgm. per 100 ml. of the solution oxidized by KIO_4 is:

$$M = \frac{9.2f(A - B)}{V}, \qquad \text{Equation 1}$$

where: A = No. of ml. of $Na_2S_2O_3$ titrated against the blank KIO_4 solution.
B = No. of ml. of $Na_2S_2O_3$ titrated against the reduced KIO_4.
f = factor of the 0.005 *N* $Na_2S_2O_3$.
V = volume in ml. of the known solution added to the KIO_4.

Substituting V as calculated above, M is calculated as follows:

(*a*) $M = 6.9\ (2 + 6h)\ f\ (A - B)$, if no standard solution or water is added; 2
(*b*) $M = 6.9\ (4 + 6h)\ f\ (A - B)$, if 2 ml. of standard solution or water is added; 3
(*c*) $M = 6.9\ (6 + 6h)\ f\ (A - B)$, if 4 ml. of standard solution or water is added. 4

These equations (Equations 2, 3, 4) are the basic ones used to calculate the concentration of mannitol in serum or urine. Where 2 ml. of 100 mgm. per cent standard solution of mannitol has been added, 100 must be subtracted from the result. In all serum determinations the total serum blank must be subtracted from M as determined in these equations, to give the true value in serum. This blank is the value for non-fermentable reducing substance in the blank serum (net serum blank) plus the reagent blank. The reagent blank is the value for such substance in the yeast suspension and the cadmium sulfate and sodium hydroxide precipitating reagents. In all sera from fasting subjects the average for the total blank was 11.7 mgm. per cent with a range of 7.3 to 16.0 mgm. per cent, while the average net serum blank was 11.3 mgm. per cent with a range of 7.3 to 15.1 mgm. per cent. In 14 determinations the average reagent blank was +0.4 mgm. per cent with a range of −3.0 to +4.7 mgm. per cent.

In the analysis of 21 solutions of mannitol in serum of known concentrations between 25 and 200 mgm. per cent, the results of the observed concentrations were as follows: standard deviation = ±1.2 mgm. per cent, average deviation = 0.9 mgm. per cent, maximum deviation = 2.6 mgm. per cent. The mean difference between 54 pairs of duplicate titrations was 0.023 ml.

Analysis in urine. Urine is analyzed for mannitol in the same manner as serum, including the yeasting and precipitation. The only differences lie in the preliminary dilution of the urine and in the calculation of the blanks.

The high concentrations of mannitol in urine necessitate dilution before yeasting. By dividing the assumed glomerular filtration rate by the volume of urine in ml. per minute the approximate dilution factor is obtained which will reduce the concentration in urine to that simultaneously present in serum. If the latter value can be approximately estimated, the dilution factor can be adjusted to bring the concentration of mannitol in the diluted urine to lie between 50 and 150 mgm. per cent; further dilution or fortification is thereby avoided.

The net urine blank which must be subtracted to obtain an accurate estimation of the concentration of mannitol in urine, presents some difficulty when different urine samples are collected over intervals of time. The blank concentration of non-fermentable reducing substances varies from that in the initial specimen as the rate of urine flow varies and probably as the subject changes from a fasting to a post-prandial state. The most accurate value for the urine blank for each urine specimen (C_2), therefore would appear to be the blank concentration in the initial blank specimen (C_1) multiplied by a factor consisting of the rate of urine flow of the initial specimen (V_1) divided by that of the subsequent specimen (V_2):

$$C_2 = \frac{V_1C_1}{V_2}. \qquad \text{Equation 5}$$

In an experiment on a normal fasting subject receiving no mannitol in which variations in rate of urine flow were induced over a range of 0.83 to 7.00 ml. per minute, the observed blank concentration differed from the proportional concentration, as calculated by the above equation, by less than ½ the standard deviation of the method for urine. This method of calculating the net urine blank values between subjects can only be made in relation to rate of urine flow. In 8 blank urine specimens collected at various times under fasting conditions from the 3 normal subjects used in the present experiments, the average excretion rate of blank (non-fermentable reducing) substance was 1.9 mgm. per minute, with a range of 0.8 to 3.8 mgm. per minute.

To calculate the concentration of mannitol in urine, the reagent blank first must be subtracted from M as calculated by Equation 2. The value so obtained for the diluted urine is then multiplied by the dilution factor and the net urine blank subtracted. This gives the net concentration of mannitol in the original sample of urine.

The results of the determination of mannitol in 12 known solutions in urine ranging from 168 to 5077 mgm. per cent were as follows: standard deviation $= \pm 88$ mgm. per cent, average deviation $= 72$ mgm. per cent, maximum deviation $= 168$ mgm. per cent. When the deviation in each urine sample was divided by the dilution factor used, the average deviation was 2.7 mgm. per cent.

Summary. The modifications introduced into this method to improve its accuracy are listed as follows: (*1*) fortification of solutions containing low concentrations of mannitol, (*2*) cooling at 5° C. of the partially reduced KIO_4 solution between heating and titration, (*3*) avoidance of the use of dichromate cleaning solution in the titrating burette, (*4*) immersion titration using amylose rather than starch as an indicator, (*5*) calculation of the net urine blank from the rate of urine flow.

EXPERIMENTAL PROCEDURE

Three young male physicians in good health served as *normal subjects.* On arising in the morning the bladder was emptied and then ½ to 1 hour later, just before the injection of mannitol, the bladder was again emptied yielding the urine specimen for blank determination. These normal subjects were not catheterized. The subjects were fasting until the end of the fourth hour after injection, food and fluids were then taken *ad libitum.* During the preliminary period for obtaining the blank urine specimen, 2 cups of black coffee were allowed; thereafter till the fourth hour, 100 ml. of water per ½ hour were drunk immediately after each blood and urine collection.

The subjects were weighed stripped, 15 ml. of blood taken for the serum blank determination, and 12.0 to 25.9 grams of mannitol in a 25 per cent solution were injected intravenously from a calibrated syringe.[2] At the end of each period the bladder was emptied and 15 ml. of venous blood were taken from the arm opposite to that in which the mannitol was given. During the entire experiment the subjects were on their feet doing their usual work around the laboratory. With the exception of Experiments 1 and 2 which were 5 days apart, the intervals between experiments in each subject ranged from 3 to 9 weeks.

One other "normal" subject (M. W.) is included in Table I. This patient was a control to the above 3 subjects in that he was catheterized and his bladder was washed at the time of each urine collection. He was a 25 year old negro male receiving penicillin therapy for latent lues but with a normal state of hydration as far as could be ascertained.

Two patients with excessive accumulations of body fluids served as *abnormal subjects.* Distribution studies were done by the same technique outlined above before and after removal of part of the excess fluid. Both patients were catheterized and the bladder washed at each urine collection. The chloride balance was determined for the periods between the mannitol distribution studies. Patient L. M. (Experiments 9 and 10) was a 55 year old white male with massive ascites due to portal cirrhosis and carcinoma of the liver who was studied before and after a paracentesis. Patient F. J. (Experiments 11, 12, and 13) was a 60 year old white female with peripheral edema due to hypertensive heart disease. This patient on bed rest, digitalis, and a low salt diet, was given 6 grams of ammonium chloride daily and 3 intramuscular injections of *Mercuhydrin.* Mannitol distribution studies were done before and after the first mercurial injection and again at the end of a 10-day period during which she received 2 more injections.

METHODS OF CALCULATION

The apparent volume of distribution (V) of mannitol was calculated as follows:

$$V = \frac{A}{C},$$

where A equals the net amount retained in the body, and C equals the concentration of mannitol in serum water. The serum water content was determined by direct weighing of serum before and after drying. The mannitol space (E_M) is taken to be that volume of distribution of mannitol which remains constant within experimental error between two points of determination.

Chloride concentration in serum was determined by the method of Hald (4) and in urine by the Volhard-Harvey titration (5). The change in chloride space (ΔE_{Cl}) was calculated from the chloride balance (b_{Cl}) and the extracellular water chloride concentrations (Cl_1 and Cl_2) as described elsewhere (6), using the initial mannitol space (E_{M_1}) as E_1:

$$E_{Cl_2} = \frac{(E_1 Cl_1) + b_{Cl}}{Cl_2},$$

$$\Delta E_{Cl} = E_{Cl_2} - E_1.$$

RESULTS IN NORMAL SUBJECTS

Recovery of mannitol. In 3 experiments in 2 subjects the mannitol recovered in the urine 8 hours after injection was 89, 93, and 99 per cent of that injected; 24 to 26 hours after injection the recovery was 154,101, and 108 per cent (Table I). Mannitol evidently was not destroyed. The greater than 100 per cent recovery at 24 to 26 hours is probably due to increased excretion of non-fermentable reducing substances after the fasting period (*i.e.*, an unmeasurable increase in urine blank). Unpredictable changes in the urine blank in this period do not affect the calculation of volume of distribution of mannitol. It is unlikely that this increased blank is mannitol formed in the body, but direct proof of this is lacking.

Attainment of equilibrium. When the concentrations of mannitol in serum water are plotted semi-logarithmically against time after injection, the concentration at ½ to ¾ hour lies above the straight line passing through the subsequent points, in 6 of the 8 experiments. That is, the rate of all in concentration was greater between ½ hour and 1 hour than in the later periods. This is strong evidence that equilibrium in mannitol concentration was attained through the "mannitol space" between ½ and 1 hour in these experiments. In Experiment 1, equilibrium appeared to have been reached by ½ hour, and in Experiment 3 not until some time between 1 and 1½ hours. These variations may be related to the fact that it was in these experiments that the smallest and largest doses of mannitol, respectively, were given.

Volume of distribution. In 5 of the 8 experiments the volume of distribution of mannitol remained essentially unchanged between 1 and 3 hours after injection (Table I); after 3 hours the analytical error was too great to draw any conclusion. In 2 of the other experiments it appeared to expand. In Experiment 1, however, the small dose of mannitol rendered the error of the determination after 1 hour too large to be definitive. In Experiment 5 there was either a true but slight increase in the volume of distribution or the subject failed to empty his bladder completely. In Experiment 8 the volume of distribution was not determined after 1¼ hours. In all of the experiments the distribution volume at ½ hour was significantly lower than at 1 hour, due to the fact that equilibrium had not been attained (see above).

Agreement between the volumes of distribution at 1 hour after successive injections was remarkably good in each subject, the widest variations being not more than 0.06 per cent of the body weight or 4 per cent of the absolute volume. Uniformity between volumes of distribution of the different subjects at 1 hour was not so great; the range was 18.7 to 23.0 per cent of the body weight.

The error of the determination of the volume of distribution is complicated in that it is the resultant of 2 different analytical errors: those of serum and urine. If these 2 errors are in opposite directions they tend to cancel, if in the same direction they augment each other. Although there is 1 chance in 2 that the latter occurred in each instance, the degree of error in each volume of distribution has been calculated which would result from an error of the standard deviation in the same direction in serum and urine. The value thus obtained is designated as the *maximum standard deviation error* of the volume of distribution.

The magnitude of the error so calculated at any one time is the direct resultant of the concentration of mannitol in serum and the concentration in, and volume of, urine. The lower the concentrations are or the larger the urine volume is, the greater is the error. Thus, the error is

TABLE I

The volume of distribution and clearance of mannitol in normal subjects

* Maximum standard deviation error (see text).

greater with a smaller dose of mannitol (Experiment 1) than with a larger dose. Given approximately the same dosage, the lower the amounts of mannitol retained, the lower are the concentrations in serum and urine, and hence the greater is the error. In Experiments 2 to 8, inclusive, in normal subjects the maximum standard deviation error of the volume of distribution does not exceed ± 0.5 liter until only 44 per cent or less is retained; after this period the error greatly increases in magnitude. Finally, given the same dosage and the same proportion of mannitol retained, the larger the urine volume the greater the error (Experiments 8 to 12).

For the volumes of distribution calculated at 1 hour after injection of 20.7 to 25.9 grams of mannitol, the average maximum standard deviation error was ± 0.3 liter or ± 2.1 per cent of the volume calculated. In these experiments the deviation from uniformity of the calculated volumes of distribution between 1 and 8 hours after injection could be explained by this maximum standard deviation error, with 2 exceptions only (Experiment 2, 3 hours, and Experiment 5, 2 hours).

Glomerular filtration rate. The mannitol clearance or glomerular filtration rate in the 3 subjects ranged from 75 to 121 ml. per minute per 1.73 square meters of body surface (Table I). These values are considerably below those given by Goldring and Chasis (7) for normal males, namely, 131 ± 22 ml. per minute per 1.73 square meters, but our subjects were not at rest. The maximum standard deviation error for the 1 to 1½ hour periods averaged ± 5 ml. per minute or ± 4.8 per cent of the clearance, and increased as the excretion rate diminished.

RESULTS IN ABNORMAL SUBJECTS

Attainment of equilibrium. In the 2 subjects with abnormal accumulation of body fluid, as might be predicted, equilibrium throughout the mannitol space was not reached as soon as in the normal subjects (Table II). In the patient with ascites, equilibrium apparently was not reached at 4 hours after injection in Experiment 9, before paracentesis; or at 3 hours in Experiment 10, after paracentesis. In Experiment 9 the concentration of mannitol in ascitic fluid water was determined directly at 4½ hours and found to be 50.4 mgm. per cent; the concentration in serum water at 4 hours was 52.3 mgm. per cent. These findings suggest that equilibrium actually had been reached at 4 hours but was not confirmed by a subsequent point. In the patient with cardiac edema, equilibrium appeared to be attained at 4, 3 and 2 hours after injection as the edema progressively diminished.

Volume of distribution. In both of these subjects before any removal of excess fluid, the mannitol space or volume of distribution, after approximate equilibrium had been reached, was a much larger proportion of the total body weight than it was in the normal subjects, namely 37.6 per cent of the body weight in L. M. with ascites and 40.7 per cent in F. J. with cardiac edema (Table II).

In both patients the change in mannitol space (ΔE_M) was compared with the change calculated for the chloride space (ΔE_{Cl}). In patient L. M. the volume of cell-free ascitic fluid removed by paracentesis was 4.9 liters, ΔE_{Cl} was − 4.9 liters, and ΔE_M was − 3.0 maximum σ error ± 0.7 liter. In patient F. J. the check between ΔE_M and ΔE_{Cl} was very good for Experiments 11 and 12 which were done before and immediately after the first mercurial diuresis. ΔE_{Cl} was − 5.6 liters and ΔE_M was − 6.0 maximum σ error ± 0.8 liter. The agreement between the 2 in Experiments 12 and 13, done 10 days apart, was not so close, ΔE_{Cl} being − 5.3 liters and ΔE_M being − 6.9 liters. The agreement of ΔE_M with the change in weight, − 6.6 kgm., was better, and suggested that a cumulative positive error existed in the chloride balance, probably due to failure of complete absorption of the 6 grams of enteric coated NH_4Cl ingested daily. Such an error, of course, would be considerably less in the 24-hour period between Experiments 11 and 12. It should be noted that between Experiments 11 and 13 in which period $\Delta E_M = -12.9$ liters, the patient's 4 + pitting edema of the legs, sacrum and lower abdominal wall almost completely disappeared.

Glomerular filtration rate. The range of the mannitol clearance, 35 to 69 ml. per minute per 1.73 square meter, was definitely lower in these 2 patients than in the normal subjects. No change in clearance occurred in patient L. M. be-

† Water content equaled 974 grams per liter.

fore and after paracentesis. However, in patient F. J. the clearance was higher in Experiment 13 when most of her edema had been removed.

DISCUSSION

The evidence presented in these experiments indicates that in the normal subject mannitol is distributed throughout a definite fraction of the body fluids. This fraction remains essentially constant between 1 and 3 hours after intravenous injection and is reproducible in the same subject after repeated injections. The assumptions necessary to the calculation of a constant volume of distribution, as outlined in the beginning of this paper, are supported by the data presented. Mannitol was completely recovered in urine. It appeared to be uniformly distributed throughout 1 portion of the body fluids, and the concentrations of mannitol in ascitic fluid checked very closely with that in serum, when equilibrium probably had been attained.

The time required in normal subjects for equilibrium to be reached between serum and the rest of the mannitol space was found in these experiments to lie between ½ and 1 hour. This is definitely longer than the 20 minutes reported by Newman, Bordley, and Winternitz (2), but approximates the time of 1 hour reported by Alving and Miller (8) for inulin. Certainly for any measurement of the mannitol space it is essential that this equilibrium be reached, as indicated by a constant value for the volume of distribution between 2 separate points. In patients with abnormal accumulations of extracellular fluid, the time for equilibration may be greatly extended. In patient L. M. with ascites, it was only approached at 3 to 4 hours. In patient F. J. with edema, equilibrium was reached more rapidly as

the edema and mannitol space diminished in size, namely, at 3 to 4 hours, 2 to 3 hours, and 1 to 2 hours (Experiments 11, 12, and 13). Prolongation of the time for equilibration probably occurs in the presence of any type of circulatory impairment.

No direct evidence is presented regarding the relation between the absolute mannitol space and the extracellular fluid. In the normal subjects the magnitude of the former approximated the accepted value for the volume of the latter, namely, ⅕ of the body weight. The range in these experiments was 18.7 to 23.0 per cent of the body weight. These values are slightly higher than the average for 11 normal subjects found by Newman, Bordley and Winternitz (2) which was 17.7 per cent of the body weight. The volume of distribution of sucrose, a similar polysaccharide, was shown by Lavietes, Bourdillon and Klinghoffer (9) to range in 3 normal subjects between 17.2 and 20.3 per cent of the body weight.

No one substance has ever been shown to be completely excluded from all body cells. Due to the relatively small amounts of chloride in tissues (10), radioactive chloride, Cl^{38}, is probably the best reference substance yet found. In dogs the volume of distribution of Cl^{38} has been demonstrated to be smaller than those of radioactive sodium, Na^{24}, and sulfocyanate (11). However, the very short life of Cl^{38} makes it an extremely difficult substance to use experimentally. The author knows of only 1 human subject in whom the volume of distribution of Cl^{38} has been determined: the value obtained by Moore (12) was 18.9 per cent of the body weight. As the volume of distribution of Na^{24} in the same subject was 26.5 per cent of the body weight, it is obvious that radioactive sodium is no more useful as a reference substance in man than in the dog. Kaltreider, Meneely, Allen and Bale (13) obtained an average value of 24.8 per cent of body weight in 14 normal subjects for the volume of distribution of Na^{24}, 3 hours after injection. This value is close to that of Moore's stated above. In the absence of a simultaneous study of the volumes of distribution of Cl^{38} and of mannitol in the same subjects, it can only be stated that the range of mannitol volumes of distribution found in our experiments lies between those of Cl^{38} and Na^{24} as found by these other workers in other subjects. This is hardly definitive.

Studies of the phase distribution of sugars in individual tissues have not been extensive. Mannitol does not penetrate erythrocytes (1, 2). Wilde (14) demonstrated that inulin and sucrose were confined to a phase in skeletal muscle smaller than that of chloride. These tissue studies appear to confirm the results of the volume of distribution studies as indicating that mannitol and allied polysaccharides are in the main confined to extracellular fluid.

Another type of evidence is available in our experiments on the patients with ascites and edema. The *change* in mannitol space approximated the change in chloride space as calculated from the balances of and changes in serum concentration of chloride. This evidence does not indicate that the absolute size of the mannitol space is the same as that of chloride (11), but it does suggest that determination of the mannitol space may be a useful and independent measure of *changes* in extracellular fluid volume. Furthermore calculation of such change from the changes in balance and serum concentrations of chloride is possible only if the initial extracellular fluid volume, E_1, is known. In a normal subject this value can be estimated reasonably from the body weight. But in patients with dehydration or edema some direct measurement of E_1 is necessary. Direct determination of the mannitol space may be used for this purpose.

Successive determinations of the volume of distribution of mannitol in the same subject require some consideration of the rate of excretion of this substance. The rapidity of excretion probably prevents the detection of significant changes in the extracellular fluid volume between multiple points determined, following a single injection. On the other hand, the substance must be completely excreted before volumes of distribution can be determined following a second injection. Residual amounts in the serum and urine would introduce an unknown error into the calculation of blank concentrations, and hence into the calculation of the distribution volume.

The errors have also been studied which are involved in the measurement of the mannitol clearance, or the rate of glomerular filtration.

Theoretically, when the mannitol clearance is calculated for the ½- to 1-hour period, when the serum concentration of mannitol is higher than that in the interstitial fluid, it does not measure the glomerular filtration rate alone. Part of the removal of mannitol from the plasma is extrarenal and hence the clearance value should be higher than the true renal clearance. The data in Table I, however, reveal that the clearances in this period were not significantly higher than the succeeding period (with the possible exception of Experiment 5). Failure to reach complete equilibrium, therefore, did not introduce a significant error into the determination of the rate of glomerular filtration.

Newman, Bordley, and Winternitz (2) propose to calculate the clearance of mannitol from the rate of fall in serum concentration only, thus obviating the necessity of accurate urine collections and analyses. To do so, however, the volume of the extracellular fluid or mannitol space must be known. No other method of measuring extracellular fluid volume appears to be readily available, and its measurement by determination of the volume of distribution of mannitol requires the analysis of urine for mannitol.

These workers also state the opinion that the mannitol clearance or glomerular filtration rate is more significant physiologically if it is quantitated per unit of extracellular fluid volume than per unit of body surface or merely per unit of time. This seems to the author to be erroneous in that the size of the reservoir containing a substance to be excreted has no relation to rate at which the kidney is able to excrete it. The kidney can only act on that portion of the extracellular fluid volume which runs through it, the plasma. Thus in comparing the mannitol clearance between 2 and 3 hours after injections in Experiments 11 and 13, in terms of ml. per minute it rose from 35 to 49 (+ 40 per cent); in terms of ml. per minute per 1.73 square meters of surface area it rose from 35 to 54 (+ 55 per cent); and in terms of ml. per minute per liter of extracellular fluid volume (mannitol space) it rose from 1.2 to 3.0 (+ 150 per cent). In each experiment it was the same pair of kidneys; *i.e.*, per unit of kidney the change in filtration rate was only + 40 per cent. Because the extracellular fluid volume happened to be reduced by almost ½, it does not seem significant from the standpoint of renal function to correct the change in rate to + 150 per cent.

SUMMARY

In normal human subjects following a single intravenous injection of mannitol:

1. Mannitol was fully recovered in the urine in 24 hours.
2. Equilibrium appeared to be complete between ½ and 1 hour after injection.
3. The volume of distribution was constant between 1 and 3 hours after injection, ranged between 18.7 and 23.0 per cent of the body weight, and was reproducible in each subject following repeated injections.
4. Under specified conditions the maximum standard deviation error in the volume of distribution did not exceed ± 0.5 liter.

In 2 patients with ascites and edema following a single injection of mannitol:

1. Four hours or more were required for diffusion to equilibrium.
2. Equilibration was speeded as edema was reduced.
3. The decrease in mannitol space compared favorably with the decrease in chloride space as produced by paracentesis and mercurial diuresis.

The glomerular filtration rates in both groups of subjects were determined. The error due to failure of attainment of complete equilibrium was less than that due to the analytical error.

The relation of the mannitol space to the extracellular fluid is discussed.

Certain modifications in the mannitol method are described.

EFFECTS OF EXPERIMENTAL HYPERTONIA ON CIRCULATING LEUKOCYTES [1]

By JAMES L. TULLIS [2]

(From the Department of Biological Chemistry, Harvard Medical School, and the Laboratory of Pathology of the New England Deaconess Hospital, Boston)

(Received for publication May 5, 1947)

During the 50 years that have elapsed since Arneth originally studied the behavior of circulating leukocytes, many substances and physical factors have been shown to exert an effect of either depressing or stimulating the total numbers of circulating white cells. Most of the substances have been protein in nature. Thus bacterial products (1), peptone (2), enzymes (3), tissue extracts (4), and pseudoglobulins (5), have all been shown to cause temporary alteration in the peripheral leukocyte picture. Among the physical factors that can similarly influence white cell circulation are cold (6) and ultraviolet light (7). Boyd (8), in 1913, was the first to show that inorganic ions can stimulate an increase in the total white count. While treating insanity with intravenous salt solution, he noted an increase in the polymorphonuclear cells of the blood. Later Bluemel and Lewis (9), in 1924, were able to demonstrate a transitory leukocytosis under the same circumstances. Beard and Beard (10), in 1928, working with rabbits, showed that the intravenous injection of salt caused a transitory leukopenia followed by a leukocytosis. They postulated that the cation Na^+ might play some role in regulation of white counts.

While working with leukocyte tissue cultures, it was observed (11) that polymorphonuclear neutrophiles exhibited a lengthened survival in hypertonic media whereas lymphocytes showed a corresponding slightly lengthened survival in hypotonic media. Although such studies dealt solely with cell survival, they raised interesting possibilities of correlation with *in vivo* effects on regulation of circulating leukocytes. The present study was therefore undertaken to determine whether simple alteration in the tonicity of serum would similarly effect leukocyte maturation and release into the peripheral circulation. That is: would experimental hypertonicity induce a selective polymorphonuclear leukocytosis?

METHODS

Subjects: Healthy 10- to 14-kilogram dogs. Hypertonicity was induced, both acutely and chronically, by diverse means. Prior to the start of any 1 experiment, the animals were maintained on a standard diet and fluid intake for 1 week. In experiments which extended over a several-day period, all blood studies were done at the same time of day, under the same circumstances and by the same set of observers, to minimize, as far as possible, the effects of activity, excitement and variation in the diurnal tide on the peripheral leukocyte pattern. Total white counts and smears were made with standard techniques. Red cell counts and/or hematocrits were done throughout each experiment. All variations in absolute leukocyte counts were thus corrected for the factor of hemoconcentration. All variations in tonicity of the extracellular fluid were determined by the technique of freezing point depression on defibrinated blood and are reported in milliosmoles per liter (conversion factor: $\Delta T_f = 1.86$ M).

CHRONIC HYPERTONICITY

Chronic hypertonicity was attained over a 5- to 10-day period by the following means: (*1*) Chronic water and food deprivation; (*2*) chronic water deprivation in the presence of a dry protein diet; (*3*) chronic water deprivation in the presence of a dry protein diet plus hypertonic salt solution parenterally. As shown by Danowski (12), and others, the diuretic effect of the end products of nitrogen metabolism hastened the onset of chronic hypertonia. Chronic hypertonia was effected 1 time on each of 3 seperate dogs, "A," "C" and "F."

RESULTS

The average resting (pre-experimental) molarity was 308 milliosmoles. The levels of hypertonicity that were attained varied from 364 to 484 [3] milliosmoles. In each instance the hyper-

[1] The author is indebted to Miss Jean Sunderlin for technical assistance.

[2] Donner Foundation, Research Fellow.

[3] When this exceptionally high molarity was reached the dog (Exp. A-2) was in extremis and convulsing. Immediately after the tests were made, the dog was successfully revived by large amounts of hypotonic fluid i.v.

tonicity was accompanied by an increase in the absolute numbers of circulating neutrophiles. The lymphocytes and eosinophiles remained essentially unchanged. The absolute numbers of monocytes decreased. In Figures 1 and 2, the increase in absolute neutrophile counts are plotted against the rise in molarity which occurred in each of the 3 experiments, A-2, C-1, F-1. It will be seen that the molarity of the serum and the absolute neutrophile count bore a linear relation to one another. Under the experimental conditions which existed, the absolute numbers of circulating polymorphonuclear neutrophiles appeared to be a factor of the tonicity of the extracellular fluids.

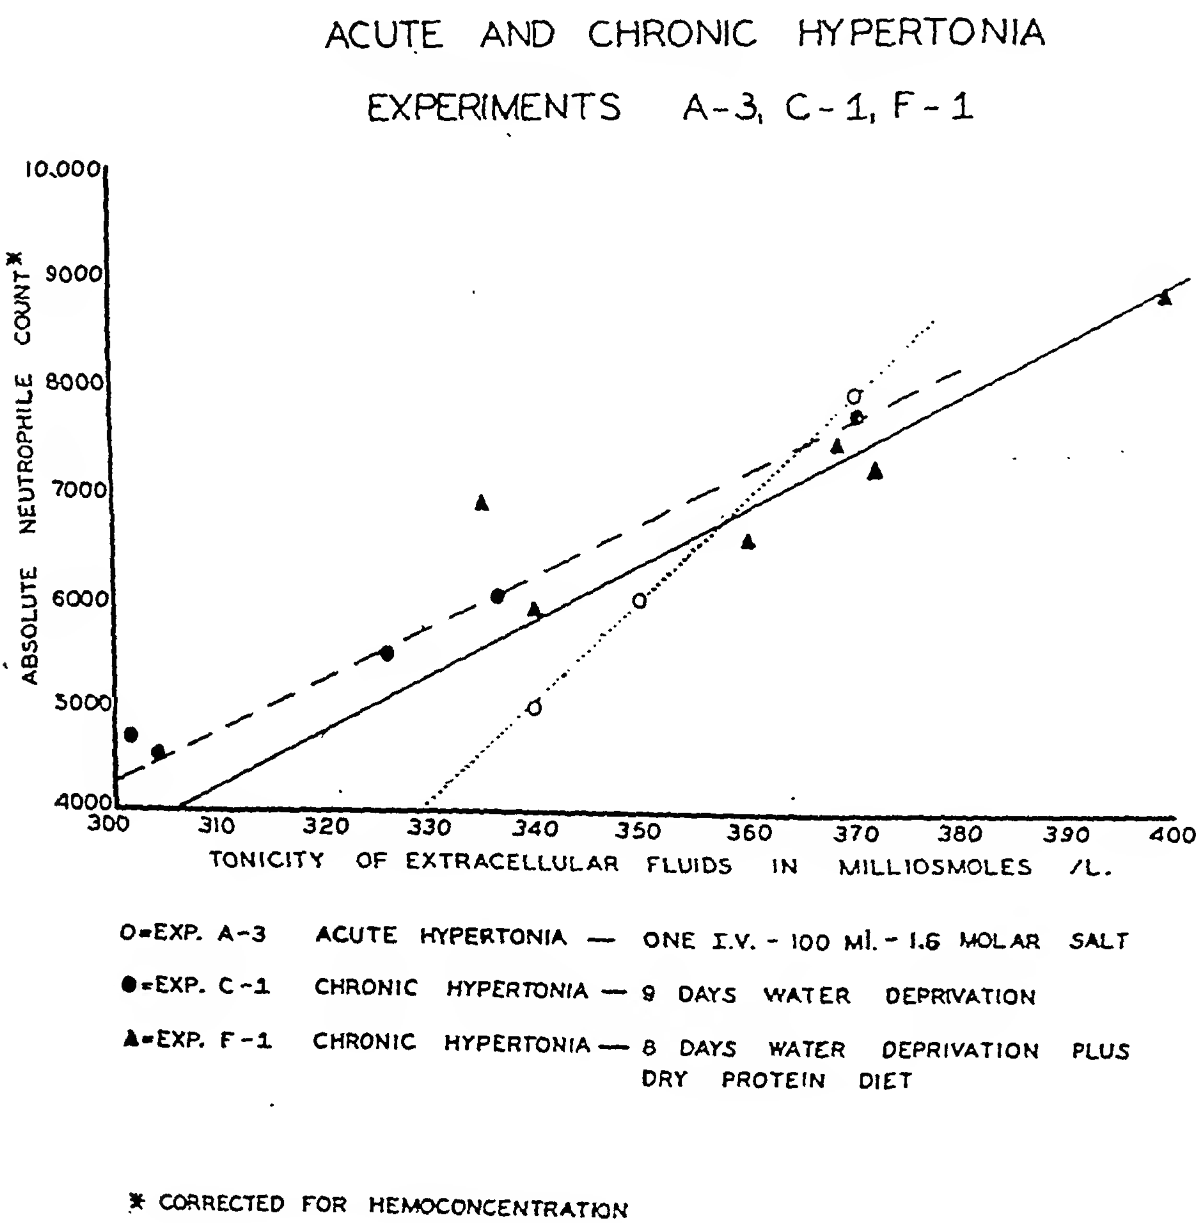

FIG. 1.

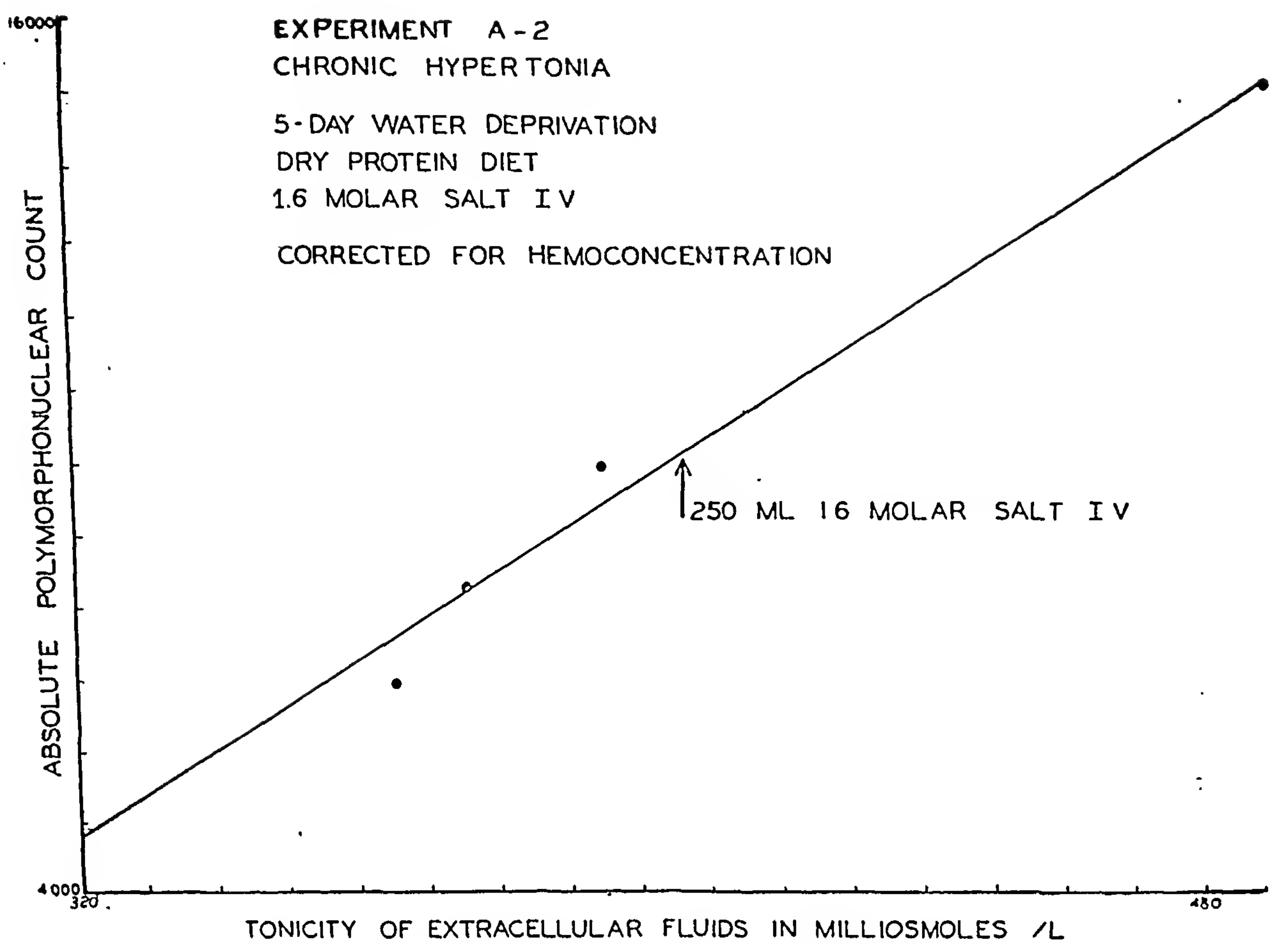

Fig. 2.

ACUTE HYPERTONICITY

Acute hypertonicity was produced, in all instances, by the intravenous administration of hypertonic sodium chloride solution. The experiment was performed 6 times on 2 animals, dogs "A" and "G." In Experiment A-3, 100 ml. of 1.6 molar sodium chloride were infused. In all other experiments, G-2, 3, 4, 6 and 7, 250 ml. of 1.0 molar sodium chloride solution were infused. If sufficient time was allowed for the administration of the infusions (45 to 90 minutes), this amount of salt was exceptionally well tolerated and produced no objective signs of physiologic disturbance. If, however, the rate of infusion was reduced to ¼ hour or less, profound cerebral irritability, clonic convulsions and death occurred.

RESULTS

Administration of hypertonic salt solution intravenously resulted in acute hypertonia. The molarity of the serum rose rapidly to an average level of 370 milliosmoles and returned to normal in about 7 hours. In all instances, the rise in molarity was followed by a selective increase in the absolute numbers of circulating neutrophiles.' The neutrophile rise was statistically significant and of an order of magnitude of 50 per cent or greater. Immediately following the infusion of the hypertonic salt solution, there was a slight decrease in the total numbers of all cell types, both red and white. This was felt to be due to a simple dilution effect from the volume of infused solution and not to be indicative of any specific action on blood cells. Then the rise in absolute numbers of granulocytes began abruptly, around ¼ to ½ hour after the infusion was completed, and reached its highest level in from 7 to 10 hours. In acute hypertonicity, as in chronic, the increase in absolute neutrophile count bore a linear relationship to the increase in molarity of the extracellular fluids (Exp. A-3, Figure 1). Since, with acute hypertonicity, the rise in molarity usually preceded by an hour or more the rise

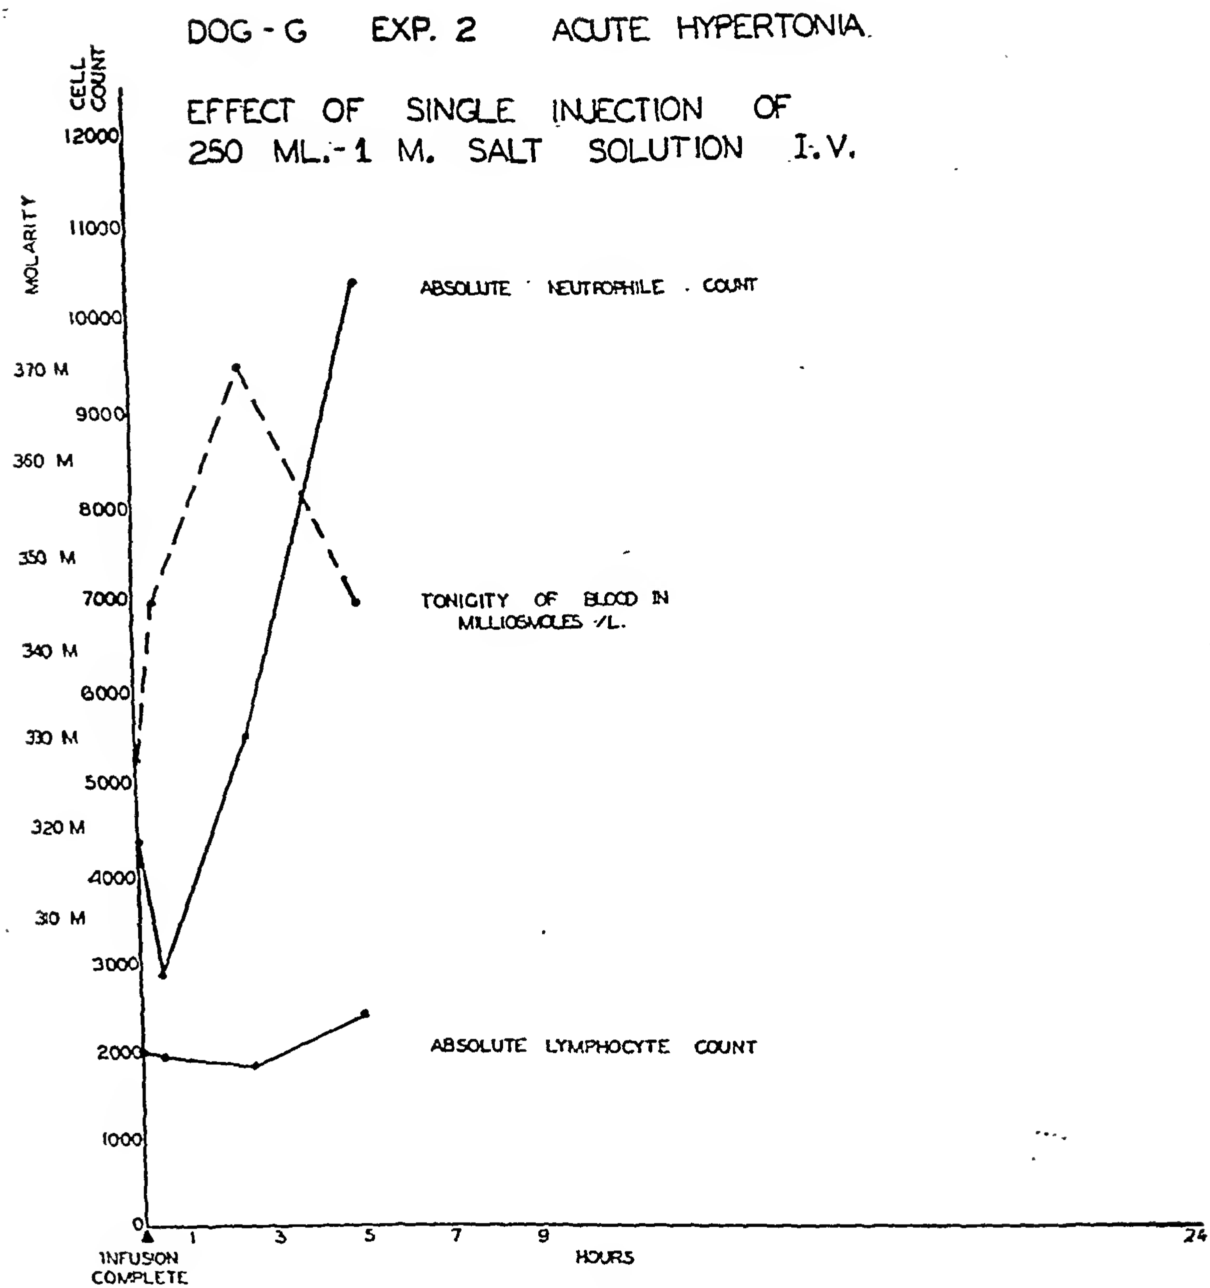

FIG. 3.

in neutrophiles, the fluctuations in count and tonicity are best plotted against time. Thus in Figures 3, 4 and 5, the 24-hour variation in absolute counts following a single infusion of 250 ml. of hypertonic saline may be seen for Experiments G-2, 3 and 4. As a control experiment it was next decided to test the effect of an infusion of a similar amount of isotonic saline to determine how much of the polymorphonuclear rise, if any, could be attributed to a non-specific "washing out" of cells secondary to an increased rate of blood flow.

In Experiment G-5 (Figure 6), it will be seen that a transitory rise in *neutrophile count did* occur after isotonic saline. The rise was slight, however, and not sustained. It was felt that part of this rise might be due to splenic contraction from the stimulus of the intravenous infusion. The animal was therefore splenectomized and the experiments repeated, with both isotonic and hypertonic saline.

In Experiment G-8 (Figure 7), it will be seen that removal of the spleen completely abolished the non-specific rise that occurred in the control injection of isotonic saline. However, in Experiments G-6 and 7 (Figures 8 and 9), it will be seen that removal of the spleen did not affect the rise in count which follows hypertonicity. The rise in neutrophile count, as previously, was

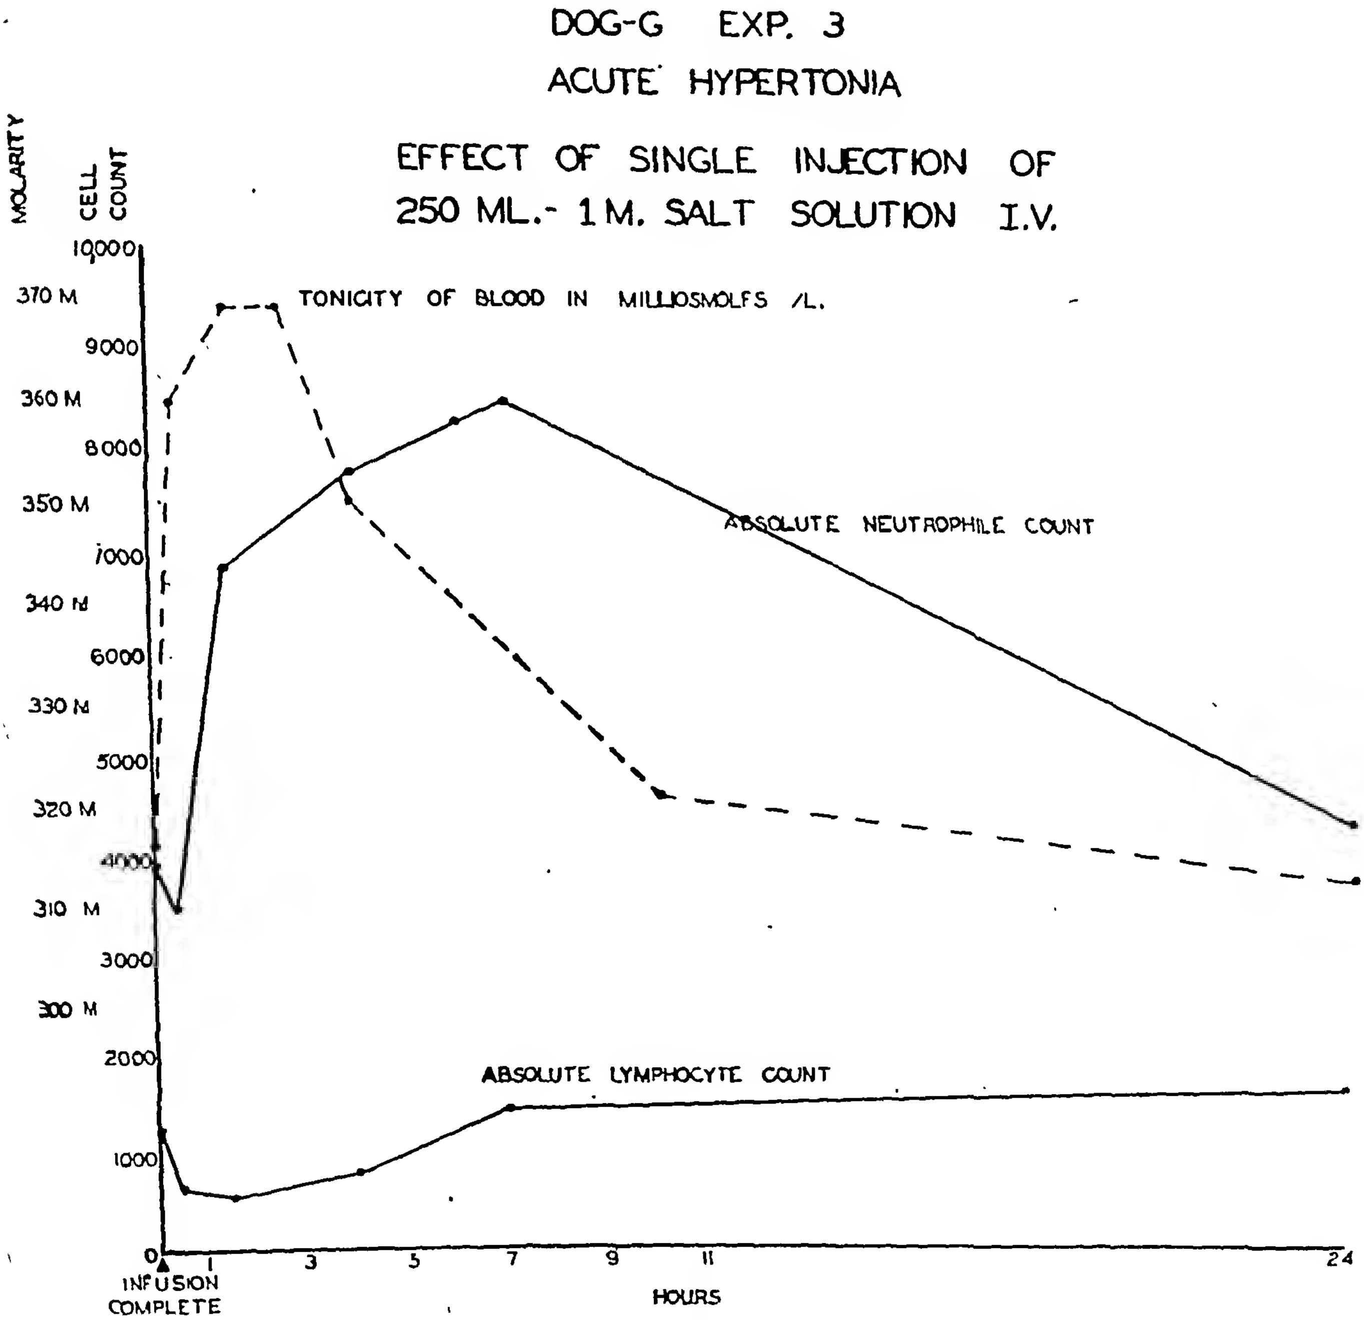

FIG. 4.

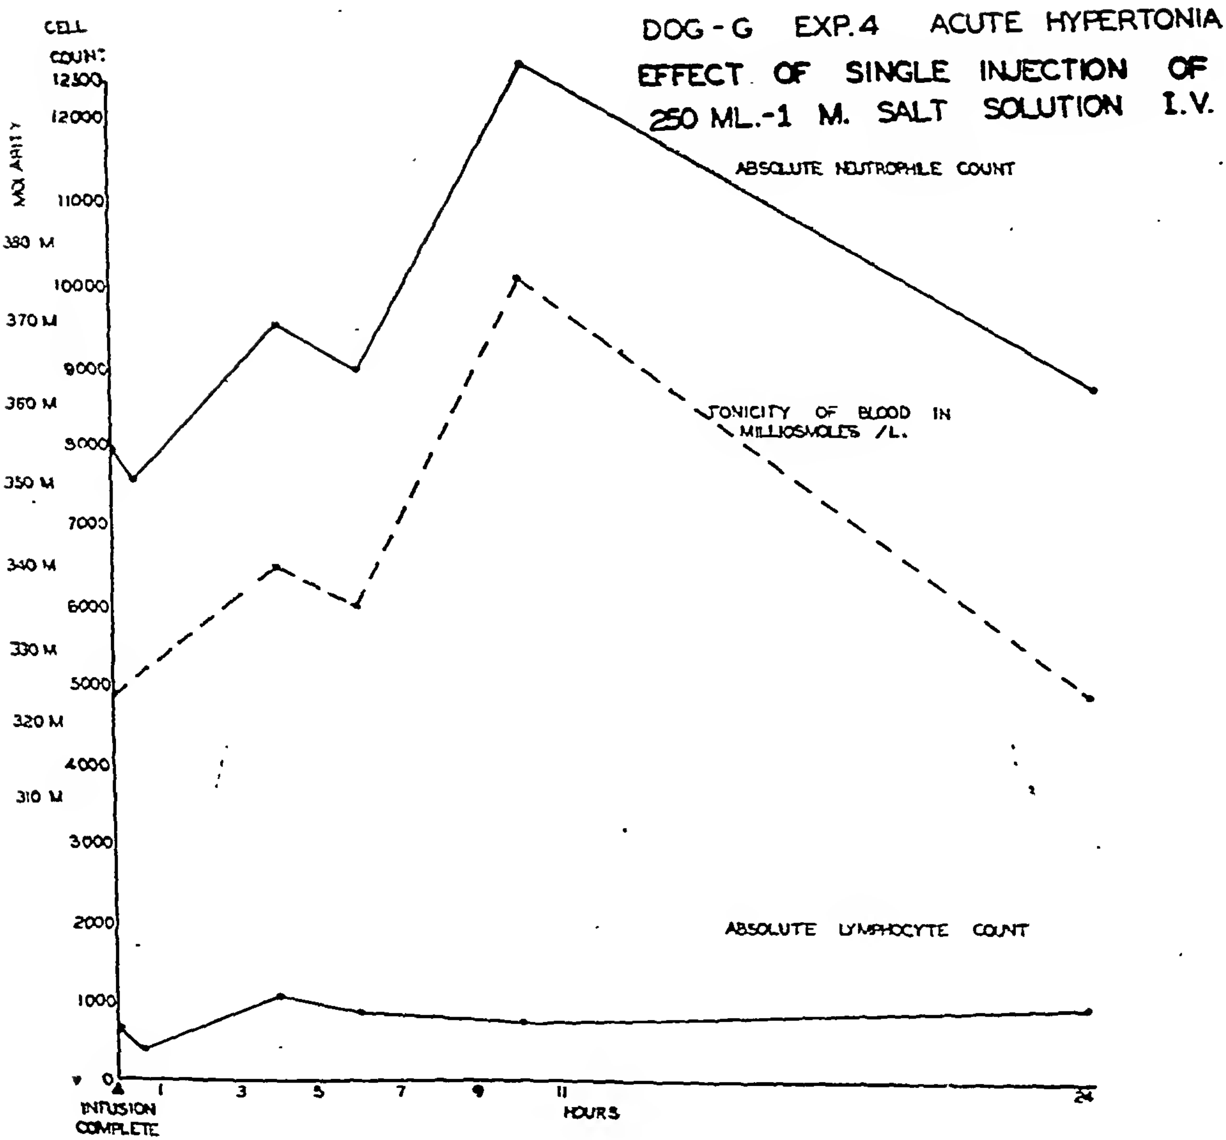

Fig. 5.

prompt, selective (unaccompanied by lymphocytosis) and statistically significant.

DISCUSSION

Within the limits of these experiments it is reasonable to ascribe a cause and effect relationship between the milliosmolar strength of the serum and the absolute numbers of circulating neutrophiles. Due to the fact that the leukocyte variations in these experiments were produced by alterations in osmotic pressure rather than through the use of foreign proteins or other substances alien to the blood stream, it is not unreasonable to postulate that variations in milliosmolar strength of the extracellular fluids may play a role in determining the leukocyte pattern in some diverse disease states. For example: (*1*) The unexplained polymorphonuclear leukocytosis which regularly accompanies the hypertonicity of diabetic coma. (*2*) The unexplained granulopenia and

relative lymphocytosis which regularly accompanies the hypotonicity of Addison's disease. Studies are currently being carried on to investigate these relationships.

The mode of action of the hypertonic polymorphonuclear leukocytosis produced in these experiments is unknown. Its prompt occurrence in acute hypertonicity makes it obvious that it is not due to the effect which originally stimulated these investigations, namely: The lengthened survival time of neutrophiles in hypertonic media (11). The recent work of Lawrence (13), who places the *in vivo* survival time of leukocytes at 16 hours, would similarly tend to make such an effect improbable. The 2 most likely mechanisms would seem to be either a release of preformed cells from some theoretical "store house" in the body or an accelerated maturation and release of immature cells from the bone marrow. If the first mechanism obtains, it would be difficult to visualize the absence of a simultaneous rise in all leukocyte types (lymphocytes, monocytes,

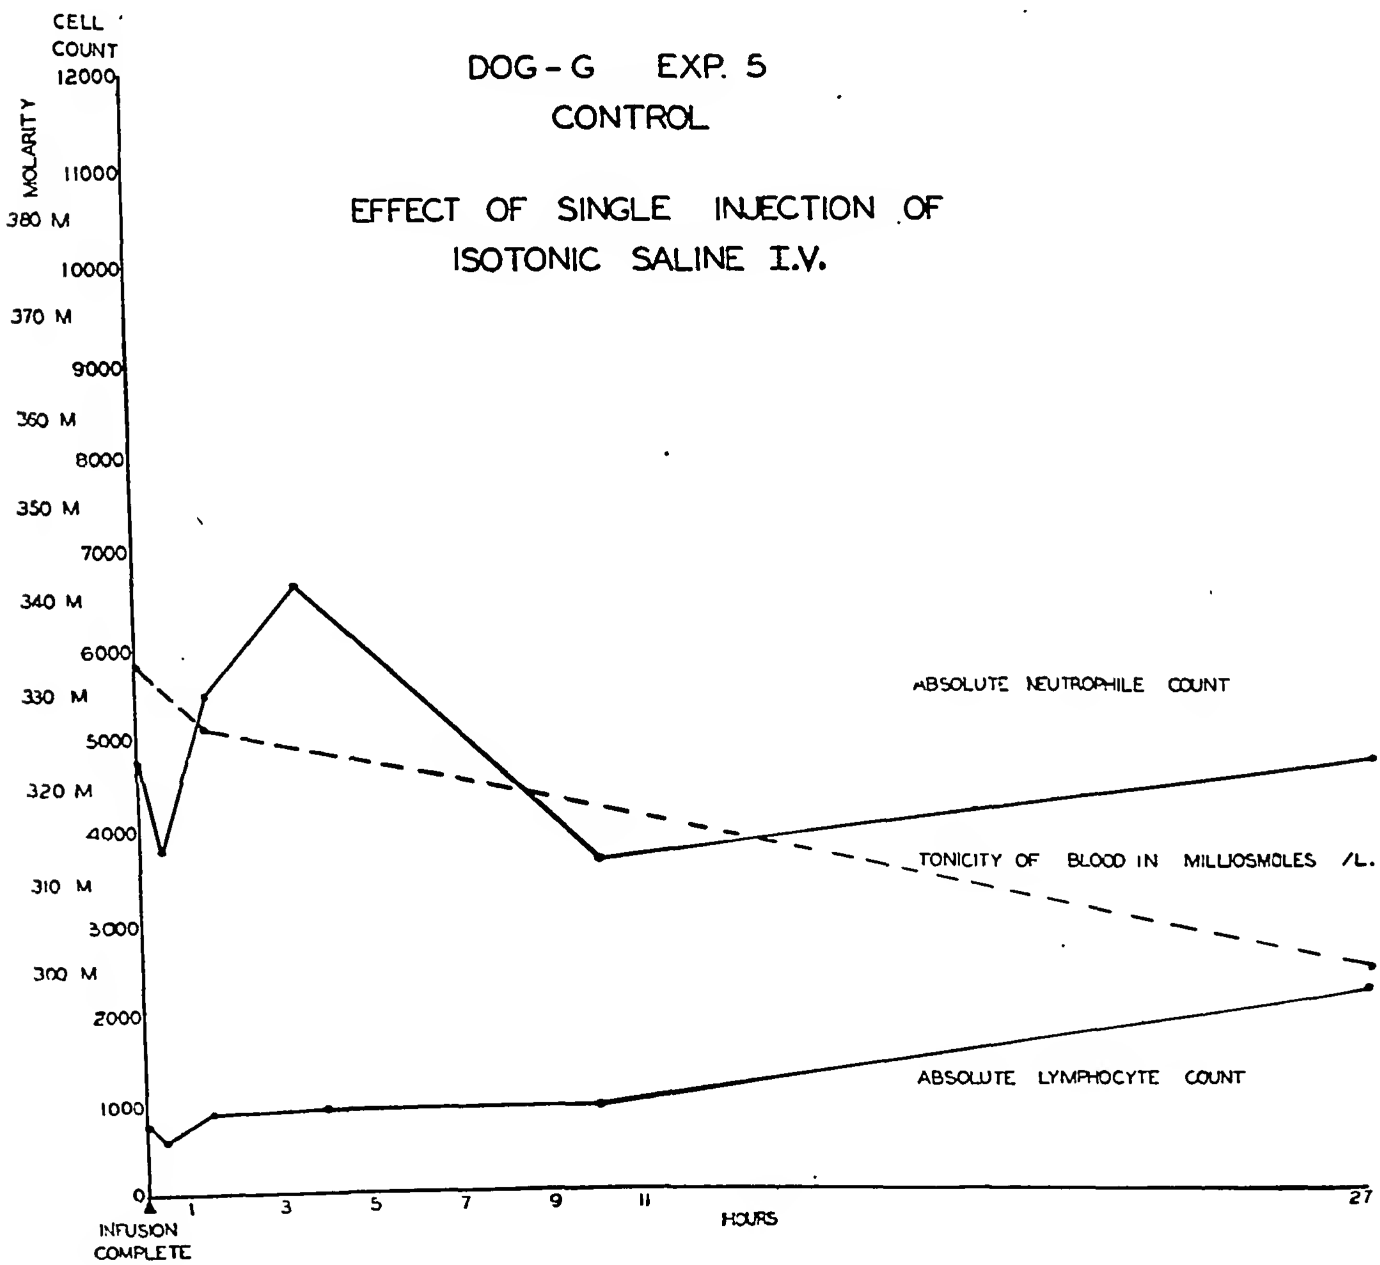

FIG. 6.

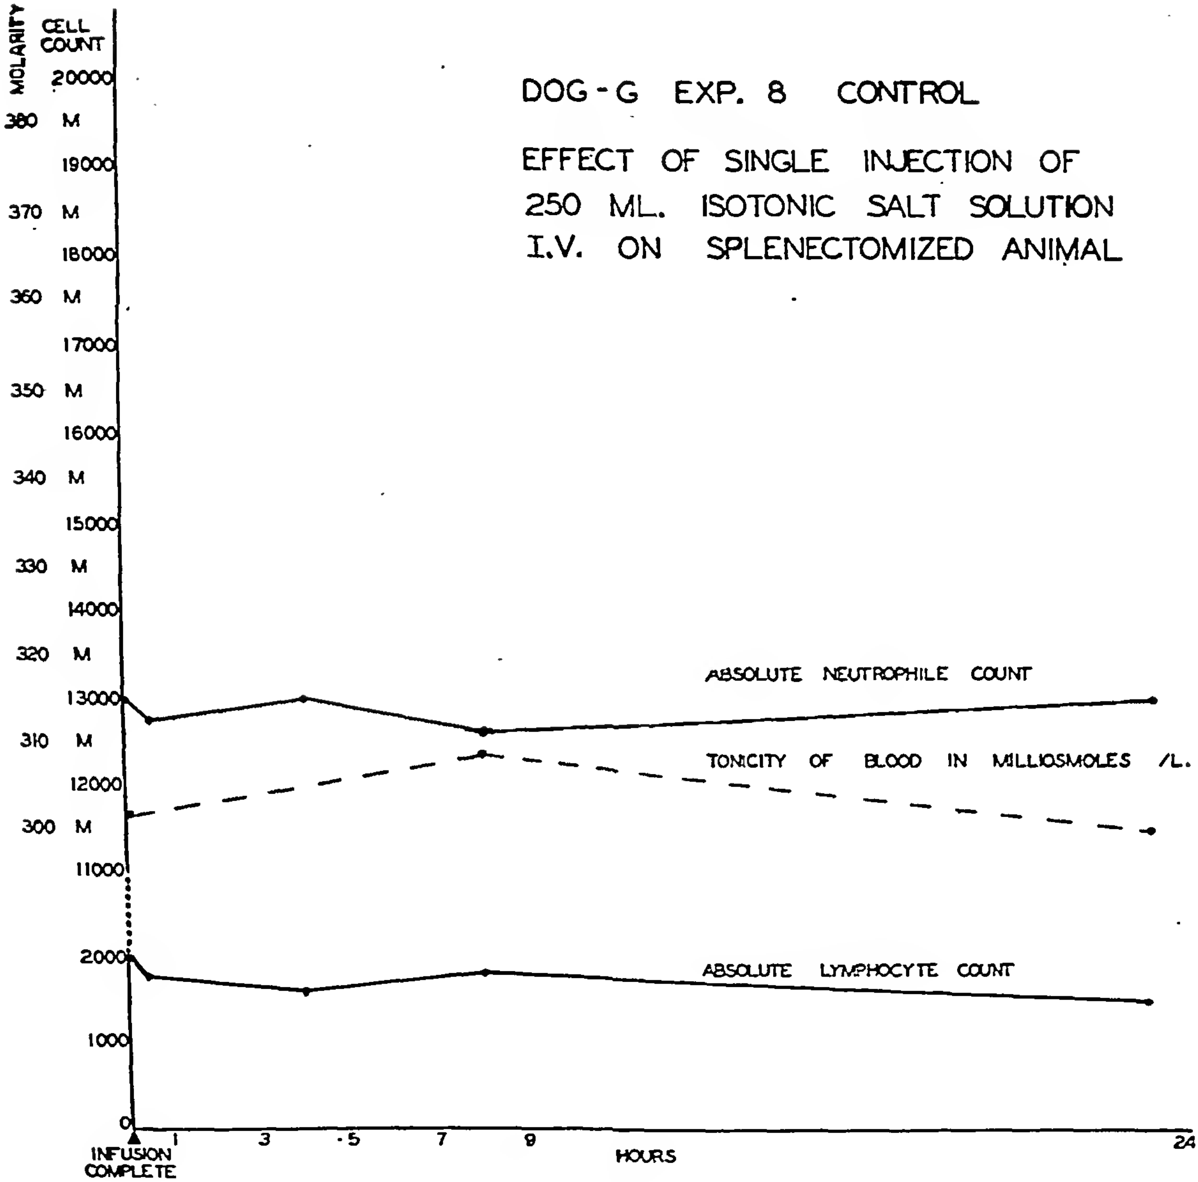

FIG. 7.

eosinophiles) and the persistence of the rise in the case of the chronically induced hypertonicity. If the second mechanism obtains, one would expect rather large numbers of juvenile neutrophiles to appear in the peripheral circulation. Although this phenomenon was looked for, and sometimes found, its appearance was too irregular to lend weight to this possibility. On the basis of these experiments, no explanation of the mechanism can be offered. Further investigation into the mode of action of hypertonic polymorphonuclear leukocytosis should include serial bone marrow observations.

SUMMARY

Hypertonicity of the serum of dogs was produced both acutely and chronically. In all in-

stances it was accompanied by relative and absolute increases in the numbers of circulating neutrophiles. The absolute numbers of lymphocytes remained essentially unchanged with increases in molarity. Monocytes, when present in numbers to be statistically significant, showed a slight decrease with increases in molarity.

CONCLUSION

Under the conditions of these experiments the increases in absolute numbers of circulating neutrophiles were directly proportional to the increases in the milliosmolar strength of the extracellular fluids.

THE RELATIONSHIP OF SODIUM CHLORIDE TO HYPERTENSION [1]

By GEORGE A. PERERA and DAVID W. BLOOD

(From the Department of Medicine, Columbia University College of Physicians and Surgeons, the Presbyterian Hospital, and the Research Service, First [Columbia] Division, Goldwater Memorial Hospital, Department of Hospitals, New York City)

(Received for publication May 15, 1947)

Restriction of the sodium chloride intake as a therapeutic measure in hypertensive vascular disease was first advocated many years ago (1, 2, 3). Although subsequent investigators (4, 5, 6, 7) claimed that the addition or removal of salt from the diet failed to influence the blood pressure level significantly, interest in the subject has recently been renewed.

Selye and his coworkers (8) noted a striking hypertensive effect when sodium chloride was administered to experimental animals receiving injections of desoxycorticosterone acetate. Grollman and his associates (9) observed that drastic reduction in sodium intake resulted in a decline in blood pressure in some hypertensive patients. They believed it probable that the beneficial effects of the diet proposed by Kempner (10) might be due to the restriction of salt. Recently evidence has been presented (11) that sodium chloride potentiates the pressor activity of desoxycorticosterone acetate when injected into rats rendered nephritic with nephrotoxic serum.

The present study was undertaken to reexamine the relationship of sodium chloride to hypertensive vascular disease in man.

METHODS

Men and women with uncomplicated hypertensive vascular disease were studied on the wards of the Presbyterian Hospital and the Research Service, First Division, of the Goldwater Memorial Hospital. Subjects were included only if the antecedent blood pressure consistently exceeded 140/90 mm. of mercury and in the absence of cardiac pain or insufficiency, renal or cerebral complications or fever. All patients were free of albuminuria, showed normal phenolsulfonephthalein excretion and urine concentration tests, and in all instances the venous pressure was within normal limits.

Blood pressures were measured each morning in the same arm by the same observer, with the subject quiet and relaxed in bed, the head of which was raised to a 30° angle. At least 5 and usually 7 or 8 readings were taken at half-minute intervals and the lowest systolic and diastolic value recorded. This value was designated the *"resting"* blood pressure as compared to *"casual"* readings taken under various conditions of activity at other times during the day. In order to secure an adequate baseline, it was found obligatory to carry out preliminary observations for at least 3 weeks.

All subjects were kept in bed until after blood studies and blood pressure measurements were made, and ambulatory activity was standardized at a constant level the rest of each day. The patients were weighed daily before breakfast on the same scales. The daily fluid intake and urine output were recorded, distilled water being supplied for drinking purposes.

Throughout the study the patients were given a constant diet and fluid intake. Identical salt-poor daily menus were prepared. Repeated direct analyses of aliquots taken from an entire day's cooked diet gave values of between 0.25 to 0.35 grams of sodium or considerably less than 1 gram of sodium chloride per day. These salt-poor diets yielded 1,700 to 2,200 calories and 70 to 80 grams of protein, and did not include special ingredients such as dialyzed milk. Sodium chloride was administered by mouth using weighed salt shakers, additional supplements being given in some instances in the form of enteric-coated tablets. When indicated, desoxycorticosterone acetate [2] (DCA) was injected subcutaneously in doses of 5 mgm. twice daily.

The urine chloride was determined daily from the 24-hour collection, daily aliquots being measured at approximately weekly intervals for their sodium content. Fasting blood samples were obtained at intervals for CO_2 content, chloride, sodium, potassium, protein and urea nitrogen determinations. The serum volume was measured with the blue dye T. 1824. Weekly electrocardiograms were taken and in no instance showed evidence of significant myocardial damage or serial changes.

A sample chart (Figure 1) illustrates the general form

[1] This study was made possible through the generosity of the Albert and Mary Lasker Foundation. We are indebted to Miss Ann D. Barrows, dietitian, Miss Margaret G. Hawthorne, head nurse, Miss Katherine Vislocky, technician, John T. Sharp and Dominic G. Iezzoni for their invaluable assistance.

[2] Desoxycorticosterone acetate (Doca) was supplied through the courtesy of Dr. L. A. Pirk of Roche-Organon, Inc., Nutley, New Jersey.

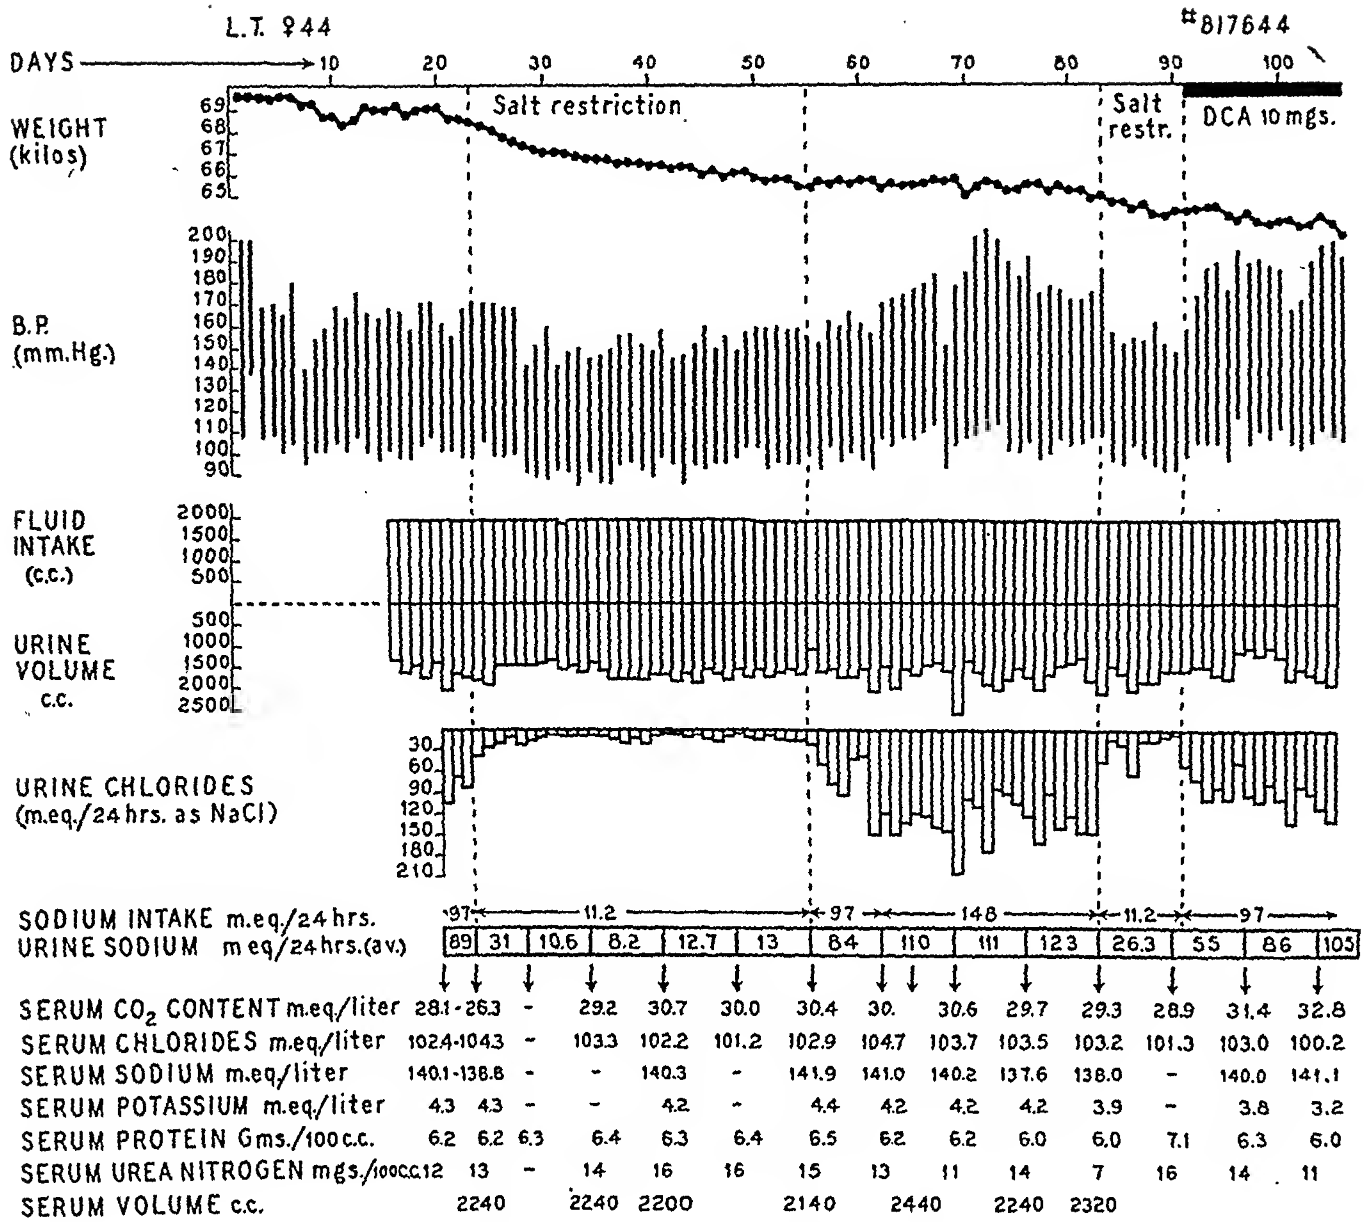

FIG. 1. SAMPLE CHART ILLUSTRATING GENERAL FORM OF INVESTIGATIONS ON EACH HYPERTENSIVE SUBJECT

in which subsequent investigations were conducted and recorded on each patient.

RESULTS

I. *Effect of rigid sodium chloride restriction on blood pressure.* Six hypertensive patients were studied following a preliminary baseline period and constant regimen which included 4 grams of sodium chloride added to the salt-poor diet. A decrease in *"resting"* blood pressure was observed in all patients in from 3 to 5 days after the withdrawal of the sodium chloride from the diet, with a return to previous levels only after sodium chloride administration was resumed (Figure 2, I). The majority of blood pressure readings, during the period of observation, remained above 140/90 mm. of mercury. *"Casual"* readings were apparently uninfluenced by sodium chloride restriction, and each patient exhibited the same variation, the same response to such stimuli as activity, apprehension or the cold pressor test as was demonstrated during the fore-period.

The withdrawal of sodium chloride from the diet for a period of 2 weeks was tolerated in these subjects without discomfort. Slight weight loss and small increases in urine output were generally observed. The decreased intake was sharply

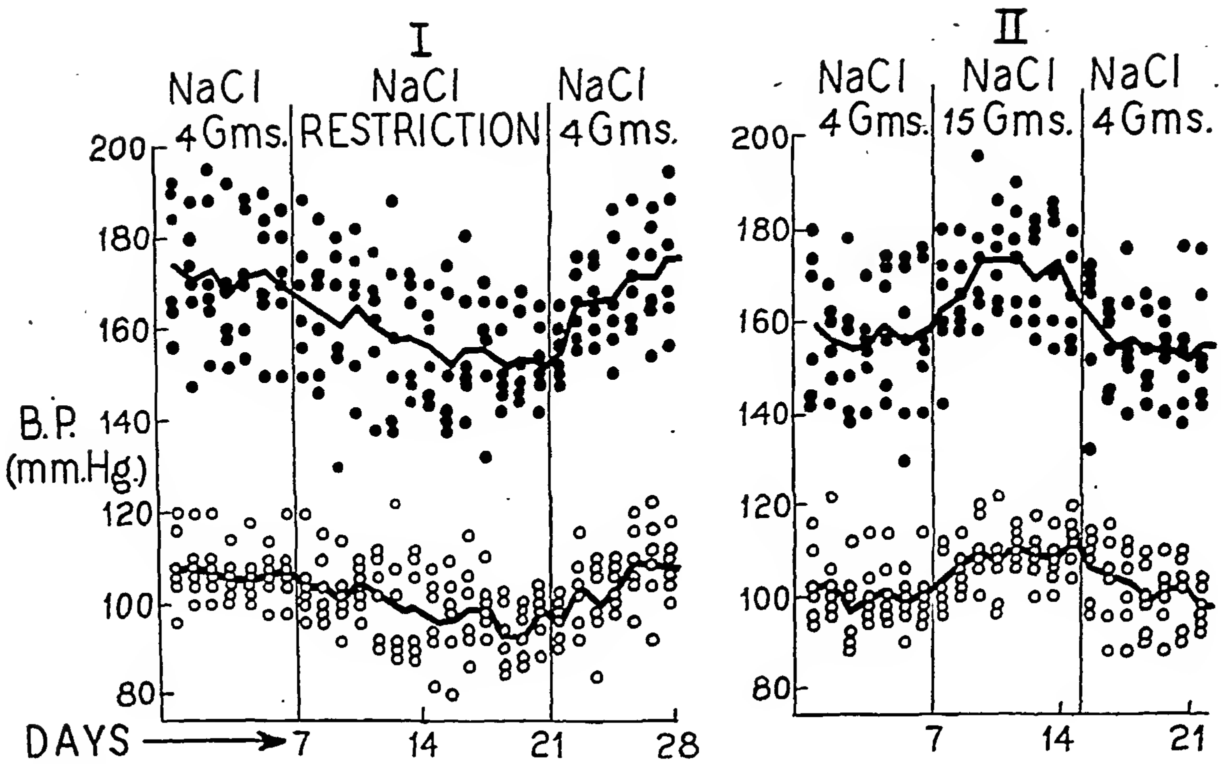

FIG. 2. EFFECT OF RIGID SODIUM CHLORIDE RESTRICTION AND OF INCREASED SODIUM CHLORIDE INTAKE ON 6 PATIENTS WITH HYPERTENSION

reflected in urine sodium and chloride levels, but serum CO_2, chloride, sodium, potassium, protein, urea nitrogen and volume measurements were not materially influenced (Table I). Ballistocardiographic tracings were unchanged on repeated records taken before and after sodium chloride restriction in 2 of these patients, both of whom exhibited a significant drop in blood pressure on salt restriction.

II. *Effect of increased sodium chloride intake on blood pressure.* Six hypertensive patients, 4 of whom had been included in the previous study, were investigated following a preliminary baseline period and constant regimen which included 4 grams of sodium chloride added to the salt-poor diet. The intake of sodium chloride was then increased to 15 grams daily for an 8-day period. These subjects were able to tolerate this dosage without gastric intolerance or diarrhea.

A rise in *"resting"* blood pressure was observed in 5 patients within 1 to 4 days after the addition of sodium chloride to the diet, with a return to previous levels after the initial dosage was resumed (Figure 2, II). (In 2 patients a week's trial with placebo pills was without effect on the blood pressure.) Again *"casual"* readings were uninfluenced and each patient exhibited the same variation, the same response to such stimuli as activity, apprehension or the cold pressor test as was demonstrated before the increased sodium chloride intake.

The further addition of sodium chloride for a period of 8 days was followed by an increase in urine sodium and chloride excretion, and slight weight gain and decreases in urine output were generally observed. No significant change was recorded in serum CO_2, chlorides, sodium, potassium, protein, urea nitrogen, or volume measurements (Table II).

III. *Effect of rigid sodium chloride restriction*

on pressor action of DCA (12). Five hypertensive patients, 3 of whom had been investigated in the previous studies, were studied following a preliminary baseline period and constant regimen which included 4 grams of sodium chloride added to the salt-poor diet. DCA was then injected subcutaneously in doses of 5 mgm. twice daily, with added dietary sodium chloride increased in 3 subjects but maintained at 4 grams in 2. After 10 days, all added sodium chloride was withdrawn from the diet without other change in regimen and while the subjects continued to receive DCA.

In all instances an increase in *"resting"* blood pressure followed the injection of DCA, this rise not being maintained when sodium chloride was withdrawn (Figure 3). During the period of sodium chloride and DCA administration, the expected slight increases in weight, hemodilution and serum volume were generally noted, together with slight reduction in urine volume (12, 13). Significant increases in serum chloride and sodium were observed in 2 patients, while reductions in serum potassium of from 0.4 to 1.5 m.eq. took place in all subjects. When DCA injection was continued but with rigid sodium chloride restriction, slight reductions in weight and serum volume were seen, together with hemoconcentration, slight increases in urine volume, and a sharp decrease in urine sodium and chloride values. The serum chloride and sodium were significantly reduced by sodium chloride restriction in 2 instances, while the serum potassium levels showed

* Mean values for each period.

no further consistent change (Figure 4, Table III).

As the pressor action of prolonged DCA injection was on occasion found to be transitory, the order was reversed in 2 additional patients, *i.e.*, following the usual baseline observations, rigid sodium chloride restriction was instituted simultaneously with the start of DCA administration. These were patients who had not been subjected to previous studies. No rise in *"resting"* blood pressure ensued until the addition of sodium chloride (Figure 5).

COMMENT

The present study, utilizing measurements of the *"resting"* blood pressure, confirms the reports of some previous observers that the rigid restriction of sodium chloride in the diet may lower the blood pressure of patients with hypertensive vascular disease. Conversely, it has been shown under similar conditions that large amounts of dietary sodium chloride may exert a pressor effect in hypertensive subjects. Lastly, the observations of Knowlton and her associates (11), that sodium chloride participates in the potentiation of the pressor activity of DCA, have been supported by studies in patients with an elevated blood pressure. It has been previously shown that this pressor response to DCA is not due to salt and water retention alone (12).

Because of the great variability of blood pressure readings in association with any of a large

number of environmental changes, the need has been stressed for an adequate baseline and constant regimen as well as for the differentiation between *"resting"* and *"casual"* values. It must be emphasized that the magnitude of blood pressure fluctuation observed in this study was often small, although consistent, and that standard conditions were required.

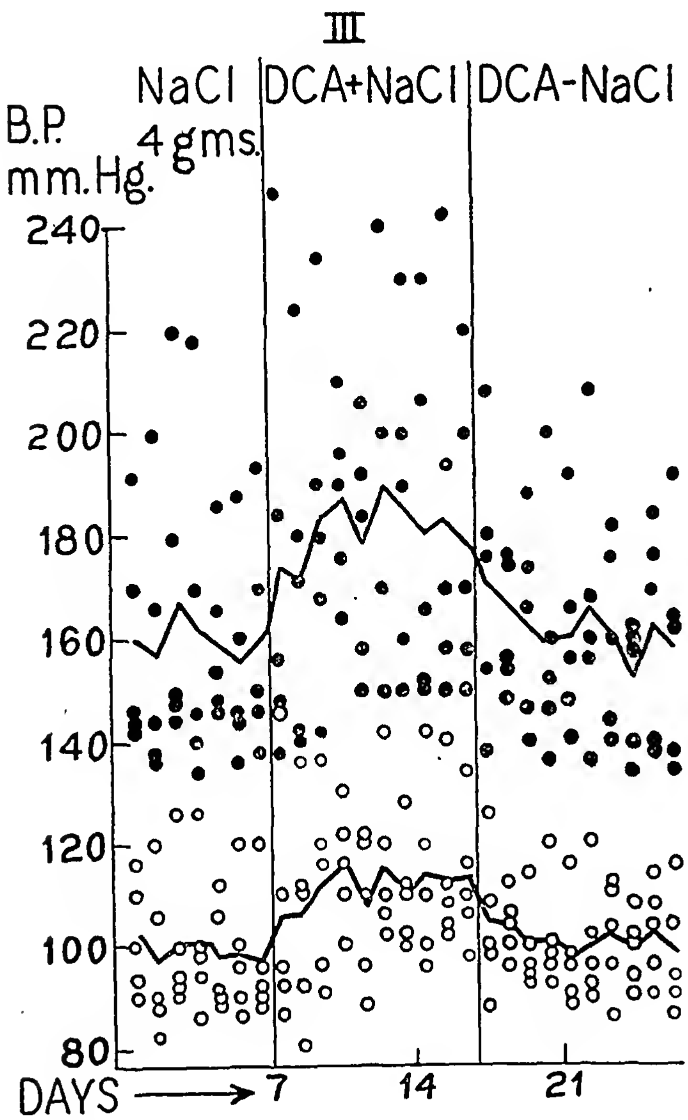

FIG. 3. EFFECT OF RIGID SODIUM CHLORIDE RESTRICTION ON PRESSOR ACTION OF DCA IN 5 HYPERTENSIVE SUBJECTS

The effect of rigid sodium chloride restriction is apparently unrelated to changes in circulatory volume or cardiac output, hence must be concerned with alterations in peripheral resistance. It must be noted that a normal blood pressure is not routinely achieved by salt restriction and that the patient's ability to respond to autonomic or neurogenic stimuli is unaffected. The demonstration in this study that there is an absence of correlation between *"resting"* and *"casual"* blood pressure readings, suggests that the factors (at least in part neurogenic) influencing the "casual" readings may be independent of those influenced by sodium chloride or DCA. This may explain the results of sympathicolytic drugs and of surgical procedures which modify vasoconstriction of sympathetic origin yet do not invariably relieve the hypertensive state. Previous uncertainties concerning the effect of many therapeutic agents may have been due to the failure to dissociate between extrinsic (neurogenic) and direct actions on peripheral resistance, both of which seem to be involved—in variable proportions—in the clinical picture of hypertension.

There is nothing to suggest that the small changes in *"resting"* blood pressure associated with rigid sodium chloride withdrawal are of therapeutic significance or that prolonged restriction will exert any influence on the natural history of this disorder.

The modification of *"resting"* blood pressure levels by sodium chloride and the relationship of sodium chloride to the pressor action of DCA are consistent with the view that some product of the adrenal cortex may play a part in the mechanism of hypertensive vascular disease (12, 14, 15).

CONCLUSIONS

1. Observations have been made on patients with uncomplicated hypertensive vascular disease under controlled conditions of diet and activity.

2. Despite an otherwise constant regimen, rigid sodium chloride restriction resulted in a slight decrease in *"resting"* blood pressure in 6 subjects, whereas large amounts of dietary sodium chloride produced a slight rise in *"resting"* blood pressure in 5 of 6 subjects.

3. The pressor action of desoxycorticosterone acetate was observed in 7 subjects, but only when sodium chloride was included in the diet; the rigid restriction of sodium chloride obliterated this pressor response.

4. It is suggested that vasoconstrictive factors (at least in part neurogenic) in hypertensive patients are independent of those alterations in peripheral resistance influenced by sodium chloride or desoxycorticosterone acetate.

CAPILLARY PERMEABILITY IN RELATION TO ACUTE ANOXIA AND TO VENOUS OXYGEN SATURATION[1]

By J. HENRY, J. GOODMAN and J. MEEHAN with the technical assistance of R. FRANKEL

(*From the Departments of Physiology and Aviation Medicine, University of Southern California, Los Angeles*)

(Received for publication June 2, 1947)

INTRODUCTION

It has often been assumed that moderate degrees of hypoxia render the capillaries abnormally permeable to fluid and protein. During the course of work concerned with methods of insuring pilot survival at altitudes above 45,000 ft., it became desirable to know the degree and duration of anoxic anoxia that could be tolerated before permeability changes of the capillary bed occurred. The studies of Landis (1) have demonstrated that complete ischemic anoxia of 3 minutes' duration will cause temporary damage to the capillaries of the frog's mesentery and result in abnormal permeability to fluid and protein. Pochin (2) working with the rabbit's ear has found that complete occlusion of the circulation for 2 hours will lead to demonstrable edema following re-establishment of the circulation. He also showed that 16 to 18 hours of occlusion resulted in edema fluid containing approximately 5 grams per cent of protein. Calvin (3) has found that during the terminal stages of fatal asphyxia there is evidence of a marked loss of protein and of the protein-attached dye T 1824 from the capillary bed.

These experiments involved very intense anoxia and on turning to work done under less severe conditions the results are seen to be less conclusive. Thus Calvin (3) and also Hopps and Lewis (4) found no change in the rate of filtration of plasma protein and of the dye T 1824 in the course of severe but non-fatal anoxia. On the other hand Maurer (5) and Warren and Drinker (6) have shown that, in the dog, the flow of cervical and lung lymph increases during severe but non-fatal anoxic anoxia. However the percentage of protein in this lymph decreases with the increased flow and the results do not unequivocally demonstrate an increase in capillary permeability as a result of the acute anoxia. Observations concerning the influence of anoxia have been made in humans. McMichael and Morris (7) have used nitrogen-oxygen gas mixtures of an oxygen percentage (9.5 per cent) that would induce approximately 65 per cent arterial hemoglobin saturation. They found no increase in the rate of swelling of the congested arm. Their results suggested that the permeability of the arm capillaries to fluid is unchanged by anoxia. However, the technique employed did not give them any information on the concentration of the protein in the filtrate and their report is in abstract form only. Another study is that by Stead and Warren (8) who have estimated the protein content of the edema fluid in 2 emphysematous patients whose arterial oxygen saturation was 50 to 60 per cent. They found no significant change from the normal figure of 0.25 gram per cent or less and concluded that this degree of chronic anoxia had not increased the permeability of the capillaries of the limbs. In an earlier report (9) the authors found no significant change in fluid or protein loss from the capillaries of the forearm when under the influence of acute anoxia.[2] The following paper confirms these results and extends them to an estimation of the approximate oxygen tension at which a significant increase in protein filtration from the capillary bed occurs.

[1] This work was supported in part by the AAF Aero Medical Laboratory, Air Materiel Command, Wright Field.

[2] A systematic error which does not however invalidate the conclusions drawn has been detected in the calculation of the protein data presented in this report to the CAM of the OSRD and summarized in the Fed. Proc., 1946, 5, 44. The corrected figures for the calculated protein in the filtrate are 1.5 grams ± 1.5 grams per cent when anoxic and 1.2 grams ± 0.5 gram per cent when at sea level.

METHOD OF APPROACH

The best measure of the permeability of the capillary wall would be a direct determination of the concentration of protein in the capillary filtrate (10). A significant increase in this concentration over the normal near zero (0.2 to 0.3 gram per cent) values found in the limb may be regarded as evidence of a change in the permeability of the wall (1, 8). Failing a direct determination an estimate of this measure was made by Landis *et al* (11) in their experiments, using various degrees of venous congestion supplied by the blood pressure cuff. The congestion cuff causes a marked slowing of blood flow without stopping it when the venous pressure imposed by it (60 or 80 mm. Hg) is less than the arterial blood pressure. The increased filtration pressure of the slowly flowing blood results in a loss of fluid into the tissues. Comparison of the hematocrit values shown by the blood in the median antecubital vein of the congested arm with that in the uncongested control arm permits an estimation of the fluid loss in ml. per 100 ml. of the blood flowing through the congested arm. These investigators have devised a formula by which they can calculate the percentage of protein in the capillary filtrate from observations on the relative changes in hematocrit values and plasma protein levels in the blood from the control and congested arms. In such studies on the human arm, they have observed a calculated protein in the capillary filtrate at a congestion pressure of 80 mm. Hg of approximately 1.5 grams per cent. This procedure produces the double effect of an increase of the hydrostatic pressure in the capillaries and an ischemic anoxia due to slowing of the blood flow through the vessels. It has been pointed out (11) that if it were possible to be sure that the high pressure in the congested capillary bed was not directly responsible for this abnormally high content of protein in the filtrate, then the experiment would provide evidence of the effect of ischemic anoxia on capillary permeability. Kunkel, Stead and Weiss (12), and more recently Allen *et al* (13) have shown that adrenalin injections will lead to a marked increase in the amount of blood flowing through a limb. If this increase in blood flow is enough to effectively eliminate the ischemic anoxia resulting from a congestive cuff then it should be possible to eliminate the protein loss in a congested arm by increasing the blood flow through it by the use of adrenalin. If the protein loss is eliminated in spite of the use of cuff pressures of 80 mm. Hg then it can be assumed that such pressures have little effect on the permeability of the blood vessels. Another method of dissociating the effects of pressure from those of anoxia would be to decrease the venous oxygen tension while keeping the capillary pressure constant. This could be accomplished by exposing the subject to a lowered alveolar oxygen tension at a cuff pressure at which the protein in the filtrate was at the upper limit of the normal values. Reduction of the arterial oxygen saturation to 60 to 70 per cent would cause a considerable fall in the mean capillary oxygen tension. This fall should increase the protein in the capillary filtrate if permeability is significantly affected by changes in oxygen tension. Since the oxygen tension is lowest at the venous end of the capillary, the oxygen content of the venous blood should be a measure of the oxygen tension in that part of the capillary bed which is exposed to the most severe anoxia. If the content of protein in the filtrate is a measure of the permeability of the capillary wall and if this permeability is affected by the oxgen tension, then it should be possible to demonstrate a correlation between the oxygen content of the venous blood from the congested arm and the concentration of protein in the capillary filtrate.

METHODS

The subjects employed were chosen for their familiarity with experimental procedures and the majority of the tests were performed on only 3 persons. These were in good health and of an active habitus. The 2 subjects employed for the altitude studies showed no gross vasomotor disturbances with acute anoxic anoxia. There was no significant change in blood pressure, pulse or respiration rate with reduction of the arterial oxygen saturation to values of the order of 60 per cent for periods of 30 minutes. It was hoped that by employing repeated tests on a few well-trained subjects it would be possible to decrease the inherent differences between various subjects and the variations due to fluctuations of subject response.

Adrenalin hypertension was obtained by the intramuscular administration to the recumbent subjects of 6/10 ml. of 1/500 adrenalin in peanut oil followed in 15 minutes by 1/10 ml. doses of 1/1000 adrenalin subcutane-

ously in sufficient number to maintain the blood pressure 20 to 40 mm. Hg above the normal resting level for the subject. In the subjects employed this meant that the systolic blood pressure was maintained at 140 to 160 mm. Hg for the 30 minutes of 80 mm. Hg cuff application.

During the altitude tests each subject rested for 30 minutes before putting on the cuff at 60 mm. Hg for 30 minutes. The temperature of the chamber in which the tests were conducted was uniform. However, no readings of skin temperature were made and it is thought that some of the variations in the results noted may have been due to minor changes in the condition of the skin and deep circulation from day to day as the tests progressed. The same arm was always used for congestion in order to decrease experimental variations.

Bloods were collected with 0.1 ml. of liquid heparin in 10-ml. syringes and immediately set up in duplicate in Wintrobe hematocrit tubes. Duplicate hemoglobins were estimated using the acid hematin technique. R.B.C. volume was obtained by correcting the hematocrit readings by a factor of 8.5 per cent for fluid trapped between the cells (14). Plasma protein concentrations were determined in duplicate using the falling drop technique. Venous oxygen content and saturations together with venous carbon dioxide contents were determined in duplicate by Van Slyke blood gas analysis in a number of the tests using 60 mm. Hg congestion and anoxia and in all those using 80 mm. Hg congestion with adrenalin hypertension.

Anoxia involving 55 to 65 per cent saturation of the arterial blood was obtained by ascent in a decompression chamber to a simulated altitude of 19,000 to 20,000 ft. The subjects were relaxed and dozed in a recumbent posture on a couch. Respiratory rate, blood pressure and pulse were checked every 5 minutes and the oxygen saturation followed throughout by a Millikan compensated oximeter. Contamination of the altitude chamber atmosphere by oxygen was avoided by using an oxygen mask with an exhalation valve which was connected to a tube venting directly into the chamber exhaust. The oxygen saturation, rarely higher than 65 per cent, was maintained at 60 per cent and frequently fell to 55 per cent.

Calculations

The equations used to determine the per cent protein in the filtrate were those developed by Landis *et al* (10). As they have pointed out (10, 11) these equations become less accurate with lower degrees of fluid and protein loss. In order to assess the variability introduced by these calculations of protein in the filtrate, the standard errors of the hematocrit and protein readings were determined. These were found by making repeated measurements of the same sample. They were ± 0.2 per cent for the hematocrits and ± 0.06 gram per cent for the plasma proteins. These values were inserted into the equations and the maximum positive and negative deviations were calculated for each set of experimental data. In Figure 1 such values obtained for each experiment have been plotted against the product of the hematocrit and protein differences, yielding a parameter which indicates in part at least the variability to be anticipated in the protein in the filtrate. If the product $(Ht_2 - Ht_1)(Pr_2 - Pr_1)$ is small, a condition which would be associated either with a low fluid loss and usually small protein leakage or both, then the variability is great. High values show an increased accuracy. Inspection of Figure 1 also reveals a negative bias which is largest at the lowest values of protein change and fluid loss.

In a considerable proportion of the experiments the calculations yield negative values for protein concentration in the filtrate. Such negative values might result from a failure to take account of unrecognised physiological variables. Alternatively, in view of the large random error and more especially of the negative bias introduced by the equation, the values obtained could be the result of the mathematical skewing of the formula with consequent negative bias noted above.

RESULTS

1. Adrenalin hypertension. In Table I are presented the results of 8 cuff experiments on 3

subjects using a cuff at 80 mm. Hg for 30 minutes. There is fair agreement between the mean values for the fluid loss as calculated from the changes in the hematocrit, 13.4 ± 1.7 ml. per 100 ml., and those calculated from the hemoglobin values, *i.e.*, 12.8 ± 1.8 ml. per 100 ml. This suggests that no significant changes in cell volume occur as a result of the stasis induced by the cuff experiment, for such changes would affect only the hematocrit values (10). The marked individual variations from experiment to experiment may be in part attributed to changes in rate of forearm blood flow due to differences in temperature, activity and other variables. Attempts to obtain more reliable figures by using an indwelling needle in the radial artery (15) as a source of the control blood led to no improvement. However, it is of interest that in their original series of 5 experiments using 80 mm. Hg cuff pressure, Landis, *et al* obtained a mean fluid loss figure of 15.0 ml. per 100 ml. This compares favorably with the above values.

In Table II are seen the data obtained from the same number of experiments on the same 3 subjects performed in the same way except that a hypertension of 140 to 160 mm. Hg was maintained throughout the ½-hour period of cuff application. The fluid loss figures show good concordance between the hemoglobin and hematocrit values. The values of 6.0 ± 0.6 and 6.6 ± 0.8 ml. per 100 ml., respectively, are almost exactly ½ those obtained for the normal controls. This is interesting in view of the observation by Allen *et al* (13) that adrenalin administration can double blood flow through the uncongested arm. For if the blood flow rate were doubled and other factors such as tissue pressure remained relatively unchanged then the fluid loss per 100 ml. blood should be decreased in the same proportion.

It might be expected that the A-V O_2 difference would be greatly decreased if such a change in flow rate had occurred. In practice the mean venous oxygen saturation rose from 18.0 per cent to 30.5 per cent. It is of interest that numbness, tingling and eventual loss of sensation to light touch developed in the congested arms in the controls. Such symptoms never occurred at 80 mm. Hg cuff pressure in the cases with adrenalin hypertension. This suggests that the blood flow under these conditions is adequate to maintain normal metabolism but that the reduced flow in the absence of hypertension is insufficient to do so. It may be noted that Griffith, *et al* (16) point out that it is probable that adrenalin has no significant effect on tissue oxygen utilization. Therefore the rise in oxygen saturation following its use is probably not due to a decrease in tissue metabolism.

The change in the average protein percentage in the filtrate from + 0.8 ± 0.5 gram per cent to a mean value of − 1.0 ± 0.3 grams per cent as a result of the use of adrenalin is significant. It is not probable that the percentage of protein in the filtrate would change with changes in the rate of flow of the plasma past the filtering area. It would seem likely that the increase in mean venous oxygen saturation has had some part to play in the decrease in protein in the filtrate. The negative mean value for the protein figures can be explained by the bias of the expression for protein in the filtrate to negative values by the random errors of sampling and estimation. As has been

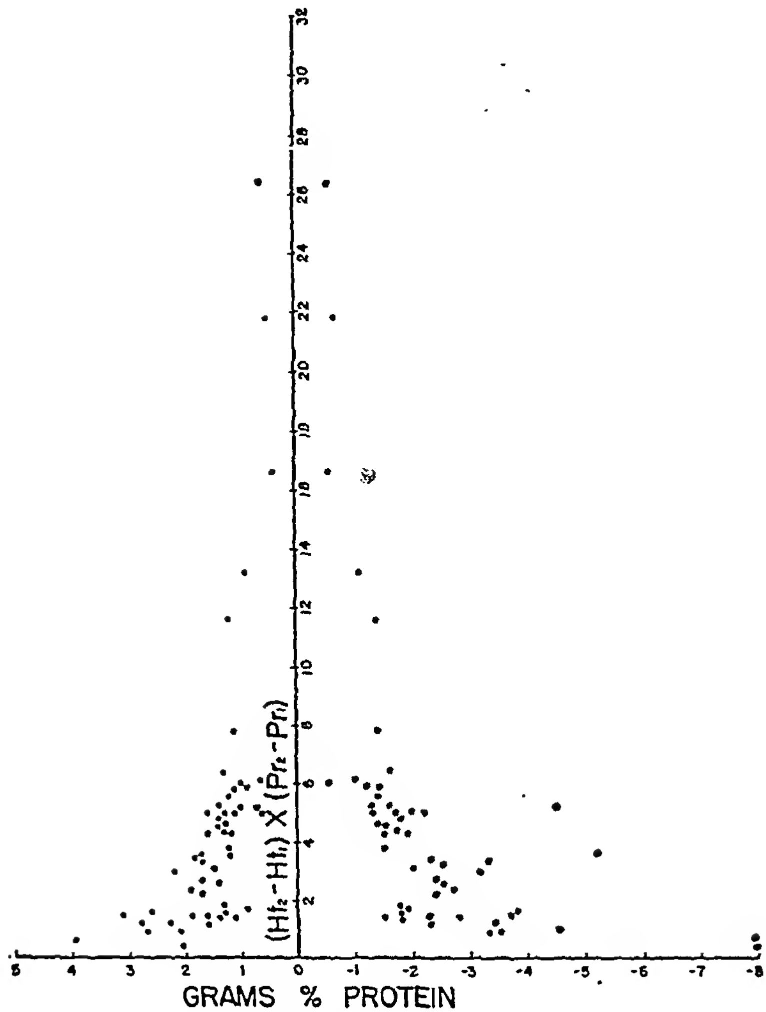

FIG. 1. DEVIATION IN GRAMS PER CENT PROTEIN OF THE PROTEIN IN THE FILTRATE ESTIMATIONS PLOTTED AGAINST THE PRODUCT OF THE CHANGES IN THE HEMATOCRIT ($HT_2 - HT_1$) AND THE PROTEIN VALUES ($PR_2 - PR_1$)

pointed out under calculations (Figure 1) this error is greater in the case of the adrenalin experiments in which the fluid loss is small than in those where these changes are larger, as in the control experiments. It is not certain, however, whether there may not also be some undetermined variable which may account in part for the high negative values found in the adrenalin experiments.

The object of the adrenalin tests was to decrease the ischemic anoxia while keeping the capillary pressure constant. Since the protein in the filtrate decreased under these circumstances the possibility that the high intracapillary pressure was responsible for the increased filtration of protein in the 80 mm. Hg cuff without adrenalin can be considered small. This leaves ischemic anoxia as the most probable factor responsible for the permeability changes.

2. *Anoxia.* In Tables III and IV are presented a series of 23 control, sea level, 60 mm. Hg cuffs on 7 subjects, and 12 altitude experiments using 2 subjects. The mean sea level fluid loss of 7.6 ml. per 100 ml. ± 0.5 ml., as calculated from the hematocrit values, was again close enough to that calculated from the hemoglobins

of 8.2 ml. per 100 ml. ± 1.1 ml. to suggest that there is no significant change in red cell volume during the stasis induced by the cuff.

The mean venous oxygen saturation during the altitude experiments was 26.4 per cent. The arterial oxygen saturation was maintained at 55 to 65 per cent throughout the period of cuff application. The oxygen tension along the entire capillary was therefore much less than its normal value. On the other hand, in the subjects employed, repeated checks of systolic blood pressure during the course of the cuff application at altitude showed no significant change. The absence of a significant change in the mean fluid loss when using anoxia (7.9 ml. per 100 ml. at sea level and 6.3 ml. per 100 ml. at altitude) contrasts with the marked change found in the experiments with adrenalin. It suggests that the pressure in the capillaries and the rate of blood flow through the forearm were not significantly affected during these latter tests. The changes found in the percentage of protein in the filtrate can therefore be attributed to the reduction in oxygen tension of the blood in the vessels. The difference between the mean value of 1.2 ± 0.4 grams per cent obtained during the tests at altitude when contrasted with that of 0.4 ± 0.3 gram per cent for the controls, represents a definite increase in protein in the filtrate as a result of the change in venous oxygen saturation from the mean of 26.4 per cent at sea level to 11.4 per cent at altitude.

In Table V the evidence obtained from the 2 sets of experiments is summarized. When the data from the altitude work are considered in conjunction with the evidence obtained in the adrenalin studies a picture is obtained which suggests that anoxia has some effect upon capillary

Mean protein in filtrate	+0.8 gram per cent		−1.0 gram per cent	
Standard deviation	±0.5 gram per cent		±0.3 gram per cent	
Mean venous O_2 saturation	18.0 per cent		30.5 per cent	

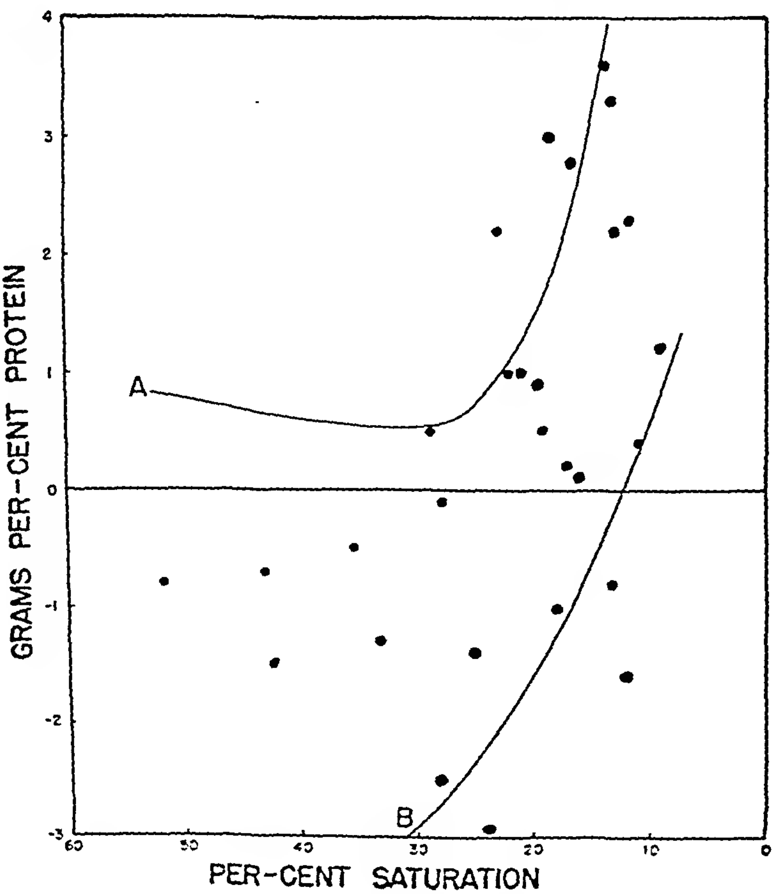

Fig. 2. Per Cent Protein in the Filtrate Plotted against Per Cent Oxygen Saturation of the Venous Blood

permeability in the forearm when the oxygen saturation falls below the general value of 25 per cent.[3]

In Figure 2 the values for protein in the filtrate are plotted against those for oxygen saturation in the venous blood. Inspection reveals a definite upward trend of these protein values at oxygen saturations of less than 25 per cent. Curve A, Figure 2, was obtained by adding to each determination of protein in the filtrate the positive deviations as calculated for Figure 1 and plotting the resulting points. Curve B was plotted in a similar manner using the negative deviations. They have no quantitative significance but represent an attempt to indicate qualitatively the skewing and relative accuracy of the data over the range of venous oxygen saturations considered. The convergence of these curves towards the higher values of protein in the filtrate is an expression of the lower random error at the higher values for protein and fluid loss. The marked negative bias of the error especially in the determinations with higher values of oxygen saturation probably accounts in large measure for those negative values observed . The essential feature portrayed is the increase in the protein in the filtrate with oxygen saturation values of less than 20 to 30 per cent. This is clearly shown on inspection of the data and can be confirmed by the above mathematical considerations.

DISCUSSION

The foregoing results suggest that it is necessary for the oxygen tension in the capillary bed of the human arm to drop to values below 15 to 25 mm. Hg corresponding to an oxygen saturation of 15 to 25 per cent, or an oxygen content of 4 to 6 vols. per cent in those with a normal hemoglobin content, before any significant changes in permeability to protein can be expected. However, if the oxygen tension falls below this value, there is good evidence that the anoxia is then of sufficient severity to increase capillary permeability even when it is of short duration. It is of interest that even during decompensation the oxygen content in blood from the antecubital vein of cardiac patients only rarely falls to such values (17). Nor are such values met in pneumonia except in moribund cases (18). In the cases of emphysema with cardiac failure described by Stead and Warren (8), in which there was no increase in protein in the edema fluid in spite of an arterial saturation of 50 to 60 per cent, the venous oxygen content was not recorded. It is possible that despite the severe anoxic anoxia the venous O_2 saturation was not below the critical level of 15 to 25 per cent. One reason for making this assumption is the fact that such patients often have polycythemia and their blood can therefore yield more oxygen before reaching any particular degree of desaturation than can the blood of those with a normal hemoglobin content.

In severe anemia the reverse of the above-mentioned condition occurs and subjects with hemoglobin concentration values of 20 per cent or less show very low venous oxygen saturation values of the order of 20 per cent (19). Strauss and Fox (20) have pointed out that the tendency to water retention on administration of sodium salts to those with severe anemia was not due to a low plasma protein level or to an increased venous pressure. Although endocrine factors (21) and the effect of changes in renal blood flow (22) must first be considered in assessing the cause of this water retention, it is possible that a part of the edema sometimes noted in severe anemia may be due to increased capillary permeability as a result of anemic anoxia. It is of interest in this connection to note the incidence of edema in cases of *erythroblastosis foetalis* occurring *in utero* (23). For in such cases in addition to the severe anemic anoxia present as a result of red cell destruction there is a considerable anoxic anoxia as a consequence of the incomplete oxygenation of the fetal blood by the placenta.

Aub and Cunningham (24) have shown that in irreversible traumatic shock the venous oxygen content may fall as low as 3 to 4 vols. per cent, representing saturations of the order of 15 to 20 per cent. It is possible that in this condition the venous oxygen tension may be low enough to

[3] Although venous oxygen determinations were not made for all of the 60 mm. cuff experiments (7 of 23 controls and 6 of 12 altitude experiments) the arterial oxygen saturation was reduced by the same amount in all cases. It is therefore assumed that the average venous oxygen saturation of those samples in which this measurement was not made would have been of the same order as the determined values.

result in a generalized increase in capillary permeability. This conclusion would fit with the observations of Fine and Seligman (25, 26). They have noted that following saline therapy in hemorrhagic shock, plasma proteins are carried out of the blood stream with the saline and that this occurs to a greater extent in irreversible than in reversible shock. These authors state their impression that "in irreversible shock the integrity of the capillaries as measured by the passage of radioactive protein may be impaired." Even in their more severe cases the venous oxygen saturation rarely fell as low as 5 vols. per cent and it would seem probable that only in the terminal phases of shock does the capillary oxygen content fall to values of 3 to 4 vols. per cent; that is, to levels where definite evidence of an increase in capillary permeability can be anticipated.

In their studies of the effects of anoxia on lymph production Maurer (5), working with the cervical lymph of dogs, and Warren and Drinker (6), with that from the lungs, both demonstrated a marked increase in lymph flow when the oxygen content in the inspired air was reduced to values of 10 per cent or less. Although they did not make direct estimations of venous oxygen tensions it is possible to interpolate figures from the data supplied by Davies (27) concerning the mean venous oxygen tension during varying degrees of anoxic anoxia. His data suggest that the oxygen saturation of the mixed venous blood in the lungs in their studies was probably not less than 35 per cent except in the cases where the oxygen percentage in the inspired air was considerably less than 10 per cent. Adrenalin secretion may be stimulated by anoxic anoxia of this degree and there is increased lymph production from the cervical lymphatics following the use of adrenalin (28). Although there was an increase in the total amount of lymph protein produced by their dogs, there was a decrease in the concentration of protein in the lymph collected during the anoxic episodes. This decrease is unexpected if the cause of the increased lymph flow is an increase in permeability of the capillary wall. If, however, the increased lymph production is due in large measure to changes in the blood flow through the capillary bed, then the fall in lymph protein concentration can be more readily explained. In those cases where the oxygen content in the inspired air was less than 10 per cent and in which the arterial oxygen saturation fell to less than 50 per cent, it is probable that the oxygen saturation of the mixed venous blood was within the critical range of 15 to 25 per cent necessary for the development of an increased capillary permeability. If our figures, determined from studies using the human forearm, also apply to the pulmonary capillary network, it is probable that in these cases anoxia played a direct part in the increased lymph flow.

Pochin (2) was led to his study of the relation of gross ischemia to edema formation by his observation of edema in a human limb, to which the circulation had been obstructed for 10 hours. It is possible to develop far higher grades of recoverable anoxia in isolated parts of the body such as a limb, ear, or finger, than in the entire organism which includes regions of very great sensitivity to anoxia such as the brain. Consequently, it is to be anticipated that evidence of edema formation as a result of anoxia of the capillary walls would be found in cases where the arterial blood supply to a region was grossly impaired. De Takats (29) has observed the frequent occurrence of edema in conditions such as traumatic angiospasm, acute peripheral trophoneurosis and even in Buerger's disease. He emphasizes that this edema will vanish after sympathectomy or sympathetic paralysis. These procedures do not necessarily relieve any venous obstruction that may be present in such cases. This points to a relief of the anoxia of the capillary wall, resulting from the improved blood flow, as the probable cause of the improvement of the edema. Homans (30) has recently confirmed this opinion that the edema so frequently observed in arterial spasm is due to anoxia of the capillary wall. Oschner and De Bakey (31) in a discussion of the mechanism of development of edema in thrombophlebitis, conclude that it is not solely due to the increase in venous pressure as a result of the obstruction to the venous drainage from the part. They consider that reflex vasospasm of the arteries is a most important factor and that as a result of the vasospasm there is a relative anoxia of the capillary endothelium with an en-

suing increase in permeability. If blocking the sympathetic pathways is effective in relieving arterial spasm, then the blood flow through the part increases, the oxygen saturation in the venous blood rises and at the same time the edema decreases. It would be of interest to know the oxygen saturation of blood draining from the edematous regions before and after sympathetic paralysis in such cases.

It is known that in the liver which largely depends on venous blood for nourishment, the oxygen tension in the blood in the hepatic veins may fall to very low levels. Thus Engel, Harrison, and Long (32) and also McMichael (33) note hepatic venous oxygen saturations in the cat of 3 to 30 per cent during hemorrhage. These low values were often obtained before the blood pressure had fallen significantly below its initial level. Frank, Seligman, and Fine (34) have associated the susceptibility of the liver to damage in shock with this peculiarity of the blood supply. It would be of interest to know what part anoxia of the liver capillaries might play in their known high permeability to protein (10) and whether the effects of anoxia on capillary permeability to protein differ in the different regions of the body. Finally, it may be noted that this work has been carried out with acute anoxia lasting for 30 minutes only. It is not known whether prolonging the duration of the anoxia would significantly raise the critical level of oxygen tension at which capillary damage first occurs. However, the failure of Stead and Warren (8) to observe an increase in protein in the extracellular fluid in their subjects with chronic anoxia would suggest that this does not occur.

The preceding observations indicate that anoxia commences to affect capillary permeability to the point of significant protein leakage at a very low oxygen tension. The result is that it usually requires a combination of one or more of the factors, ischemia, anoxic anoxia, anemia, or a great increase in tissue oxygen consumption, to attain a sufficiently low level. It may be concluded that in states of uncomplicated mild anoxic anoxia there is no reason to anticipate changes in the capillary permeability of the limbs. On the other hand, in conditions such as fatal asphyxia, irreversible shock, and ischemia in which the venous oxygen saturation may fall below the critical level of 15 to 25 per cent a significant increase in permeability probably occurs a few minutes after the commencement of such anoxia.

SUMMARY

1. A number of venous occlusion experiments of 30 minutes' duration were performed with and without anoxic anoxia and with and without adrenalin hypertension.

2. The calculated protein in the capillary filtrate was not increased until the local anoxia was of such a degree that the oxygen saturation in the venous blood draining from the arm was 15 to 25 per cent or less.

3. The experiments with adrenalin hypertension suggested that ischemic anoxia and not the concomitant increase in capillary pressure is responsible for the increased amount of protein found in the filtrate resulting from the use of an arm cuff at a pressure of 80 mm. Hg.

4. In states of mild anoxia there is no reason to anticipate changes in the capillary permeability of the limbs. However, in asphyxia, irreversible shock, and in severe local ischemia or other states in which the venous oxygen saturation may fall below a critical level of 15 to 25 per cent, a significant increase in permeability to protein probably occurs a few minutes after the commencement of such anoxia.

THE HEPATIC BLOOD FLOW AND SPLANCHNIC OXYGEN CONSUMPTION OF MAN—THEIR ESTIMATION FROM UREA PRODUCTION OR BROMSULPHALEIN EXCRETION DURING CATHETERIZATION OF THE HEPATIC VEINS[1]

By J. D. MYERS

(From the Medical Service of Grady Hospital and the Department of Medicine, Emory University School of Medicine, Atlanta)

(Received for publication June 16, 1947)

The hepatic blood flow was first estimated in normal man by Bradley, Ingelfinger, Bradley and Curry (1). Before applying this bromsulphalein procedure to clinical problems, it seemed advisable not only to confirm their measurements but to estimate hepatic blood flow by a fundamentally different method. The urea method for hepatic blood flow, worked out in the dog by Lipscomb and Crandall (2), has been adapted to normal unanesthetized human subjects. The hepatic venous-arterial oxygen difference, total oxygen consumption, and cardiac output have been measured in the same subjects. By multiplying the hepatic vein flow by the hepatic venous-arterial oxygen difference, one obtains an estimate of the splanchnic oxygen consumption.[2] The oxygen consumption and blood flow of the brain and kidney have been estimated by other investigators. Thus, the measurement of oxygen consumption and blood flow of the splanchnic area allows one to construct a fairly complete picture of the degree of oxygen utilization by and the blood flow through the most important areas of the body.

Urea, among the various metabolites involving the liver, has several attributes which adapt it as a test substance for the estimation of liver blood flow. As far as is known, urea is produced in the human organism only by the liver (3, 4) and, once formed, is not converted to other compounds. Urea is very diffusible not only through the various elements of the extracellular fluid but through cell membranes as well. Since the level of urea in arterial blood generally is constant over a period of several hours under conditions of fasting, urea must be lost from the body at the same rate as it is formed, and the total urinary excretion of urea under such conditions approximates hepatic production.

The hepatic blood flow can be calculated, by the "Fick principle," if one knows (*a*) the concentration of urea in the blood entering the liver (hepatic arterial and portal venous bloods), (*b*) the concentration of urea in the blood leaving the liver (hepatic venous blood), and (*c*) the quantitative excretion of urea in the urine during the period when the hepatic blood flow is being measured. Item (*c*) makes the urea method unadapted to the hepatic blood flow over a short period of time; the flow obtained is really the mean liver blood flow for the period of collection of the urine.

Samples of blood from the hepatic artery and portal vein cannot be obtained in man except by surgical means. Peripheral arterial blood has the same urea content as hepatic arterial blood. Bloods from the portal vein and femoral artery have been found to have identical urea contents in dogs (2), and it is reasonable to assume that this same circumstance holds for man. With this assumption, then, one can utilize the blood of the femoral or brachial artery in place of the true inflow blood of the liver for the determination of urea concentration. Blood from the hepatic vein of man can be obtained directly by the process of venous catheterization as described by Warren and Brannon (5).

METHODS

Patients, with the one exception noted, had all fasted 6 hours or longer prior to the test. The entire procedure

[1] This work was supported by a grant from the Life Insurance Medical Research Fund.

[2] The splanchnic area as used in this paper constitutes the liver plus the area drained by the portal vein. The splanchnic blood flow will be equal to the total hepatic blood flow, but the splanchnic oxygen consumption is greater than that of the liver because the oxygen consumption of all of the portal viscera is included.

was performed in an air conditioned room and excessive urea loss by perspiration was avoided. The urine sample was collected in the standing position by having the patient empty his bladder as completely as possible at the beginning and the end of the procedure. The time interval of collection of the urine averaged about 2 hours.

Catheterization of the hepatic veins

With the subject in the supine position on the fluoroscopic table, the catheter was inserted into a superficial arm vein under local procaine anesthesia. It was passed under fluoroscopic control into the superior vena cava, through the right atrium and thence into the hepatic veins (1, 5). A continuous infusion of 0.9 per cent sodium chloride solution was maintained through the catheter. The subject received on the average 200 to 300 ml. of the solution during the entire procedure. In most instances, the catheter entered one of the right hepatic veins. It was introduced so that its tip was located near the center of the right lobe of the liver as visualized by fluoroscopy in the frontal plane. If the catheter was placed farther out along the hepatic veins, it became more difficult to obtain blood samples because the single hole near the tip of the catheter would become occluded intermittently against the wall of the vein. In the larger radicles of the hepatic veins this difficulty is encountered uncommonly. The blood sample is withdrawn gently and necessarily slowly due to the small caliber of the catheter. Under these circumstances, and because of the rapid flow of blood through the hepatic veins, reflux of blood from the inferior vena cava, or right atrium in those cases in which the hepatic veins open directly into that chamber, would appear unlikely if it can occur at all.

Forty-milliliter samples of blood were collected in heparinized syringes from the hepatic vein and femoral artery either simultaneously or within 2 minutes of one another. After a 20- to 30-minute interval, second samples of both hepatic venous and arterial blood were withdrawn. In most instances, a blood sample was taken from the hepatic vein for measurement of oxygen content. The catheter was then partially withdrawn and placed either in the right atrium or preferably in the right ventricle or pulmonary artery. Arterial and mixed venous bloods were taken and a 2-minute sample of expired air collected in a Douglas bag to be used in determination of the cardiac output.

An attempt was made in each patient to assay the amount of anxiety produced in response to the entire procedure.

Determination of urea in blood

Because of the small difference in urea concentration between hepatic venous and femoral arterial blood, the determination of the levels of urea in the 2 bloods must be done with maximum accuracy. The method used was a modification of the urease method of Van Slyke and Cullen (6), which utilizes 20 ml. of blood in each assay, so that relatively large amounts of urea are being measured. Ten-milliliter samples were found to be too small.

Twenty milliliters of whole heparinized blood were pipetted into a 200-ml. volumetric flask and 100 mgm. of urease (Squibb double strength) in 2 ml. of distilled water were added. No additional buffer was used. After allowing the urease to act for 30 minutes, a tungstate filtrate was made from the blood-urease mixture. A 100-ml. aliquot of this filtrate was steam-distilled, using a macro-Kjeldahl distilling apparatus, after the addition of 100 ml. of saturated sodium tetraborate solution. The distillate was caught in an Erlenmeyer flask containing 20 ml. of 4 per cent boric acid solution and methyl red as an indicator, and titrated against 0.01 N sulphuric acid. All determinations were done in duplicate and the results were discarded unless they checked within 0.2 ml. of 0.01 N acid, which is equivalent to 0.06 mgm. of urea in the specimen, or .6 mgm. of urea per 100 ml. of whole blood. Most duplicate determinations checked within 0.1 ml. or less of 0.01 N acid. The accuracy of this method in detecting small differences in urea concentration in human blood was determined by means of recovery experiments. In each experiment, blood from a normal subject was divided into 4 portions of 20 ml. each. A known quantity of urea in aqueous solution, usually 1.0 mgm. per 100 ml. of blood, was added to 2 samples, and an equal amount of distilled water to the other pair. All 4 were then analyzed for urea content by the procedure outlined above. No experiment was considered satisfactory if the variation between the duplicate determinations exceeded 0.2 ml. of 0.01 N acid. The recoveries in 14 such experiments ranged from 79 to 130 per cent with a mean recovery of 102 ± 12.4 per cent. At an urea difference of 1 mgm. per 100 ml., this equals 0.12 mgm. Twice this standard deviation is 0.25 mgm. per 100 ml. This result would indicate, in the comparison of 2 values (such as an arterial and an hepatic venous urea level) each of which may have a deviation of ± 0.25 mgm. per 100 ml., that a difference of less than 0.5 mgm. per 100 ml. cannot be considered significant. The accuracy of the method was further investigated by performing 8 analyses on a single specimen of blood. The values obtained for blood urea concentration, in mgm. per 100 ml., were: 14.2; 13.8; 13.9; 13.9; 13.9; 14.2; 13.9; 14.2. The mean of these results is 14.0 ± 0.17 mgm. per 100 ml.

Determination of urea in urine

A volume of urine approximately equal to 1 minute's output was diluted with 20 ml. of distilled water and the ammonia removed with 3 grams of permutit. A 10-ml. aliquot of this ammonia-free filtrate was treated for 30 minutes with 1 ml. of a 5 per cent solution of urease (Squibb, double strength). A tungstate filtrate was then prepared and a large aliquot, usually 50 ml., was steam-distilled with sodium tetraborate. The procedure from this point on is the same as for blood.

The oxygen content of the mixed venous and arterial bloods was determined by the method of Van Slyke and Neill (7). The oxygen and carbon dioxide contents of the expired air were measured by the method of Haldane.

Experimental procedure for bromsulphalein method

The general conditions of study and the procedure of catheterization were the same as for the urea method. Bromsulphalein in physiological saline was administered as described by Bradley *et al*, using a tunnel clamp (8) and a calibrated Murphy drip. A priming dose of 150 mgm. of bromsulphalein was used. Then an equilibration period of about 30 minutes, with the constant infusion running, is allowed before blood samples are withdrawn. These were then taken simultaneously from the femoral artery and hepatic vein at intervals of approximately 10 minutes.

The bromsulphalein in the serum was determined by means of the Beckman spectrophotometer at a wave length of 580 mμ. As a rule, 1 ml. of serum was diluted with 5 ml. of 0.9 per cent sodium chloride solution and 0.1 ml. of 10 per cent sodium hydroxide added just before reading. All determinations were made in duplicate with identical values usually being obtained.

Plasma volume determinations were done on every patient whose hepatic blood flow was estimated by the bromsulphalein method. The 10-minute Evans blue (T-1824) technique was used. The plasma volume was utilized in calculating the hepatic blood flow in the presence of a rising or falling arterial serum concentration of bromsulphalein (1). No data are included if the bromsulphalein concentration was changing at a rate exceeding 0.0002 mgm. per ml. of serum per minute.

RESULTS

Hepatic blood flow by the urea method

Fairly complete sets of data were collected on 11 males. Six of these had no disease which is known to involve the liver (epilepsy, low back strain, psychoneurosis, herniated intervertebral disc, brachial neuritis, lacerated thumb). Five were fasting for 6 hours or longer; the sixth was studied 2 hours after his usual lunch. The 5 other patients were well convalescent from acute infection (acute bronchitis, gonococcal arthritis, pneu-

mococcal pneumonia—2, and mild typhus fever). The data on both groups of patients are recorded in Table I. There appeared to be no significant differences in the findings on the 5 normal, fasting subjects as compared with the 5 who were convalescent from acute infections. Accordingly, both groups are combined in summarizing results.

The levels of urea in the arterial blood fell between 16.4 and 38.3 mgm. per 100 ml., and the levels in the hepatic venous blood between 17.3 and 39.4 mgm. per 100 ml. Hepatic venous-femoral arterial urea differences ranged from 0.51 to 1.08 mgm. per 100 ml. of blood. The rate of excretion of urea in the urine varied between 9.8 and 15.3 mgm. per minute, for an average of 13.4 mgm. per minute. This has been determined on an additional 8 subjects on whom liver blood flows were not measured. In these individuals, the urinary excretion of urea lay between 12.3 and 20.4 mgm. per minute with an average of 16.2 mgm. per minute. There was no correlation of urinary excretion of urea with the minute volume of urine in the range encountered (0.5 to 5.0 ml. per minute). The 1 subject (W. B.) who was studied 2 hours after a meal demonstrated a rate of urea excretion of 24.3 mgm. per minute.

The total hepatic blood flows for the 10 fasting patients range from 1.0 to 2.7 liters per minute. When calculated per square meter of body surface, the range of flows is 0.5 to 1.6 liters per minute with an average flow of 1.0 liter per minute. The hepatic blood flows comprise from 11 to 35 per cent of the total cardiac output, averaging 22 per cent.

Total oxygen consumptions were measured in 6 patients and ranged from 147 to 216 ml. per minute per square meter of body surface. These values are in general higher than normal basal oxygen consumption, which is not unexpected in view of the fact that the oxygen consumption was determined near the end of a somewhat trying 2-hour procedure. Every effort was made, however, throughout each study to allay anxiety and keep the subject as comfortable as possible.

The arterial-mixed venous oxygen differences ranged from 3.2 to 5.1 volumes per cent, and the arterial-hepatic venous oxygen differences from 3.5 to 5.8 volumes per cent. In 3 instances the arterial-mixed venous oxygen difference exceeded the arterial-hepatic venous difference, and in 4 subjects the situation was the reverse. It must be remembered that the oxygen contents of mixed venous blood and hepatic venous blood were never determined simultaneously. There was in general a 5- to 10-minute delay involved in moving the catheter from the hepatic vein into the right heart and collecting the mixed venous blood specimen. The cardiac indices (outputs per minute per square meter) varied from 3.6 to 4.9. The average value for cardiac index was 4.2 liters per minute per square meter, which is about 30 per cent above normal but which is in keeping with the degree of anxiety which was generally encountered. The splanchnic oxygen consumption varied from 21 to 61 ml. per minute per square meter in the 7 fasting subjects in whom it was measured. These figures average 42 ml. per square meter and equal from 14 to 28 per cent of the total oxygen consumption.

The data for hepatic blood flow, cardiac output, splanchnic oxygen consumption, and total oxygen consumption for the 1 non-fasting subject studied do not vary significantly from the corresponding data for the fasting subjects.

Hepatic blood flow by the bromsulphalein method

The data for the 9 fasting subjects whose hepatic blood flows were estimated by the bromsulphalein method are recorded in Table II. One female subject (J. E.) is included in this group. Six subjects had conditions thought not to involve the liver (brachial neuritis, psychoneurosis—2, latent bronchial asthma, no disease, and asymptomatic neuro-syphilis). The other 3 subjects were well convalescent from mild, acute infections (pneumococcal pneumonia—2, primary atypical pneumonia—1). Since there is no apparent difference in the results on the normal subjects as compared with the convalescents, the 2 groups of data may be combined.

The range of total hepatic blood flows was from 0.6 to 1.2 liters per minute per square meter, averaging 0.8 liter. This represents from 14 to 26 per cent of the cardiac output, or 19 per cent as an average. Two subjects (H. B. and H. F.) had liver blood flow estimated simultaneously by the urea and bromsulphalein methods with values for H. B. of 0.6 liter per minute per square meter by

urea and 0.7 by BSP, and for H. F. of 1.0 by urea and 0.8 by BSP.

Oxygen consumption, which was measured in 7 of the 9 subjects, ranged from 130 to 178 ml. per minute per square meter. The corresponding metabolic rates vary from plus 3 to plus 28 per cent of the normal basal metabolic rate, values again in keeping with the amount of anxiety expected and observed. The arterial-mixed venous oxygen differences in 7 subjects ranged from 3.3 to 4.5 volumes per 100 ml. of blood, and the arterial-hepatic venous oxygen difference from 4.0 to 5.8 volumes per cent. In 6 of the 7 cases the arterial-hepatic venous difference exceeded the arterial-mixed venous difference. The cardiac indices varied from 3.8 to 4.9 liters per minute per square meter, with an average of 4.2 liters. The splanchnic oxygen consumption was determined in 7 subjects and varied from 26 to 56 ml. per minute per square meter with an average of 40 ml. These consumptions represent from 17 to 41 per cent of the total oxygen consumption.

In addition to the 11 subjects whose data for hepatic blood flow by the urea method are included in Table I, the urea procedure was carried out in 3 other individuals. The first of these (W. J. B.) had an hepatic venous-arterial urea difference of only 0.4 mgm. per 100 ml. of blood. This cannot be considered significant in light of the degree of accuracy of the method. A second patient (W. S.) showed the concentration of urea in the femoral arterial blood to be higher, by 0.8 mgm. per 100 ml., than the concentration in the hepatic venous blood. Fluoroscopically, the catheter appeared to be in the hepatic veins but the observer could have been mistaken. The third subject (H. H.) also demonstrated lower levels of urea in the hepatic venous blood than in arterial blood. The difference between the first arterial and hepatic venous samples was 0.4 mgm. per 100 ml.—not a significant difference. The second arterial and hepatic venous samples showed a urea difference of 1.05 mgm. per 100 ml. This hepatic venous sample was obtained with considerable difficulty due to

partial occlusion of the catheter by blood clot. A few minutes later, the catheter was completely thrombosed. This situation may have interfered with the clearing of the catheter of saline before the blood specimen was taken and thus resulted in dilution of the sample with the residual saline in the line. These 3 subjects had urinary urea excretions of 13.9, 12.3, and 19.3 mgm. per minute, respectively. Two of these subjects (W. J. B. and H. H.) had simultaneous determinations of liver blood flow by bromsulphalein with values of 1.0 and 1.2 liters per minute per square meter.

Two of the subjects (H. B. and C. S.) who are included in Table I showed, over time periods of 34 and 10 minutes, respectively, corresponding falls in arterial and hepatic venous urea concentrations with maintenance of essentially constant hepatic venous-arterial urea differences. In H. B. the arterial urea level fell from 16.4 to 15.6 mgm. per 100 ml. while the hepatic venous level changed from 17.3 to 16.5 mgm. per 100 ml. Thus, the hepatic venous-arterial urea difference remained constant at 0.9 mgm. per 100 ml. C. S. showed a fall in arterial urea concentration from 27.6 to 27.1 mgm. per 100 ml.; at the same time the hepatic venous concentration fell from 28.5 to 27.8 mgm. per 100 ml. The corresponding urea differences are 0.9 and 0.7 mgm. per 100 ml. It would not seem likely that the corresponding falls in arterial and hepatic venous urea concentrations were due to temporary dilution of the blood volume by the saline infusion through the catheter. In all other subjects the 2 arterial blood urea levels were identical, within the limits of error of the method.

DISCUSSION

The estimation of hepatic blood flow by the urea method has several disadvantages. The hepatic venous-arterial urea difference is small and requires a meticulous technique for its determination. Even so, small technical errors greatly influence the calculated hepatic blood flow. Because urea is so diffusible throughout the body fluids, *i.e.*, throughout a volume of water equal to approximately ⅔ of the body weight, the retention of a considerable proportion of the urea produced by the liver over a short period of time could occur without a significant rise in urea concentration in the arterial blood. Under such conditions, the urinary excretion of urea would not quantitatively represent urea production by the liver. Hepatic production and renal excretion of urea are probably at or close to equilibrium, however, under the resting and fasting conditions of this study. Kidney function may be affected by such factors as pain and anxiety, which were present in small to moderate degree during the test. The collection of the urine, for determination of urea output, over a period of 2 hours or longer would seem to reduce any effect of pain or anxiety on urea excretion.

The bromsulphalein method gives reproducible results as our average value for hepatic blood flow, 0.8 liter per minute per square meter, agrees closely with that of Bradley *et al* of 0.9 liter (1). The bromsulphalein method, however, involves several assumptions: (*a*) that bromsulphalein is removed from the blood stream only by the liver, (*b*) that the concentration of bromsulphalein in the portal vein is the same as that in peripheral systemic arterial or venous blood, (*c*) that the percentage of dye extracted by the portion of the liver which is catheterized represents the extraction percentage for the liver as a whole, and (*d*) that bromsulphalein and/or catheterization of the hepatic veins do not in themselves alter liver blood flow. Those assumptions which are inherent to catheterization of an hepatic vein are involved in the urea method as well.

One must conclude that the urea method is not only technically more difficult but probably considerably less accurate in estimating hepatic blood flow than is the bromsulphalein method. The urea procedure has served a useful purpose in demonstrating that the fundamental assumptions utilized in the dye method are probably correct because similar values for hepatic blood flow can be obtained by an entirely different method. We now feel safer in applying the bromsulphalein method to physiological and clinical problems.

If the values for hepatic blood flow and splanchnic oxygen consumption by both methods are combined, the average hepatic blood flow, 0.9 liter per minute per square meter, is 20 per cent of the cardiac output, and the average splanchnic oxygen consumption of 41 ml. per minute per square meter equals 25 per cent of the total oxygen con-

TABLE III

Comparison of approximate values for blood flow, arterio-venous oxygen difference, and oxygen consumption of brain, kidney and liver of man

	Visceral blood flow		Arterio-venous oxygen difference		Visceral oxygen consumption		Visceral blood flow as percentage of cardiac output		Visceral oxygen consumption as percentage of total oxygen consumption	
	Range	Av.	Range	Av.	Range	Av.	Range	Av.	Range	Av.
	ml. per 100 grams of tissue per minute		*vol. per cent*		*ml. per 100 grams of tissue per minute*					
Brain	59–75	66	5.7–7.2	6.5	3.9–4.9	4.4	18–21	20	20–30	24
Kidney	240–510	330	1.9–2.5	2.2	4.1–9.9	8.2		20		12
Liver (plus viscera drained by portal vein)										
(*a*) Urea method	58–185	117	3.5–5.8	4.6	2.4–7.0	5.3	11–35	22	14–37	24
(*b*) BSP method	69–138	92	4.0–5.8	4.9	3.0–6.5	4.6	14–26	19	17–41	25

The average body size is assumed to be 1.73 square meters and average visceral weights to be: brain, 1400 grams; kidneys, 170 grams each; and liver, 1500 grams. Data for the brain are from Kety and Schmidt (10), and for the kidney from Warren *et al* (11), Chasis *et al* (12), and Bradley and Halperin (13).

sumption. Both the hepatic blood flow and the splanchnic oxygen consumption vary over a wide range from person to person. These variations are not appreciably decreased by relating the values to the surface area of the subject. The splanchnic oxygen consumption was not closely correlated with the total oxygen consumption and only poorly with the hepatic venous-arterial oxygen difference. Both the total oxygen consumption and the cardiac index were somewhat higher than normal in a number of these subjects due, it is thought, to anxiety. It remains to be determined whether more consistent figures can be obtained by studying larger groups of more basal subjects or by studying all subjects after a procedure which will increase the work of the liver and tend to nullify the effects of anxiety. In the study of the cardiac output in the average patient the second technique has been the more useful; the spread in the resting values is considerably reduced by light exercise (9).

The liver is compared, in Table III, with the brain and kidney as to approximate blood flow, arterio-venous oxygen difference and oxygen consumption. The oxygen values recorded for the liver, of course, do not represent oxygen absorbed and utilized only by that viscus, but oxygen metabolized by all the viscera drained by the portal vein as well. The liver and its associated viscera lie between the brain and the kidneys in respect to blood flow per 100 grams of tissue and percentage of oxygen extracted from the arterial blood. The brain has a relatively low blood flow and higher arterio-venous oxygen difference; the kidneys have a very high blood flow but a low A-V difference. The liver and brain are about equal in oxygen consumption per 100 grams of tissue; the kidneys have a considerably higher consumption. Each viscus receives around 20 per cent of the resting cardiac output. Together, these viscera account for about 60 per cent of both the cardiac output and the total oxygen consumption of the body at rest.

SUMMARY AND CONCLUSIONS

1. The hepatic blood flow has been estimated utilizing the Fick principle with urea as the test substance.

2. The hepatic blood flow in 10 normal or convalescent subjects ranged from 0.5 to 1.6 liters per minute per square meter with a mean of 1.0 liter. Hepatic blood flow was estimated on 9 similar subjects by the bromsulphalein method with a range of flows from 0.6 to 1.2 liters per minute per square meter and an average of 0.8 liter. These hepatic blood flows by the 2 methods comprise 22 per cent and 19 per cent, respectively, of the average cardiac outputs.

3. Arterial-hepatic venous oxygen differences, determined at the same time as the hepatic blood flows, provided estimation of the splanchnic oxygen consumption. By the urea method, this ranged from 21 to 61 ml. of oxygen consumed per

minute per square meter with an average of 42 ml. By the bromsulphalein method, the splanchnic oxygen consumption varied between 26 and 56 ml. per minute per square meter and averaged 40 ml. These averages make up 24 per cent (for the urea method) and 26 per cent (for the bromsulphalein method) of the total oxygen consumption.

4. Because of the small difference in urea concentration between arterial blood and hepatic venous blood, a meticulous technique is required for the urea method, and small technical errors make large variations in the calculated hepatic blood flow. These disadvantages render the urea procedure less suitable for clinical use than is the bromsulphalein method. The fact that these 2 widely different methods give comparable estimates of hepatic blood flow would indicate that the basic assumptions underlying the bromsulphalein method are valid.

ACKNOWLEDGMENT

The author is indebted to Dr. E. A. Stead, Jr., and to Dr. J. B. Hickam for valuable guidance during this work. Technical assistance was provided by Miss Eloise Cavin, Dr. Shirley H. Cohen, Mrs. Barbara L. Gottlieb, and Miss Mary Norton Maddox.

THE URINARY EXCRETION OF RADIOIODINE IN VARIOUS THYROID STATES

By F. RAYMOND KEATING, JR., MARSCHELLE H. POWER, JOSEPH BERKSON, AND SAMUEL F. HAINES

(From the Divisions of Medicine, Biochemistry, and Biometry and Medical Statistics, Mayo Clinic, Rochester, Minnesota)

(Received for publication June 23, 1947)

Radioiodine and natural iodine are chemically and physiologically identical, providing the former is present in quantities so small as to be without biologic effects due to radiation *per se*. A minute quantity of radioiodine may be used to trace, by its radioactivity, the course of a given quantity of iodine through various chemical and biologic reactions. Hertz (1, 2) was the first to call attention to the unique possibilities of this method in the study of thyroid function. Hamilton and Soley (12) were the first to apply it to the clinical investigation of the human thyroid. Radioiodine tracers have subsequently been utilized in many studies dealing with the thyroid of laboratory animals, *in vitro* experiments and clinical investigations. The method has been applied to the study of the biosynthesis of thyroid hormone (1, 3 to 9), the action of thyrotrophic hormones (4, 10), the action of goitrogens (5, 11) and of other factors influencing the function of the thyroid (6), the functional activity of various thyroid tumors and a number of other problems.

It is possible that radioiodine may prove most useful in the study of thyroid function in man. To date, relatively few definitive clinical studies employing this technique have been published. The first was that of Hamilton and Soley (12), who compared the collection by the thyroid of iodine labeled with radioiodine and its excretion in the urine and feces in normal subjects and in patients having various thyroid disorders. Radioiodine in the thyroid was measured directly by the recording of its gamma radiation by means of a Geiger-Müller counter placed over the trachea and in some instances by analysis of surgically removed specimens of thyroid tissue. It was found that an orally administered dose of labeled iodine was absorbed very rapidly and could be detected in the thyroid within 20 minutes. Normal subjects excreted 74 to 89 per cent of the dose in the urine during a period of 5 days, 53 to 81 per cent appearing during the first 24 hours. Two myxedematous patients excreted 91 and 94 per cent, respectively, in the urine during 5 days but at a slower rate than did the normals. Patients who had hyperthyroidism excreted as much in the urine as did the normals. This finding may have been due to the fact that most of the patients had received strong solution of iodine (Lugol's solution) and in part to the very large amount of iodide (14 mgm.) which was administered as a labeled dose. Fecal excretion was variable but averaged only about 1 per cent of the dose.

In another series of *in vivo* measurements employing the same dose of iodide, Hamilton and Soley (13) recorded characteristic collection curves for various thyroid states. The curve typical of normal thyroids was a smooth curve which leveled off to a flat plateau in 2 days. Iodine collection by thyroids of hyperthyroid patients was greater and much more rapid than in normal thyroids. It rose to a peak within 4 to 8 hours and thereafter decreased almost as rapidly to a plateau lower than that of the normal thyroids. This curious phenomenon was also observed in 2 children who had goiters and hypothyroidism. When a dose of 0.1 microgram of sodium iodide was given instead of 14 mgm. such rapid loss of radioiodine from the thyroid was not observed (14).

Hertz, Roberts and Salter (3) studied 22 patients who had exophthalmic goiter and compared these with 2 normal subjects. The quantity of radioactivity was measured in the urine; that in the thyroid was measured *in situ* by applying a Geiger-Müller counter to the neck. Thyroid tissue was obtained in some cases following thyroidectomy. This was fractionated into diiodotyrosine-like and thyroxine-like fractions, which were also analyzed for radioactivity. The collection by thyroids in untreated exophthalmic goiter averaged

80 per cent if the accompanying dose of sodium iodide was small; when the latter exceeded 2 mgm. the uptake of radioiodine was smaller. Previous treatment with iodine reduced the quantity collected. The proportion of radioiodine which appeared in the thyroxine-like faction of thyroid tissue varied directly with the time intervening between the administration of the tracer and thyroidectomy.

Rawson and his associates (15, 16) studied the urinary excretion of radioiodine in a series of patients with various thyroid states. A patient who had a very large hyperplastic goiter resulting from treatment with potassium thiocyanate excreted only 24 per cent of a tracer dose of radioiodine, whereas a patient who had a similar goiter induced by administration of thiouracil excreted all of the tracer dose. The effect of thiouracil was also studied in a series of patients who had exophthalmic goiter and who were prepared for operation with this drug. The major part of the radioiodine appeared in the urine and very little was found to be in the thyroid. In 5 normal subjects, a total of 80 per cent of the dose appeared in the urine. A series of untreated thyrotoxic patients excreted an average of 16 per cent of the dose in the urine.

Leiter, Seidlin, Marinelli and Baumann (8) have studied the behavior of radioiodine tracers in 2 patients who had hyperfunctioning and metastatic thyroid adenocarcinomas. Both subjects excreted radioiodine in a manner comparable to that observed in cases of exophthalmic goiter. In one case thiouracil effectively reduced collection by the thyroid and in the other, in which the thyroid gland had previously been totally ablated, it proved equally effective in preventing collection of radioiodine by the metastatic thyroid tissue (17).

Leblond, Fertman, Puppel and Curtis (7) studied the form in which iodine is stored in the thyroid in cases of goiter. They found that less than 10 per cent of the quantity collected by the thyroid remained in the form of iodide; the rest was converted to diiodotyrosine or thyroxine. Comparable observations had been made earlier by Hamilton and Soley and their associates (14) in 2 cases of goiter with hypothyroidism.

All of the clinical reports which have appeared have dealt with the proportion of a given dose collected by the thyroid or excreted in the urine, or with the chemical form in which it was stored or secreted by the thyroid. No attempt has been made, thus far, to investigate the rates at which collection, excretion or secretion of iodine occurs. The collection curves reported by Hamilton and Soley are an exception in that the characteristic forms of these curves imply important differences in the dynamics involved although the differences noted were not expressed quantitatively.

The present study was undertaken to investigate the dynamics of iodine metabolism by the tracer method, and to determine, if possible, the rate at which radioiodine is collected by the thyroid, disappears from the blood and is excreted in the urine. The study was undertaken in the hope that this approach might provide the tracer method with greater precision when applied to various aspects of thyroid function in man.

The data to be presented concern chiefly the urinary excretion of radioiodine. Subsequent studies will deal with the concentration of radioiodine in blood and its collection and secretion by the thyroid as measured *in vivo*. Urinary measurements possess the disadvantage of not being directly concerned with thyroid function. There are, however, 2 reasons for directing attention first to urinary measurements: 1. The urine is the principal route for the disposal of an ingested dose of iodine in euthyroid or hypothyroid subjects. 2. The analysis of radioiodine in urine is technically much simpler and more accurate than its measurement in blood samples and much more accurate than present methods for measuring radioactivity *in vivo*.

METHODS

Iodine of mass 131 having a half life of 8.0 days was obtained from the Clinton Laboratories, where it had been prepared by the bombardment of metallic tellurium with slow neutrons in the chain-reacting pile. The isotope was supplied in solution as carrier-free iodide, with minute amounts of tellurium, sulfates and oxalates as contaminants. The solution was adjusted to pH 8.0, calcium chloride was added to precipitate oxalate, sodium iodide solution was added as carrier and the volume was adjusted so that 1.0 cc. contained 5.0 micrograms of sodium iodide and represented 500 microcuries as calculated from the stated activity of the sample as received. The usual tracer dose was 100 microcuries of I^{131} with a

total of 100 micrograms of sodium iodide as carrier.[1] In the earlier studies, the tracer doses were given in the morning after breakfast. Later they were given while the subject was fasting because it was found that food appeared to delay absorption appreciably.

Tracers usually were given to patients as outpatients. Instructions regarding the exact collection of specimens of urine were given with great care. They were first reviewed with the patient by the physician, repeated by the technician at the time the tracer was given and emphasized by means of a printed sheet on which the procedure for collection of urine was explicitly prescribed. If after diligent questioning at the time when specimens were returned, an error in collection of specimens was discovered, the data were discarded. In most cases the urine was collected every 6 hours for the first 24 hours and in 24-hour samples thereafter for 2 more days or in some instances for a longer period. In certain cases, especially in those of hyperthyroidism, the collections during the first few hours were made at 1- or 2- hour intervals. With regard to precision of collections of urine, a very satisfactory degree of cooperation has been achieved.

The urine was collected in glass bottles to which had been added sodium hydroxide (3 cc. of 2.5 normal solution) and sodium iodide (1 mgm.) as carrier. The specimens were carefully measured and 0.2 cc. was pipetted by means of a syringe pipette onto a copper planchette. Silver nitrate (0.1 mgm. silver in 0.1 cc.) was added to the drop on the planchette. If the sample was not properly centered on the planchette it was discarded and another was prepared. The specimen was then evaporated to dryness and counted at once with a Victoreen thin mica window beta-ray counter. The number of counts taken varied with the strength of the sample but, whenever possible, sufficient counts were made to keep the counting errors to within 2 to 5 per cent. All counts were made on duplicate samples. When these did not check closely the analysis was repeated on another pair of duplicates. The results were compared with a standard made from the same shipment of I^{131} as the tracer given the patient and were counted in the same manner and at the same time.

MATERIAL

Four groups of patients were studied. Group 1 included 4 normal men varying in age from 30 to 46 years, who served as controls. Group 2 consisted of 10 euthyroid patients who were given tracers because of the presence of papillary adenocarcinoma of the thyroid, graded 1 on a basis of 1 to 4 (Broders' method). So far as thyroid or renal function was concerned, these patients were essentially normal. Group 3 included 6 patients who had myxedema and in whom *in vivo* measurements failed to disclose any measurable collection of radioiodine by the thyroid. In 2 of the 6 cases the myxedema was adequately controlled by administration of desiccated thyroid at the time of this study. The remaining 4 patients were untreated at the time of this study. Group 4 included 16 patients who had uncomplicated, untreated exophthalmic goiter. None of these patients had received iodine before the study.

[1] Measurements made of aliquots of our samples in the laboratory of Dr. R. D. Evans, Massachusetts Intitute of Technology, indicated that the dose used closely approximated 200 microcuries, in terms of the standards of that laboratory. No attempt is made in this paper to discuss the problem of measurements of radioactivity indicated by this divergence of measurements.

RESULTS

Curves showing the cumulative urinary excretion of radioiodine by the subjects in the 4 groups mentioned are shown in Figures 1, 2, 3 and 4, respectively. The rate of excretion in the first 2 groups—the 4 normal men and the 10 euthyroid patients—varies somewhat but the curves are obviously exponential in form and each approaches a plateau in about 48 hours. The shape of the curves is strikingly similar to that of the curves constructed by Hamilton and Soley (13) from data obtained by *in vivo* measurement of radioactivity over normal thyroids after administration of radioiodine.

The rate of excretion of radioiodine by the myxedematous subjects is slower initially than that observed in the first 2 groups but persists much longer. A plateau may not be attained until after 4 days or more. Eventually, however, these subjects excrete in the urine much more of the administered dose of radioiodine than do the normal or euthyroid subjects.

The excretion of radioiodine by the patients who had untreated exophthalmic goiter exhibited a great deal of variation. This may not be surprising, since the severity of hyperthyroidism and the quantity of thyroid tissue present, as well as basal metabolic rates (range + 8 to + 82 per cent), varied greatly. Nevertheless the excretion rates of all but 2 of this group were well below the mean for normal persons. The 3 cases with highest excretion rates in this group are of particular interest because, although their response resembled that of the normals, they represent relatively severe exophthalmic goiter with basal metabolic rates of + 58, + 61 and + 46 per cent, respectively. The diagnosis was confirmed at operation in each instance. The excretion of radioiodine by the remaining subjects in this group was significantly less than in any of the other groups and the

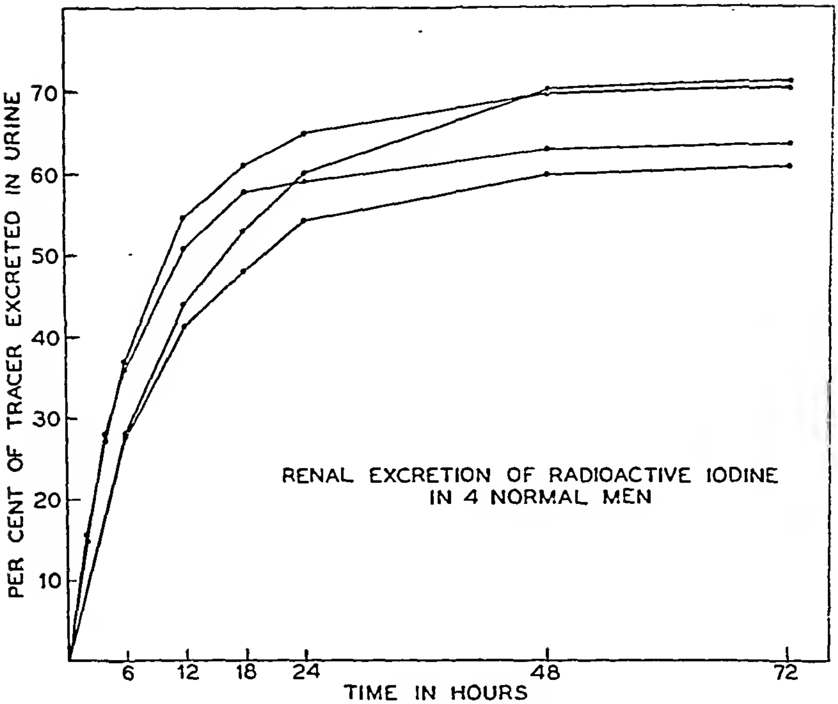

FIG. 1. URINARY EXCRETION OF RADIOIODINE IN 4 NORMAL MEN
The form of the curves suggests an exponential function.

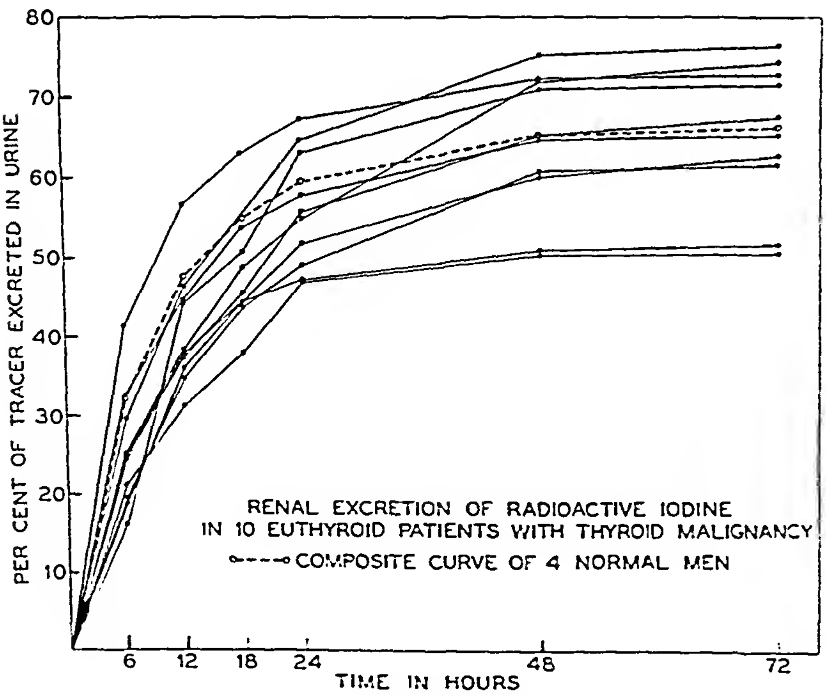

FIG. 2. URINARY EXCRETION OF RADIOIODINE IN 10 EUTHYROID PATIENTS WHO HAD LOW-GRADE THYROID MALIGNANT LESIONS

The composite curve of the normal men is included for comparison. Individual curves vary not only in the plateau which is reached but also in the time required to reach it.

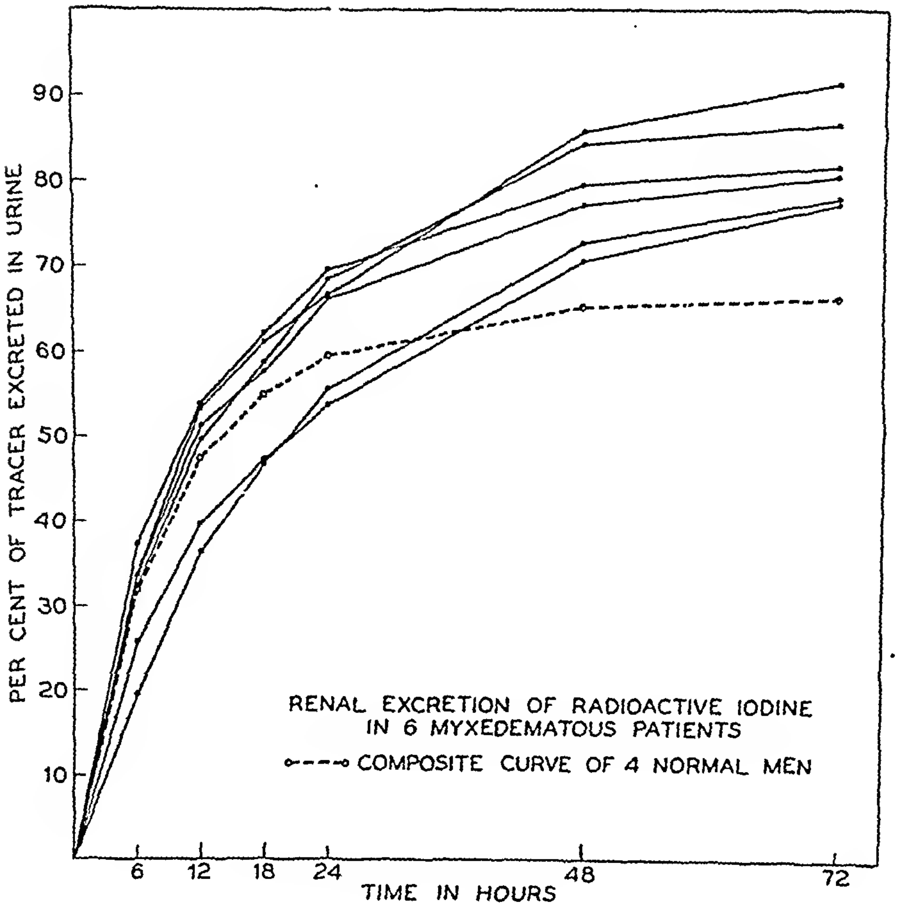

FIG. 3. URINARY EXCRETION OF RADIOIODINE IN 6 PATIENTS WHO HAD MYXEDEMA

The composite curve of the normal men is included for comparison. Not only does more radioiodine appear in the urine in myxedema but a much longer time is required to reach a plateau.

curves describing excretion appear to become asymptotic very quickly, especially in the instances of very low iodine output. Closer inspection of these curves, however, indicates that a real plateau is not reached; instead iodine excretion continues at a slow and relatively constant rate after the rather short initial phase of relatively rapid excretion is completed. In this sense the hyperthyroid curves appear therefore to be diphasic; there is an initial phase which, like that of the normal subjects, appears exponential and a second phase which is linear. As will be pointed out later, this difference from normals is more apparent than real; a linear phase is present in the normal curves also but is not apparent on casual inspection.

ANALYSIS OF DATA

The smoothness of the curves obtained, their exponential character and the variations encountered in the different groups suggested that the differences between them might be expressed quantitatively by mathematical analysis. A series of equations has been found which appears to accomplish this goal adequately.

The urinary curves are quite well represented by the function

$$Q = Q_f \ (1 - e^{-rt})$$

where Q is the amount of radioiodine, expressed as a fraction of the original dose, excreted in the urine in time t; Q_f is the asymptotic amount, that is, the total amount finally excreted, and r is a constant depending on the rate of disappearance of iodine from the blood. The function thus is seen to have 2 parameters which define it: r the rate constant, and Q_f the final value of Q. The value of r can be determined by plotting log $(Q_f - Q)$ against t (or the value of $Q_f - Q$ against t on

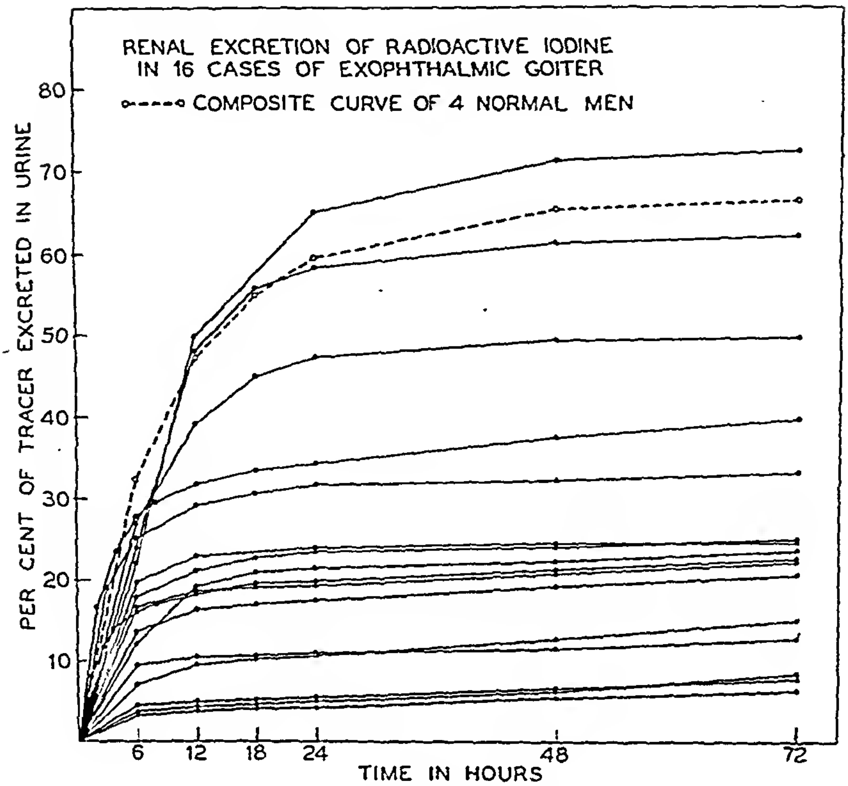

FIG. 4. URINARY EXCRETION OF RADIOIODINE IN 16 CASES OF UNTREATED EXOPHTHALMIC GOITER

The cases varied widely in clinical severity, basal metabolic rates and excretion of radioiodine. Instead of reaching a plateau, a slow and relatively constant excretion of radioiodine persists after the initial period of rapid excretion.

semilogarithmic paper) and determining the slope of the straight line function which results. This necessitates a prior knowledge of Q_f. The value of Q_f is estimated by inspection of the curve of the observed values Q versus t, and adjusted so as to give a linear function for log $(Q_f - Q)$ versus t.[2]

The proportional rate of removal of radioiodine from the blood by the kidneys and appearing as urinary radioiodine, is given by the product of r by Q_f. The value r itself is the proportional rate of disappearance of radioiodine from the blood into all tissues into which it goes. If therefore we assume for simplicity, and as a first approximation, that the iodine of the blood is going only to 2 tissues, the thyroid and the kidneys, the rate of absorption of iodine by the thyroid is given simply by the difference between the total rate and that estimated for the kidneys, that is, $r - rQ_f = r(1 - Q_f)$. This difference actually measures the rate of removal by all tissues together, other than the kidneys, and therefore, in so far as there are other tissues than thyroid involved, it does not give the true thyroid rate. However, inasmuch as variations in the disposal of iodine in the body to tissues other than the kidneys are likely to be due to variations in thyroidal absorption of iodine, the thyroid being the most important of these tissues, it seems reasonable to use the value $r(1 - Q_f)$ as an *index* of the rate of removal of iodine by the thyroid. When the radioiodine curve of the thyroid can be accurately determined by observations obtained from the subject's thyroid directly, the rate of collection by the thyroid can be estimated.

It was noted in the preliminary discussion of the results that the excretion curves of the hyperthyroid group were diphasic and included a sec-

[2] Detailed mathematical development and treatment will be given in a forthcoming publication.

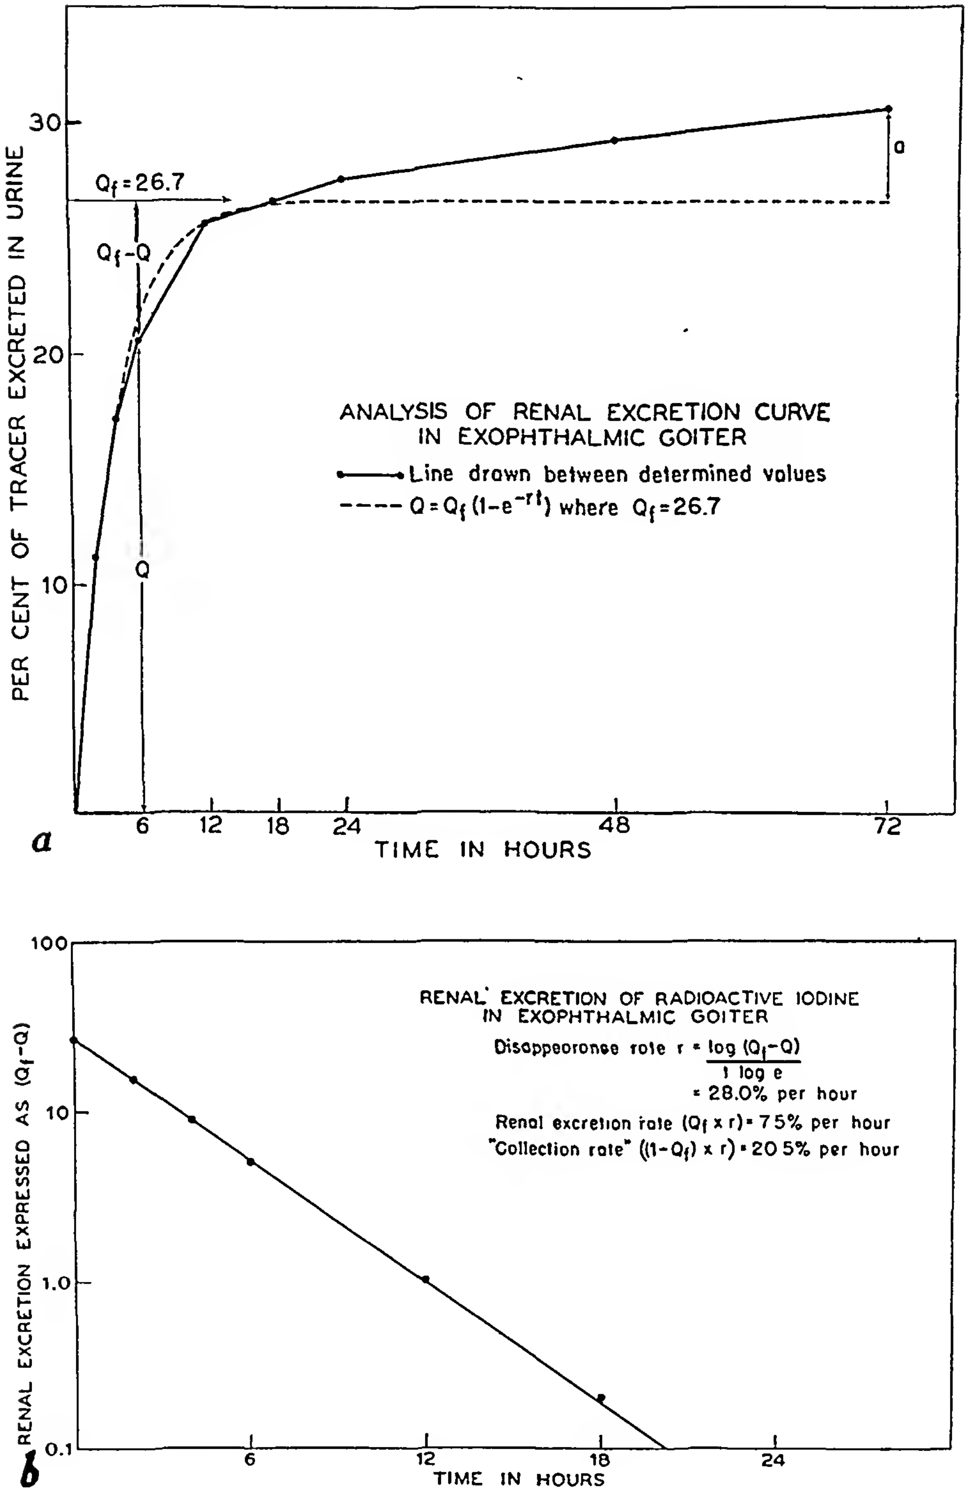

Fig. 7. Analysis of Urinary Excretion in a Case of Exophthalmic Goiter

a. The initial analysis of the curve shows clearly that, instead of a plateau, the initial phase of excretion is followed by a fairly constant or linear phase. When observations on euthyroid subjects are continued long enough, the same phenomenon is encountered. The difference between the actual excretion of radioiodine in 72 hours and that which is predicted from extrapolation of the initial excretion curve is called the quantity a for purposes of reference.

b. The initial renal excretion curve expressed as $Q_f - Q$.

5 or 6 days are required to approach it closely and since the proportion of the dose remaining is very small by that time, it cannot be concluded with certainty that this quantity is not present in these curves. However, it does not appear to be present and its apparent absence may prove both correct and significant.

It is a hypothesis that the excess excretion of radioiodine referred to in the previous paragraph is related indirectly to the secretion of radioiodine previously stored in the thyroid. Preliminary measurements of radioiodine in blood and preliminary *in vivo* measurements make it clear that this excess excretion in urine does *not* reflect *directly* the secretion of stored radioiodine by the thyroid. However, secretion of radioiodine by the thyroid is generally assumed to be largely in the form of organically bound iodine. Perhaps therefore one should not expect an immediate and direct reflection in urinary excretion.

Figure 5a and b shows the analysis of the renal excretion curve for a normal subject; Figure 6a and b, for a myxedematous one, and Figure 7a and b, for a case of exophthalmic goiter. Practically all of the cases studied fit the straight line as closely as the examples given and the fact that the data fit the mathematical assumptions so precisely lends some support to the validity of such treatment.

According to the mathematical analysis which leads to the function presented for the radioiodine curve, the value r, whether determined from the radioiodine curve of the urine or by any other method, measures the proportional rate of disappearance of radioiodine *from the blood*. Accordingly, it should be the same value however determined. Table I shows the results obtained in 4 cases in which a comparison has been made between the value for r determined from urinary data and the same quantity determined directly from blood samples, following the same tracer. The blood samples were drawn at intervals, digested with alkali and analyzed according to a technique which will be described elsewhere. The figures obtained from the 2 sources, blood and urine, agree very well. In Table II are values for disappearance rate, r, determined by 4 methods in a normal subject. The values for r were calculated from serial measurements over the thyroid *in vivo*, serial measurements of peripheral radioactivity over the thigh *in vivo*, serial blood samples and the renal excretion curve. These figures also agree reasonably satisfactorily when one considers that the measurement of radioiodine in blood is somewhat less accurate than in urine and that the *in vivo* measurements, in their present stage of development, are only close approximations.

TABLE I

Rate of disappearance of radioiodine

Case	Diagnosis	Rate of disappearance of radioiodine*	
		Urine	Blood
		per cent per hour	
1	Exophthalmic goiter	27.3	26.4
2	Exophthalmic goiter	32.6	31.4
3	Adenomatous goiter with hyperthyroidism	9.7	12.0
4	Adenomatous goiter with hyperthyroidism	12.9	12.4

* The quantity r, or disappearance rate, determined from urinary excretion curves compared with the rate determined from a series of blood samples obtained during the same period.

TABLE II

Rate of disappearance of radioiodine

Source of calculation	Rate of disappearance*
	per cent per hour
Radioiodine in urine	14.2
Radioiodine in blood	11.6
Radioactivity in thyroid, measured *in vivo*	10.2
Radioactivity in thigh, measured *in vivo*	11.9

* The quantity r, or disappearance rate, determined from 4 types of measurements in a normal subject following administration of a single tracer dose of radioiodine.

In Table III are given the means and standard deviations, for the 4 groups of cases comprising this study, of the following 4 quantities: (*1*) Q_f, which measures the fraction of radioiodine being excreted into the urine; (*2*) r, which measures the proportional rate of disappearance of radioiodine from the blood; (*3*) $r \times Q_f$, which measures the proportional rate of excretion into the urine and which will be referred to as the "renal excretion rate"; (*4*) $r\ (1 - Q_f)$, which measures the proportional rate of absorption by other tissues than the kidneys (thyroid?) and which will be referred to as the "collection rate." In addition, the mean

TABLE III

Summary of quantitative characteristics of renal excretion curves in various thyroid states

Group	Condition	Cases	Renal fraction (Q_f)	Disappearance rate (r)	Renal excretion rate ($r \times Q_f$)	Collection rate $r(1 - Q_f)$	Excess excretion in 72 hrs. (a)†
			per cent of dose	*per cent per hour*			*per cent of dose*
1	Normal conditions	4	65.2± 5.0*	11.1±3.6	7.2±2.1	3.9±2.8	1.4±1.4
2	Thyroid tumors (euthyroid)	10	65.1±11.0	8.9±2.1	5.7±1.8	3.2±1.7	0.6±0.5
3	Myxedema	6	84.6± 4.5	6.8±1.8	5.8±1.4	1.0±0.6	0
4	Exophthalmic goiter	16	24.8±22.2	28.9±5.1	5.4±2.0	23.5±8.0	2.4±1.4

* The mean of each group is given together with the standard deviation in order to indicate the relative variation encountered.

† The quantity a, which is also included, indicates the excess excretion of iodine in the urine after 72 hours. This expression does not attempt to define this factor quantitatively.

values of the excess excretion of radioiodine in urine, the quantity a, are included. The latter is expressed as the total excess after 72 hours. This is an admittedly inadequate means of expressing this quantity but it may serve until further study establishes its quantitative significance. The values as shown indicate the relative magnitude of the excess in the 4 groups of patients.

The variations in the renal fraction among the 4 groups of cases are what one would expect from inspection of the original excretion curves (Figures 1 to 4, inclusive). The normals excreted an average of 65 per cent, the myxedematous patients conspicuously larger fractions and the hyperthyroid patients conspicuously smaller and more variable quantities.

The values for disappearance rate, r, show larger differences than do the renal fractions. The values for hypothyroid subjects are significantly lower than for the normals and the values for hyperthyroid subjects are more than 2½ times as high as those for the normals.

The renal excretion rates ($r \times Q_f$) vary considerably from patient to patient and the variations are of sufficient order to account for some of the variations of iodine collection which are observed. However, no significant difference exists in the mean renal excretion rates of the 4 groups and all show approximately the same degree of individual variation. One might expect to find reduced renal excretion of significant degree in hypothyroidism. This point will have to be settled by study of a larger series of untreated patients.

The most striking differences are found in the values for collection rates, r $(1 - Q_f)$. The hypothyroid subjects show, as one would expect, exceedingly low collection rates, 0.6 to 1.6 per cent per hour. What proportion of this represents loss in feces and sweat, what proportion errors in the method, and what proportion actual collection by the thyroid or peripheral tissues it is impossible to say. The very high collection rates found in the cases of exophthalmic goiter may be regarded as due to variations of thyroid function, even though thyroid function is not here being measured directly. The mean collection rates in exophthalmic goiter were 6 times the normal rates whereas the renal fractions as such were less than half the normal values.

COMMENT

It is reasonable to assume that substantially all, if not quite all, of the radioiodine given as a tracer is either excreted in the urine or collected by the thyroid. The fraction of the total amount of iodine disappearing from the blood which is collected by the thyroid is therefore a relative quantity, depending on the function of the kidneys as well as the function of the thyroid itself. Even if the thyroid function with respect to iodine collection remains quite constant, a variation in function of the kidneys (or other iodine-collecting tissue) with respect to iodine collection will alter the picture of collection of iodine by the thyroid. Thus, if the function of the kidneys is altered so that the renal collection rate is lowered, the amount of iodine collected in any given time by the thyroid will increase, as will also the total amount of iodine eventually collected by the thyroid.

The following hypothetical case will illustrate

this point: If the thyroid-collecting rate was 3 per cent per hour and the renal excretion rate 5 per cent, the thyroid would collect in the first 24 hours 32 per cent of the original dose and asymptotically it would collect 37.5 per cent of the dose. If now the thyroid rate remained at 3 per cent but the renal excretion rate was reduced to 1 per cent, the thyroid would collect in the first 24 hours 46.1 per cent of the original dose and asymptotically 75.0 per cent. Attention only to the amounts of iodine collected by the thyroid might therefore easily give the impression that the thyroid function had been altered. Use of the formulae presented earlier in this paper would avoid this erroneous conclusion, for what remains constant in the situation of unaltered thyroid function is the product of r and Q_f, which for the situation before the alteration of the renal function would be $0.375 \times 0.08 = 0.03$ and after the alteration of the renal function would still be $0.75 \times 0.04 = 0.03$. The method of study which has been described suggests a means for determining the capacity of the kidneys to excrete iodine without regard to thyroid function and of the thyroid to collect iodine without regard to variations of renal function.

Tracers are ordinarily considered as labeling a specific quantity of iodine so as to make its behavior distinct from that of the material with which it is mixed. It is also true, however, that once a radioiodine tracer is mixed with the circulating *iodide* of the blood (either after complete absorption of an oral dose or after intravenous administration) it may be regarded as a label temporarily, not only of the tracer dose, but also of all of the *iodide* in circulation in the blood and in the body fluids which are in osmotic equilibrium with the blood. In this sense whatever happens to the tracer is a valid quantitative measure of what is happening to the circulating iodide, since the two behave identically. The quantities which have been proposed, therefore, express the percentage of the total circulating blood iodide which is being excreted or otherwise disposed of, as well as the percentage of the tracer which is disappearing. This does not necessarily imply that the circulating iodide in the blood is constant in amount. It merely implies that whatever the range of variation of circulating *iodide* in blood at the time of observation, the renal excretion rate and the collection rate (expressed as a percentage of the total quantity) are relatively constant quantities.

The radioiodine tracers which have been studied previously, as well as those described in the present study, have all been given orally. This raises the question whether the time required for absorption affects the results significantly. Preliminary observations suggest that absorption time has not been a critical factor in the majority of instances. However, a comparative study of intravenous versus oral tracers is in progress in order to elucidate this point more fully.

Hamilton, (18), in an early paper, described the remarkable speed with which an oral dose of radioiodine appeared in the blood. Using a Geiger-Müller counter over the hand as an indicator, he found the absorption was 80 per cent complete in an hour. In some preliminary studies we have found that in both normal and hyperthyroid subjects, absorption may be complete in an hour or less. Because the absorption from the gastro-intestinal tract is complete within such a short period it appears reasonable at the moment to assume that, in most instances, only a small error will result from ignoring it. There is some suggestion that the presence of food in the stomach may somewhat prolong absorption of radioiodine and on this account we have made it a practice to give tracers to patients in the fasting state.

It is obvious that sooner or later the iodine collected and stored in the thyroid is likely to be secreted from the gland. If one excepts the observations made by Hamilton and Soley and their associates (14) of the behavior of very large doses of labeled iodide in toxic goiters and in hypothyroid children with goiter, subsequent secretion of radioiodine by the thyroid appears to occur much more slowly than its initial collection. So long as it takes place relatively slowly, thyroidal secretion will not modify the exponential character of the initial collection or excretion curves until either is approaching an asymptotic level. Studies of the quantitative character of the subsequent secretion of radioiodine by the thyroid may as a matter of fact prove far more significant than collection studies. However, because of artefacts resulting from the quantity of radiation in the

tracer, they may be subject to more uncertainty than are the studies of collection rates.

The quantity of radiation employed in all tracer studies which have so far been reported substantially exceeds in the thyroid the arbitrary tolerance dose of 0.1 roentgen per day which is approved for total body radiation of persons working with radium or roentgen rays. Considering the great concentrating power of the thyroid, doses of I^{131} of the order of 1 or 2 microcuries would have to be used in order to keep the radiation exposure of the thyroid below 0.1 equivalent roentgen per day. Such minute tracers are not practicable with present methods. The radiation dosage in the present study, assuming the dose employed to be 200 microcuries of I^{131}, is of the order of 20 equivalent roentgens per day or a total integrated dose per patient of around 230 equivalent roentgens. No information is available regarding the minimal quantity of radiation per day which is capable of inducing biologic effects in the thyroid either within a few hours or within a period defined by a few half lives of I^{131}. Until this is known the possibility must always be considered that the radiation resulting from tracer doses of the magnitude employed may produce biologic effects which influence the results observed.

Another factor of importance in the evaluation of tracer studies is the quantity of carrier, or inert iodide, which is given with the radioiodine. The comparison by Hamilton and Soley of the difference in response to a 14-mgm. dose of sodium iodide compared with a dose of 0.1 microgram leaves no doubt that the size of the carrier can modify the result obtained. For most purposes it is desirable that the quantity given in a tracer be an insignificant amount or at most a small increment to the iodide already present in the body. We have so far avoided very small tracers (1.0 microgram or less) because of the fear, perhaps unfounded, that excessive losses will occur with such tiny quantities because of adherence to containers and so forth. If one assumes blood iodide to be in osmotic equilibrium with the extracellular fluid, as it probably is, the carrier which we have employed, 100 micrograms, should represent an average increment of the order of 1 microgram of sodium iodide per 100 cc. of plasma. Before it can be said with certainty that this is an increment which does not of itself modify iodine metabolism more detailed studies with varying quantities of carrier will be needed.

SUMMARY

The urinary excretion of radioiodine following its oral administration has been studied in normal subjects, euthyroid patients who had low-grade thyroid malignant lesions, patients who had myxedema and patients who had untreated exophthalmic goiter.

The urinary excretion curves differ significantly among the euthyroid, hypothyroid and hyperthyroid groups. Mathematical analysis of the urinary excretion yields the following 4 quantities: (*1*) the renal fraction (which is the fraction of the dose of radioiodine primarily excreted in the urine); (*2*) the disappearance rate (which is the proportional rate of disappearance of radioiodine from the blood); (*3*) the renal excretion rate (which is the proportional rate of excretion into the urine); and (*4*) the collection rate (which measures the proportional rate of disappearance into other sites than the kidneys). In so far as the thyroid represents the chief site in the body for collecting iodine, the last of these 4 values serves as an index of thyroid-collection rate. When the radioiodine curve of the thyroid can be determined by observations obtained from the subject's thyroid directly, the true rate of collection by the thyroid can be estimated.

Estimations of disappearance rate, based on analysis of renal excretion, have been found to agree fairly closely with estimations of the same quantity based on direct measurements of blood samples, measurements of the thyroid *in vivo* and measurements of peripheral radioactivity *in vivo*.

The renal fraction is greater than normal in hypothyroid patients and is less than normal in hyperthyroid patients. The disappearance rate is less in hypothyroid patients than in normal subjects and is markedly greater than normal in cases of hyperthyroidism. Significant individual variations occur in renal excretion rates but no significant differences were observed in the mean renal excretion rates among the 4 groups of cases studied. The most significant variation observed occurred in the collection rates, which were very much less than normal in the hypothyroid cases,

and averaged 6 times the normal in the hyperthyroid patients.

The significance, the limitations and the possibilities of this technique have been discussed.

STUDIES ON PAIN: DISCRIMINATION OF DIFFERENCES IN INTENSITY OF A PAIN STIMULUS AS A BASIS OF A SCALE OF PAIN INTENSITY

By JAMES D. HARDY, HAROLD G. WOLFF, AND HELEN GOODELL

(From the Russell Sage Institute of Pathology, The New York Hospital, and the Departments of Physiology, Medicine, and Psychiatry, Cornell University Medical College, New York City)

(Received for publication July 9, 1947)

INTRODUCTION

In the century which has elapsed since Weber first pointed out that the ability to discriminate just noticeable differences in 2 stimuli inducing sensation depends upon the magnitude of the stimulus, psychologists and physiologists have made use of this relationship for the study of nearly all types of sensation (1). Pain has not been so studied, perhaps because of the view formerly held that pain was not a sensory entity but was the end-point of over-stimulation of any of the recognized sensory mechanisms of the body (2). Recent evidence, however, makes it appear likely that pain per se is a sensation with specific sensory apparatus in the skin and deeper tissues, and with its own neural pathways and functional properties (3).

Investigation of the Weber ratio ($\Delta I/I$, in which I = intensity) has lead to at least 3 useful formulations about sensations other than pain.

1. The range of effective intensities of the adequate stimulus has been determined. For example, the range of effective stimuli for vision between threshold stimulus and the "dazzle" point is approximately 10 billion fold (4). For warmth sense, this range from threshold to onset of thermal pain is about 2 thousand fold (5).

2. The number of just noticeable differences which the average individual can distinguish in the range of effective stimuli has also been ascertained. Thus, there are approximately 570 barely distinguishable steps for vision in the range of intensity from complete darkness to the dazzle point (6) and about 90 steps between the warmth threshold and the thermal pain threshold (7).

3. It has been suggested that large changes in the numerical value of the Weber ratio are associated with changes in the quality of sensation. As an example may be cited the attempt to correlate the change in $\Delta I/I$ at about 0.02 millilambert with the change from achromatic to chromatic vision (8).

The Weber Law states simply that as the intensity of a stimulus increases, the ability to discriminate differences in intensity of stimulus decreases proportionately. For a stimulus of intensity I, there is a minimum change in intensity, ΔI, which can just barely be detected when added to or subtracted from I. That is, $I \pm \Delta I$ can just be distinguished from I, and ΔI is the "just noticeable difference" (JND) in intensity of stimulus, or the difference limen (dl). Algebraically the Weber Law can be written: $\Delta I/I = C$, in which $\Delta I/I$ is known as the Weber ratio and C is a constant. This relationship has been shown to be valid over limited ranges of stimulus intensity for vision, hearing, and temperature sensation (7). It was Fechner who suggested that the constant in the equation could be interpreted as proportional to the minimal difference in sensation (ΔS) and that:

$C = K\Delta S$, in which K is a proportionality factor and ΔS is the just noticeable difference in sensation.

Therefore, $\Delta I/I = K\Delta S$, or upon integration,

$S = K \log I/I_0$, where: S = intensity of sensation evoked by the stimulus of intensity I, I_0 = threshold stimulus intensity.

The importance of this conception lies mainly in the fact that it has afforded another quantitative approach to the study of sensations. It is the purpose of this communication to present the results of measurements of the Weber ratio for cutaneous pain sensation, and to suggest the usefulness of these measurements as a basis for the evaluation of the intensity of pain sensation.

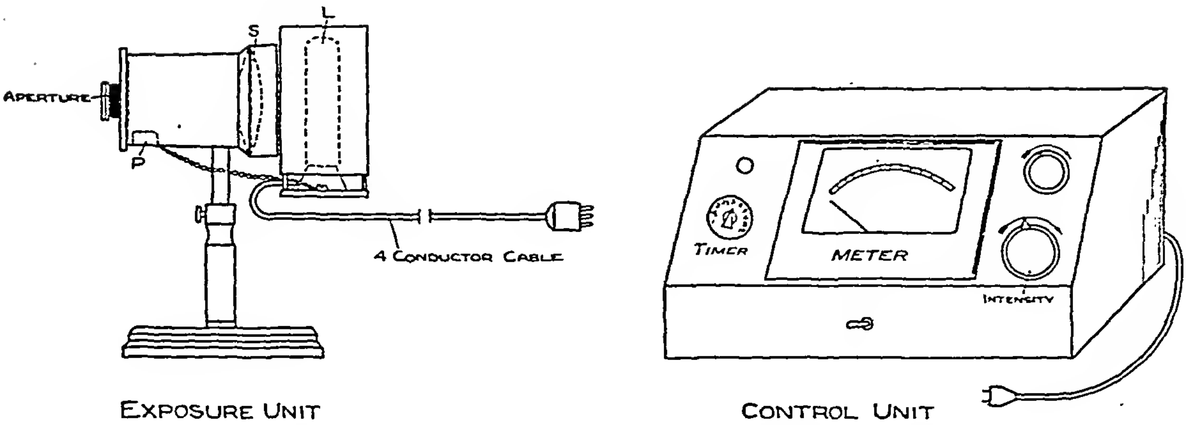

FIG. 1. SCHEMATIC DRAWING OF THE SIMPLIFIED PAIN THRESHOLD EQUIPMENT
L, 500 watt lamp; S, condensing lens of 20 cm. focus; P, shutter relay.

METHOD

The painful sensation which was studied in these experiments was induced in the skin by a 3-second exposure to intense heat radiation. A modified Hardy-Wolff-Goodell pain threshold equipment was employed as the stimulator (5). The apparatus has been altered from that originally described by replacing the rheostat with a variac transformer to alter the intensity of the light beam, and the use of a sensitive voltmeter especially adapted to indicate the intensity of the radiation in millicalories per second per cm.^{2} (0.001 gram cal./sec./cm.^{2}). The reading of the voltmeter was checked from time to time with a calibrated radiometer. This is an essential procedure for an apparatus which depends upon the measurement of electrical input to the heat source. An electronically controlled shutter gave considerable flexibility to the equipment as it was no longer necessary to employ a pendulum to limit the time of exposure. As the changes which have been incorporated give increased flexibility and make possible a greater variety of experiments, a schematic drawing of the simplified apparatus is shown in Figure 1.[1]

The method of measuring the just noticeable differences (ΔI) for the pain induced by heating the skin with radiant energy was as follows: An intensity of radiation (at or [illegible] than the pain threshold) was selected each experimental day as the "standard" for that experiment. The method of choosing the standard was to increase systematically the intensity of the stimulus by approximately the amount of ΔI as determined from the previous experiment. A series of 13 standard stimuli were used, including 220 millicalories (approximately the pain threshold). The 3 authors, serving in turn as subject and observer, were each stimulated with 2 exposures to the standard radiation. The forehead, blackened with India ink, was used as the test surface because of its uniform temperature and because this area had served satisfactorily in the past for pain threshold studies. In the series of experiments with stimuli greater than 500 millical./sec./cm.^{2}, considerable tissue damage was produced. For this reason, a second test area, the blackened volar surface of the forearm, was chosen. This area had the same pain threshold as the forehead and was more easily cared for when blistered. Following exposure to the standard, the subjects were presented, in rotation, with 3 test stimuli. The sensation induced by the standard stimulus was compared from memory with the sensations evoked by the test stimuli and a report made as to whether the test stimuli were equal to, less than, or more than the standard. It required about 10 minutes to present the test stimuli and record the reports, as it was important not to irradiate the skin in too rapid succession. Intervals of less than 1 minute between stimulations were found to introduce uncertainty due to after-sensations. Following the first series of 3 test stimuli, the standard was again presented, the subject being so informed, and a second series of tests begun. This procedure was followed with increasing and decreasing intensities of stimulus until it became evident that ΔI had been ascertained. ΔI was established as the intensity difference which the subject recognized in 2 out of 3 trials.

A high degree of attention on the part of the subject was required to obtain uniform results and, in some instances, the experiment had to be delayed because of the temporary inability of a subject to concentrate sufficiently. Some improvement in discrimination was observed in the subjects as they became accustomed to the experimental procedure. This was apparent mainly in more uniform results with fewer wide variations. The subjects were agreed that this experiment required much more in the way of concentration and attention than did measurements of pain thresholds and, for this reason, conversation and interruptions during an experiment were avoided.

[1] Changes from the original design were made by the Experimental Engineering Corporation, Bergenfield, New Jersey.

RESULTS

The results of the experiment are contained in Table I. Each value of ΔI reported in column 2 of Table I represents an average of 3 or more observations on 3 individuals.

TABLE I

Average values of ΔI and the Weber ratio for pain sensation

Standard stimulus intensities	Average ΔI	Average $\frac{\Delta I}{I}$
	millicalories/second/cm.²	
222	7	.03
240	7	.03
258	8	.03
270	6	.02
291	6	.02
300	11	.04
312	9	.03
330	15	.05
354	19	.06
366	16	.04
390	17	.04
420	29	.07
480	60	.13
680	200	.29
(1100)	(620)	(.56)

In the range of stimuli from threshold to 420 millical./sec./cm.², individual determinations of ΔI usually deviated from the average value by approximately ± 20 per cent. At the higher intensities, because of the damage done to the skin by the intense stimuli, just noticeable differences could not be so carefully ascertained, and a variation of as much as ± 50 per cent resulted.

The relationship between the intensity of the stimulus and the "just noticeable difference" is shown in Figure 2. At threshold, ΔI is approximately 7 millicalories, or ± 3 per cent of the threshold. This value of ΔI corresponds quite well with the observations previously reported on the preciseness with which the threshold can be measured by this method, that is ± 4 per cent. There is no apparent increase in the value of ΔI between the threshold stimulus and 290 millical./sec./cm.², but between this latter intensity and 340 millical./sec./cm.², ΔI more than doubles, attaining the value of 15 millical./sec./cm.². Between 340 and 400 millical./sec./cm.² there is little change in ΔI, but beginning at about this latter intensity, there is a final sharp rise in the ΔI values.

Thus, although 420 and 480 millical./sec./cm.² can be distinguished, 480 and 580 millical./sec./cm.² cannot, and it is not until the stimulus has been increased to 680 millical./sec./cm.² that a barely perceptible difference can be noted. In tests on 5 subjects, 3 subjects reported 680 as more intense than 480 millical./sec./cm.² and 2 subjects reported the sensations as indistinguishable. In 2 experiments, 2 subjects reported pain intensity evoked by 1100 as definitely more intense than that induced by 480 millical./sec./cm.² One subject reported 680 and 1100 millical./sec./cm.² as indistinguishable. Thus discrimination is such for stimuli greater than 680 millical./sec./cm.² that, although it is possible to distinguish these stimuli from 480 millical./sec./cm.², it is not possible to make a distinction between these high stimuli themselves. The sensation evoked by a stimulus of about 680 millical./sec./cm.² is therefore a "ceiling" pain since stimuli of greater intensity cause no perceptibly greater pain. Beyond the ceiling pain, ΔI increases by the amount the intensity of the stimulus is raised above that causing the ceiling pain. For example, ΔI for ceiling pain is − 200 millical./sec./cm.², ΔI for 1100 millical./sec./cm.² is − (200 + 420) millical./sec./cm.², the latter quantity being simply the difference between 1100 millical./sec./cm.² and the ceiling stimulus intensity. In the intensity range above 400 millical./sec./cm.², ΔI is changing so rapidly that the discrimination for higher intensities is considerably less than that for lower intensities. For example, 420 can be distinguished from 390 with a ΔI of 30 millical./sec./cm.² whereas 420 can barely be distinguished from 480 with a ΔI of 60 millical./sec./cm.².

DISCUSSION

a. The stimulus

It is probable that the magnitude of the ΔI and its ratio to the intensity I will depend to a large extent upon the type of stimulus used, and it is to be expected that measurements made with electrical and other types of stimulus will not necessarily correspond with the values reported here. It is desirable that the stimulus chosen be one for which the quantity measured is proportional to the amount of pain producing activity at the pain endings, that is, the algesic action of the stimulus. This is of importance because measurements of

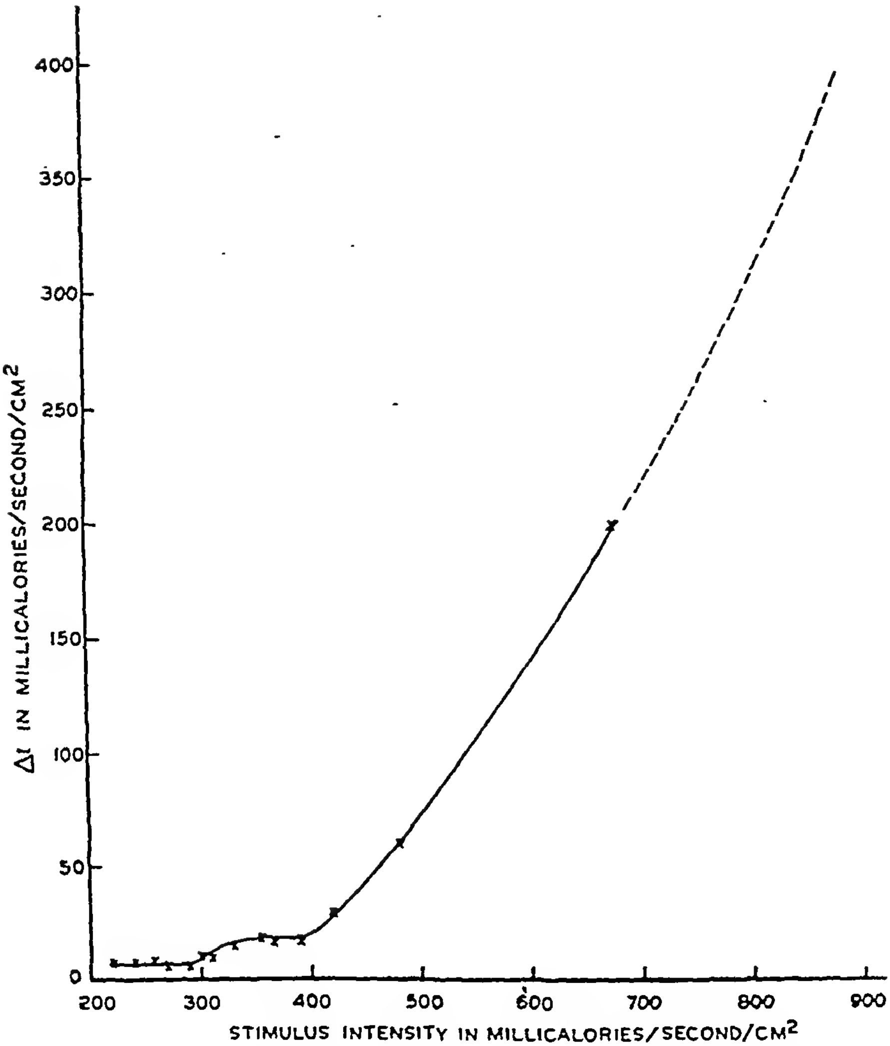

FIG. 2. ΔI FOR INTENSITIES OF THERMAL RADIATION INDUCING CUTANEOUS PAIN

ΔI with an indirect type of stimulus, such as the electrical stimulation of the tooth, may require a different interpretation. For example, the direct electrical stimulation of a nerve fiber subserving pain should yield a series of ΔIs which are dependent upon the condition of the nerve fiber and its electrical relation to the stimulating electrode. In the usual investigations of sensation, attention has been rightly focused on the "adequate" stimulus and, as radiant heat stimuli affect pain endings in a physiological manner, it is likely that thermal radiation is an adequate stimulus for producing pain sensation in the skin. It is apparent from Table I that by means of a suitable stimulus, reproducible measurements can be made of the just noticeable difference of painful stimuli.

The painful sensation caused by the highest stimulus intensities is distinctly different from the pain experienced in the stimulus range below 480 millical./sec./cm.². After the greater stimuli, the subjects reported a deep aching quality as well as the bright burning quality during the 3-second exposure. At the termination of the exposure, the deep aching pain persisted at a high intensity for some seconds as an after-sensation. For the weaker stimuli, the after-sensation had a low intensity burning quality which was generally not observed after a strong stimulus. This difference in the after-sensations may be due to the functional elimination by damage of most of the superficial endings, and to the stimulation of the deeper pain endings. The most intense stimuli

evoke the ceiling pain in about ½ second and the level of pain does not increase during the exposure time, whereas the weaker stimuli evoke sensations which build up during the exposure. This experience supports the idea that stimuli greater than 680 millical./sec./cm.^{2} evoke the "ceiling" pain.

The reproducibility in any given individual of the amount and nature of the damage caused in the skin by the thermal radiation suggests the possible usefulness of this technique in the production of experimental lesions.. For example, on the skin of the volar surface of the forearm, stimuli of 400 to 480 millical./sec./cm.^{2} caused erythema; those of 500 to 700 millical./sec./cm.^{2} caused bleb formation, whereas those of approximately 1000 millical./sec./cm.^{2} caused necrosis without obvious bleb formation except at the margins of the exposed area.

b. The Weber ratio for pain

The value of $\Delta I/I$ is approximately constant in the range of stimuli from threshold to about 320 millical./sec./cm.^{2}, beyond which intensity there is an increase in the Weber ratio. An interpretation of Figure 2 may be made on a basis similar to that for evaluations of the Weber Ratio for stimuli producing other types of sensation. That is, the range of intensities between 220 and 320 millical./sec./cm.^{2} represents the stimulation of a type of cutaneous pain for which $\Delta I/I$ = constant = 0.03. At about 320 millical./sec./cm.^{2} another sensory element may have been added to the total sensory experience. This agrees with the experience that the quality of the pain sensation changes at about this point from a definite pricking sensation to one with an added burning quality. Indeed, this particular sensation has been chosen by 1 investigator as the pain threshold sensation rather than the sensation of minimal pricking pain which begins at about 220 millical./sec./cm.^{2} for a 3-second exposure (9).

c. A scale of pain intensity

That pain has the property of intensity is well recognized. Estimates of the intensity of painful sensations have been made commonly in terms such as severe, moderate or mild, and, in the past, the judgments of the subject have been useful in experimental and clinical procedures. Although it is not possible to say that the sensation induced by a given painful stimulus in one individual will be exactly reproduced, under apparently the same experimental conditions, in another individual, on the basis of the observed predictability of behavior and of report this appears to be quite likely. Also, useful scales have been devised for other sensations, such as the scale of visual brightness and the scale of the loudness of sound (10). Therefore, on the basis of the predictability of sensory phenomena in general, we might expect to set up a sensory scale of pain and, from the data presented in Table I, we have made such an attempt.

The stimulus intensity which gives rise to the threshold sensation marks the lower limit of the range of effective stimuli. The threshold sensation is arbitrarily assigned the value 0, meaning simply the beginning of the sensory scale. A stimulus which induces the ceiling pain determines the upper limit of the scale.

TABLE II
Scale of pain intensity

Stimulus intensity	Size of step	Number of steps	Number of dols	Amount of stimulus above threshold
millicalories/second/cm.^{2}				*millical./sec./cm.^{2}*
220			0	0
227	7	1		
234	7	2	1	14
241	7	3		
248	7	4	2	28
255	7	5		
262	7	6	3	42
269	7	7		
276	7	8	4	56
283	7	9		
290	7	10	5	70
300	10	11		
310	10	12	6	90
320	10	13		
335	15	14	7	115
350	15	15		
365	15	16	8	145
380	15	17		
395	15	18	9	175
425	30	19		
480	55	20	10	265
680	200	21		

From Table II, it can be seen that there are 21 barely perceptible steps between the threshold sensation and the ceiling pain. Except under the best experimental circumstances, it is not possible to distinguish stimuli closer together than 2 steps,

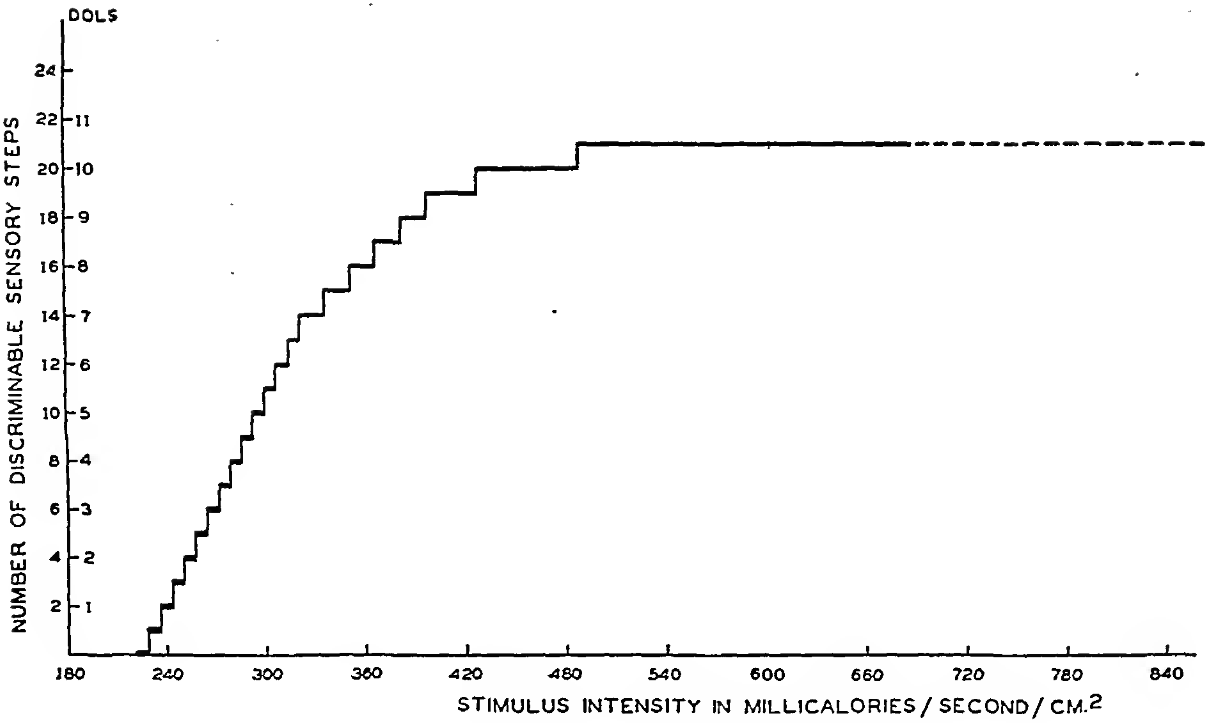

FIG. 3. GRAPHIC REPRESENTATION OF SCALE OF PAIN INTENSITY

and for this practical reason, the unit for pain sensation has been chosen as equivalent to 2 steps. It is suggested that the term "dol" be used to signify this unit. The ceiling pain intensity will therefore have the value of 10½ dols, as there are 21 barely discriminable steps in sensation between the pain threshold and the ceiling pain under our experimental conditions. Fortunately, as the threshold stimulus on the forehead and on the forearm is generally very near 220 millical./sec./cm.^{2}, little correction is required of the scale in Table II when these skin areas are used. A sensory scale of pain, such as that presented in Table II, is in keeping with the assumption of Fechner that the intensity of sensation evoked by a given stimulus is equivalent to the number of the discriminable steps from the threshold sensation. Figure 3 is a graphic representation of the relationship between the stimulus intensity, number of discriminable steps, and the dol scale of pain. The scale as represented in Figure 3 refers, of course, only to skin areas which have a pain threshold at 220 millical./sec./cm.^{2}.

There are 2 advantages in setting up a scale of pain sensation on the basis of the present data, namely: (*1*) the sensory range is clearly defined by the threshold sensation and the maximal possible, or ceiling pain sensation, and (*2*) the intensity of the pain can be related to an easily controlled and reproducible adequate stimulus. The usefulness of such a scale for pain sensation is further indicated by studies which will be reported in detail elsewhere. It permits the quantitative estimation of pain intensity above the pain threshold, for instance, in the study of the nature of hyperalgesia and the effect of local and general analgesics. It also provides a useful reference scale of pain intensity against which can be made quantitative estimates of the intensities of spontaneously occurring pain in disease.

SUMMARY AND CONCLUSION

1. Measurements of just noticeable differences in estimation of painful stimuli have been made with the Hardy-Wolff-Goodell pain threshold equipment by inducing pain in the skin with thermal radiation.

2. The effective range of this stimulus is limited by the pain threshold and pain of maximal intensity.

3. Pain induced in the skin by thermal radiation has a ceiling intensity and this ceiling pain was produced on the forearm by a stimulus intensity of 680 millical./sec./cm.^{2} in a 3-second exposure.

4. The Weber ratio for pain is approximately constant between threshold and about 320 millical./sec./cm.^{2}. An increase in the ratio at this point suggests that an additional sensory entity with a different quality of pain has been stimulated.

5. Twenty-one discriminable intensities of pain were observed between the threshold pain and the ceiling pain.

6. On the basis of the evidence presented above, a scale of pain intensity is proposed, the unit of which is called a "dol," composed of 2 just perceptible steps in discrimination of stimulus intensity.

THE EFFECT OF URINE VOLUME ON UREA EXCRETION

By DONALD D. VAN SLYKE

(From the Hospital of the Rockefeller Institute for Medical Research, New York City)

(Received for publication July 16, 1947)

In recent papers Bing (1) and Williams (2) have proposed formulae which these authors believe to be more accurate than the original "standard" and "maximum" clearance equations of Möller, McIntosh, and Van Slyke (3, 4), in expressing the effects of urine volume flow on the urea clearance in human subjects. Both Bing and Williams base their formulae on the data of Möller *et al* (3).

The essential test of accuracy of such a formula is the consistency with which it permits one to calculate, from clearances shown by a subject with widely varying urine flows, the clearance that he would show with a given constant urine flow. Neither Williams nor Bing has applied such a test. In the present paper it is applied to compare their formulae with the original equations of Möller *et al*, with data from both normal and nephritic subjects. The theoretically derived equation of Dole (5), which was apparently overlooked by both Williams and Bing, is also included in the comparison, and tentative conclusions are drawn concerning permeability changes in the renal tubules in chronic nephritis.

CLEARANCE FORMULAE

Maximum and standard clearance formulae of Austin et al (6), and Möller et al (3). Simultaneous observations of urea excretion rates, urine volumes, and blood urea concentrations made by Austin *et al* (6) and by Möller, *et al* (3) showed that the urea clearance, defined as the volume of blood containing the amount of urea excreted in 1 minute, was but little affected by urine flow changes in normal human subjects when the flow (per 1.73 sq. m. body area) exceeded an "augmentation limit" which was usually about 2 cc. per minute, but that when the urine flow fell below this limit the urea clearance fell with the urine flow, the clearance then becoming proportional approximately to the square root of the flow. Chesley (7, 8) confirmed the square root rule for urine flows down to about 0.35 cc. per minute, but found that when extreme dehydration reduced urine flow below this rate, further reduction in flow was accompanied by a more rapid fall in urea clearance, which then fell in direct proportion to the urine flow, rather than to its square root.

The above empirically observed effects of urine volume on the urea clearance in the 3 respective urine flow ranges are expressed by Equations *1, 2* and *3*, in which C_r represents the clearance calculated as UV/B, for any urine volume flow V (in cc. per minute), and U and B indicate the concentrations of urea in urine and blood respectively.

When V exceeds the augmentation limit of about 2:

1. $$C_r = C_m = \text{constant for each subject.}$$

C_m is the "maximum clearance" of Möller *et al* (3), and averages 75 for normal adults.[1]

When V is between the augmentation limit and 0.5 cc. per minute:

2. $$C_r = C_1 \sqrt{V}.$$

C_1, the clearance when $V = 1$, was called the "standard clearance" by Möller *et al* (3), who found that it averaged 54 for normal adults.

Chesley's formula for maximal urine concentration. When V is less than 0.35 cc. per minute the value of C_r approximates that expressed by Chesley's (7, 8) formula:

3. $$C_r = R_m \times V.$$

R_m is a constant, the maximum U/B ratio attainable by decreasing urine flow to its minimum. The average normal value of R_m is about 75. (In nephritis the value of R_m may fall to 3 or 4 (9) and be reached with urine volumes above 1 cc. per minute [see Table IV].)

Dole's equation. Dole (5) has derived an equation, based on estimation of tubular urea reabsorption in accordance with Fick's diffusion law, which covers the effects of all ranges of urine flow.[2] Dole's equation is:

4. $$C_r = C_m/e^{b/V} = C_m/\text{antilog}_{10}\frac{b'}{V}.$$

---

[1] Correction for body size in any clearance equation is made by using as $V_{corrected}$, the observed V multiplied by the factor, 1.73/(sq. meters body area), in the calculation of C_r as UV/B, and wherever V appears elsewhere in the equation. It has been shown (10) that clearances vary in direct proportion to body area in human subjects above the age of 1 year, and that the correction can be made by applying the factor 1.73/m². to V, 1.73 being taken as the average adult surface area.

[2] Dole expressed his equation as $C_r = F \times \phi \times e^{-k/V}$, where F is the amount of urea filtered per minute, ϕ is the fraction (about 0.60) that escapes reabsorption in the first fraction of the tubular segments, and $e^{-k/V}$ is the part of that fraction that escapes reabsorption in the final tubule and achieves excretion as urine. In terms of the maximal clearance, $C_m = F \times \phi$, and C_r approaches C_m when V becomes so large that $e^{-k/V}$ approaches unity. In Equation *4* we have written C_m in place of $F \times \phi$, and have used b to indicate specifically the constant k in the

C_m, as in Equation *1*, signifies the maximal clearance obtained with large urine volume flow. Dole's equation is based on the assumptions: (*1*) that a constant fraction (normally about 40 per cent) of the urea in the glomerular filtrate diffuses back into the blood from the lumina of the proximal tubules with the "obligatively" reabsorbed water (which is estimated to be about 90 per cent of that filtered); (*2*) that in a second section of the tubule further reabsorption of water, with negligible reabsorption of urea, brings the filtrate to its final volume (the urine volume, V); (*3*) that during passage of a third tubular segment a second fraction of the filtered urea is reabsorbed, without water, into the blood by passive diffusion, this fraction being calculable by Fick's diffusion law from the permeability of the tubular wall of this segment for urea and the final volume of the filtrate. C_m represents the cc. of blood that would be cleared of urea per minute if, of the total urea filtered in the glomeruli the approximately 60 per cent that escapes reabsorption in the proximal tubules were all excreted, while the fraction $1/e^{b/V}$ is the fraction of the 60 per cent that finally attains excretion after part has been reabsorbed in the third segment. The constant, b, is the product of the surface area of the walls of the third segments and their permeability for urea, which Dole estimates to be of the order of 0.001 of the permeability of erythrocytes for urea. The constant b' in Equation *4* is b multiplied by 0.4343 to change from exponent of e to exponent of 10. If b has a high value in a given subject the effect of urine volume change on clearance is high, and vice versa.

We have estimated the approximate mean normal values of C_m and b' of Equation *4* as 80 and 0.17, respectively, from the data on the 6 normal subjects in Table II of Möller *et al* (3). The value, 80, calculated for mean normal C_m of Equation *4*, is higher than the C_m value of 75, estimated by Equation *1* as the mean of clearances observed with urine volumes above an "augmentation limit" of about 2 cc. per minute. The Dole equation assumes that the clearance increases asymptotically to a maximum reached at higher urine output; hence this calculated maximum is greater than the mean observed in the V range above 2 cc.

As Dole points out, individual and pathological variations in b may be expected. However, application of Dole's equation to the normal data of Möller *et al* (3) and to their data from patients with Bright's disease indicates that in both normal and nephritic human subjects one can calculate for each subject fairly constant results for C_m from observed C_v and V values by assuming a value of 0.17 for b' in all the subjects.

factor $e^{-k/V}$. The equation $C_v = F \times \phi \times e^{-k/V}$, with ϕ assumed to be constant, is a simplified form of a more complete equation developed by Dole in which the value of ϕ is expressed as a function of the volume of filtrate escaping "obligative" reabsorption in the first segment. The mean normal value of ϕ is estimated as the ratio, (urea clearance with maximal urine flow):(inulin clearance), which is about 0.60 in normal men. It is usually about the same in nephritis, but may be nearer unity (11).

Williams' formula. Williams (2), from the data of Möller *et al* (3) on normal subjects, evolved the equation: $(U/B)^{1.103}V = K$. This can be transformed into:

$$5. \qquad C_v = C_1 V^{0.093},$$

where C_1, as in Equation *2*, indicates the value of C_v when $V = 1$, C_1 being 54 for the average normal subject.

Bing's formula. Bing (1) believes that the most accurate calculation of C_m can be made by estimating tubular reabsorption of urea, not from V, but from the ratio, U/B, as indicated by Equation *6*, the factor f being a function of U/B that Bing estimated from the data of Möller *et al* (3) on normal subjects. For plotting the curve of f against U/B, Bing gives the following pairs of simultaneous values for U/B and f, respectively: U/B 1 to 20, $f = 1$; 30, 1.15; 40, 1.30; 50, 1.43; 60, 1.54; 70, 1.60; 80, 1.64. With values of f varying from 1 to 1.64 according to U/B, Bing's formula is:

$$6. \qquad C_v = C_m/f.$$

Although Bing introduced his formula to replace V by U/B as a factor determining C_v, it can be shown that Bing's f is in fact a function of V. By plotting the logarithms of U/B against the logarithms of the corresponding f values given by Bing, a straight line is obtained, the equation of which is $f = \left(\frac{U}{20\,B}\right)^{0.37} = 0.33\ (U/B)^{0.37}$, and which gives Bing's f values within ±2 per cent, for values of U/B over 20 (f being 1 when $U/B < 20$). Substituting $0.33\ (U/B)^{0.37}$ for f in Equation *6*, and solving for $C_v = \frac{UV}{B}$ gives, as an expression of Bing's formula applicable when U/B exceeds 20:

$$7. \qquad C_v = 2.24\ C_m^{0.73} V^{0.27}.$$

When C_m has the average normal value of 75, the equation becomes:

$$8. \qquad C_v = 52.4\ V^{0.27}.$$

The value, 52.4, for $V = 1$, approximately agrees with the normal C_1 of 54 found by Möller *et al* (3).

Equation *8* is used in Figure 1 to include Bing's formula in the comparison of the effects of V change calculated by the different formulae for a subject of average normal clearance.

COMPARISON OF RESULTS BY DIFFERENT FORMULAE

Data used. Möller and McIntosh provide data on 6 normal subjects (3), for each of whom 12 to 20 clearances were determined with urine volumes varying over the widest ranges obtainable by varying the fluid intake, and for 6 nephritics with varying degrees of abnormally lowered urea clearance, for each of whom from 9 to 26 clearances were determined with similarly varied urine volume flows. These data are used to compute Tables I to IV. As an

additional normal subject, H. A. from a previous paper (6) is added: H. A. provides 20 clearances with V values well distributed over a wide range.

Procedure for comparison. To compare the relative accuracies with which the different formulae estimate the effect of V or U/B on C_v, values of the maximum clearance, C_m, obtainable by high urine flow for each subject, are calculated by the different formulae from the C_v values obtained with the various observed flows. For each individual the standard percentage deviation is computed of the C_m values calculated by each formula from the mean C_m of the subject calculated by that formula. It is assumed that the most accurate formula will be the one that yields the smallest average percentage deviation from the means.

By any of the formulae except that of Bing, one could calculate C_1 (clearance when $V = 1$) or the clearance at any other V, instead of C_m. Bing's formula (Equation *6*), however, applied as given by its author, serves only for calculation of the maximum clearance as a function of U/B.

The self-evident rearrangements of Equations *1*, *4* and *6* to calculate C_m are indicated in the column headings of Tables I and II.

For calculation of C_m by the square root relation expressed in Equation *2*, the relation is expressed as

$$9. \qquad C_m = C_v \sqrt{\frac{A}{V}},$$

where A is the augmentation limit of V, and is assumed to be a constant. A is taken as the V value at which both Equation *1* and Equation *2* indicate the same C_v value. If the mean normal values of C_m and C_1 *viz.* 75 and 54, are inserted in Equations *1* and *2*, respectively, both equations give the same value for C_v when $V = 1.93$. We have therefore used 1.93 as a constant value for A. Substituting 1.93 for A in Equation *9* gives:

$$10. \qquad C_m = C_v \sqrt{\frac{1.93}{V}} = 1.39\ C_v/\sqrt{V}.$$

Equation *10* is used to compute values for the clearances by the formula of Möller, McIntosh and Van Slyke (3) in Tables I to IV for urine volumes below 1.93 cc. per minute. The assumption of 1.93 as a constant augmentation limit for all the subjects, normal and nephritic, introduces a variable error, since, as shown in the original papers (3, 4), the augmentation limit varies somewhat from subject to subject. The results in Tables I to IV indicate, however, that the error from assumption of a constant value for A is not great in either normal or nephritic subjects. The possible explanation for the apparent fact that the reduction of renal function in nephritis may not greatly affect the augmentation limit will be discussed later.

To estimate C_m by Williams' formula (Equation *5*) we have calculated, from observed C_v values, the clearance for a urine flow of 20 cc. per minute. As shown by Figure 1, Williams' formula for the average normal subject indicates a clearance, when V approaches 20, that approximates the 75 cc. value found by direct observation (3) as the average normal C_m. Also a urine flow of 20 cc. per minute is about the maximum obtainable by water diuresis.

Letting C_{20} indicate the clearance obtained when $V = 20$, we have from Equation *5*, according to Williams:

$$C_{20}:C_v = (20/V)^{0.093} = 1.32\,/\,V^{0.093},$$

whence:

$$11. \qquad C_{20} = 1.32 C_v/V^{0.093}.$$

The C_{20} calculated by Equation *11* is given in tables as the C_m calculated by Williams' formula.

RESULTS OF COMPARISONS

The means and standard deviations of the series of normal subjects of Möller, McIntosh, and Van Slyke (3) are given in Table I, those of their nephritic subjects (4) in Table II. Tables III and IV give the complete data on normal subject H. A., and on the nephritic, Gia, who showed the lowest clearance values of the group in Table II.

The relative accuracies of the different formulae applied to 3 normal subjects are illustrated by Figure 1. The curves are calculated for the hypothetical average normal adult; they represent C_v values calculated by the indicated equations with mean normal values for their constants. Subject H. A. is a normal man whose constants closely approximate these values. The points for very low urine volumes are taken

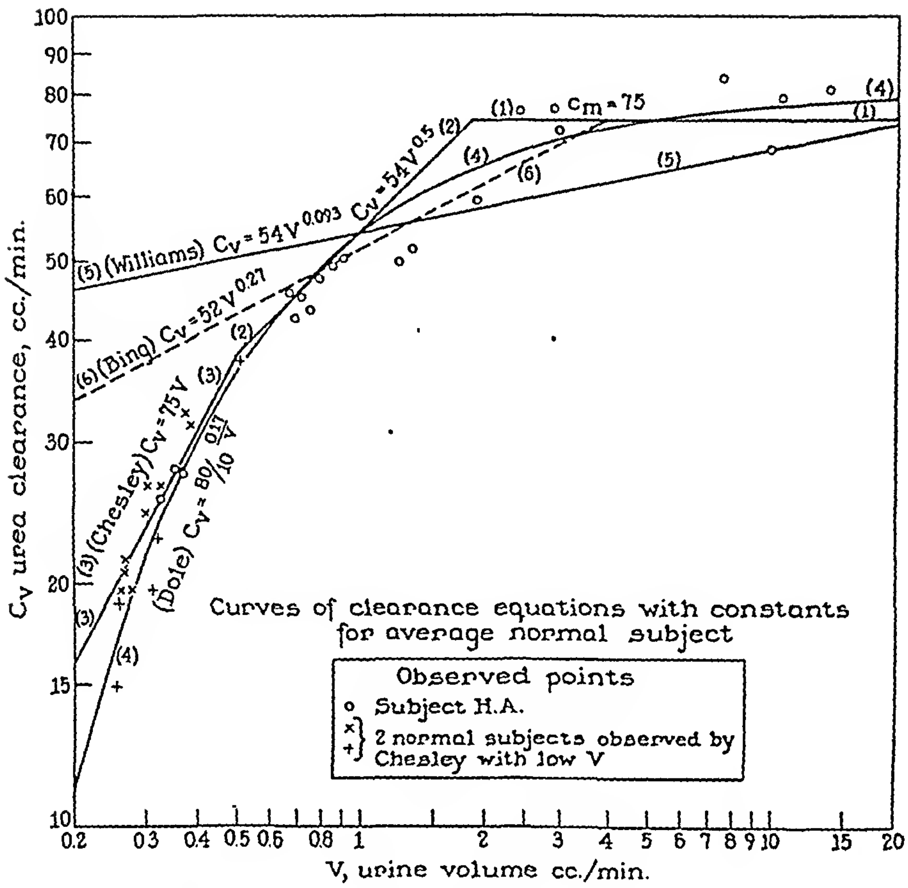

Fig. 1. Comparison of Observed Relation of Urea Clearance and Urine Volume with Relations Calculated by the Indicated Formulae for the Average Normal Subject. The number in parentheses on each curve indicates the number of the equation, in the text, by which the curve is calculated.

from data of Chesley (8) on 2 subjects who gave R_m values approximating 75. The curves illustrate the facts that Dole's theoretical equation appears to apply adequately to all urine volumes, that the 3 empirical equations of Möller *et al* (3) and Chesley (7, 8) represented by the broken-line curve, 1–2–3, fit approximately within their respective ranges of urine flow, and that the Bing and Williams formulae are less accurate, especially for low urine flows.

From Tables I and II it is evident that C_m values calculated by the formulae of Bing and Williams show consistently for each subject, both normal and nephritic, greater standard deviations from the mean of the subject than do C_m values calculated by the original "maximum" and "standard" clearance formulae of Möller, McIntosh and Van Slyke (3), or by the equation of Dole (5).

Tables III and IV show how the errors of both the formula of Bing and that of Williams are particularly great when these formulae are applied to clearances observed with low urine flows, where error in relating maximal water reabsorption to urea reabsorption in the tubules becomes most apparent.

That the standard deviations of individual C_m values in Tables I and II are not significantly greater for C_m calculated by the formulae of Möller *et al* than by Dole's equation, is attributable to the fact that but few of the urine flows in the observations recorded were below 0.5 cc. per minute. The results confirm Dole's conclusion with regard to clinical use of clearance formulae, that "the 'maximal' and 'standard' urea clearance formulae are adequate for their purposes, except for conditions of unusually small urine flows."

The conclusions concerning the relative accuracy of the "maximum" and "standard" clearance formulae compared with Williams' exponential formula reached by the above analysis

† Average normal values assumed are 75 for C_m by the equations of M. M. and V. S. and Bing, 71 for C_{22} calculated from C_1 of 54 by Williams' equation, 80 for C_m by Dole's.

are contrary to the conclusion of Williams based on the same data, in so far as the normal subjects are concerned, which were the only group considered by Williams. The difference appears to be due to different statistical procedures used by Williams and by ourselves in estimating the accuracy of the respective formulae. Williams calculated V from observed values of U/B both by his formula and by the "maximum" and "standard" clearance formulae (Equations *1* and *2*), using for all subjects average normal values of the constants of the respective equations. He calculated as d for each equation the mean difference between the V values thus calculated and the observed V values. His formula gave the lower mean d, and he therefore concluded that it was the more accurate. In these calculations Williams used for all subjects as constants the values of C_1 or C_m, *viz.* 54 and 75, found by Möller *et al* (3) as the *average* for normal adults. Thus the equations used (from Equations *5*, *1* and *2*, respectively) to calculate V were: $V = \left(54\,\frac{B}{U}\right)^{1.1[illegible]}$ (Williams [2]), $V = \frac{75\,B}{U}$ (Möller *et al* for V over 1.93) and $V = \left(54\,\frac{U}{B}\right)^2$ (Möller *et al*) for $V < 1.93$. The use of the same C_m and C_1 values for every subject of the group introduces errors into the V values calculated when the actual C_m and C_1 of any subject deviate from 75 and 54, and are

particularly large when the square root formula is applied, because with this formula the error of the calculated V increases as the error of the square of the assumed C_1. In the case of normal subject J. C. B. (3), with a C_1 value of 41, the use of 54 yields calculated V values with a plus error of almost 100 per cent. Such errors could be cancelled only by the use of a large series of subjects. The statistical procedure of Williams compares the results obtained by adding errors from 2 sources: (*1*) the error of each formula in expressing the relation of V to C_v, and (*2*) the error caused by using the group constant for each subject. The difference between his results and ours appears attributable to predominance of errors from the second source in his calculated V values.

Significance of non-decrease of the augmentation limit and the constant, b, *of Dole's equation in nephritic subjects as indication of increased tubular permeability to urea*

It was a matter of surprise to Möller *et al* (4) to find that in patients with glomerular nephritis and markedly reduced clearances the augmentation limit was usually of the same order of magnitude as in normal subjects. If the disease process affected renal function by inactivation of part of the nephrons, corresponding to the destroyed glomeruli seen histologically, while the remaining nephrons functioned normally, one might expect that the augmentation limit would fall parallel with the number of functioning nephrons, and hence with the clearance.

From the same conception one would expect the constant, b, of Dole's equation to fall parallel with the clearance. This constant is defined by Dole as the product, $b = a \times h$, where a represents the total area of the walls of the distal segments of the functioning tubules and h represents the permeability of the walls of the distal segments for urea. Destruction of part of the nephrons, and consequent decrease in the area, a, would result in a proportional decrease in b, unless the permeability, h, were increased in the tubules that remained functioning. It appears probable that such a permeability increase occurs, and provides an explanation of 2 aspects of renal function in advanced nephritis, viz. (*1*) the maintenance of the augmentation limit near the normal 2 cc. of urine per minute, and of the b constant at normal, or even higher than normal levels, in many cases, and (*2*) the inability of the damaged kidneys to excrete urine with high urea concentration.

We have estimated values of b' of Equation *4* for the 6 nephritic patients of Table II by plotting smoothed curves of C_r against V, and using values of C_r and V from points on the upper and lower parts of each curve, respectively, to calculate by simultaneous equations the constants, C_m and b' of Equation *4*. The results are given in the last 3 columns of Table II. Only in case Wol. is the b' value markedly lower than in normal subjects, and the average, 0.20, is higher than the value 0.17 found as the mean for the normal subjects in Table I. In patient Val., despite the fact that the nephritis was so far advanced that the urea clearance was only $\frac{1}{5}$ of normal, the augmentation limit was so high that urine volumes up to 3.5 cc. per minute failed to locate the limit, and the b' value, 0.33, was twice the normal. One might deduce that the permeability of the functioning tubules for urea was 10-fold normal.

The apparent reason for such behavior is that these tubular segments (presumably the distal),

where urea reabsorption is variable in the still functioning nephrons, are damaged in such a manner that they have an increased permeability to urea, so that urea concentration in the urine issuing from them must be kept at a lower level than in the normal tubule in order to prevent reabsorption of urea from becoming significant. In order to keep the urea concentration at the necessary lower level the volume of urine issuing per minute from each tubule must be kept greater than in the normal tubule. The permeability of the tubules approaches that observed by Richards (12) in the kidneys of frogs poisoned with mercuric chloride, in which the permeability was so increased that, although glomerular filtration appeared even more active than normal, the filtrate was completely reabsorbed in the tubules, with resultant anuria.

By maintaining a sufficiently large urine volume the nephritic kidney can apparently prevent the reabsorption of urea from exceeding the 40 per cent observed in the normal human kidney when urine flows exceed about 2 cc. per minute, but in order to prevent greater reabsorption the nephritic kidney must maintain a higher *ratio* of urine flow to glomerular filtrate than the normal kidney.

As a consequence of this condition, the $U:B$ ratio of urea concentrations at the augmentation limit does not remain, in the nephritic kidney, at the normal level 20:1 as assumed by Bing (1), but falls progressively as the functioning tubules become more damaged, *e.g.*, in the case in Table IV the $U:B$ appears to be in the neighborhood of 3 or 4 when urine flow nears the augmentation limit.

Significance of urine volume in maintaining elimination by the nephritic kidney

Lashmet and Newburgh (13) and Marriott (14) have emphasized that in nephritis maintenance of a large flow of urine is necessary when ability to concentrate is decreased. Figure 2 indicates how a study of the urea clearance with different urine volumes in the individual patient can indicate the volume output that is needed to approximate maximal efficiency of urea excretion. Cases Val. and Wol. both had about the same urea clearance, 20 per cent of normal when their urine volumes were as high as 4 cc. per minute. When the urine flows of the 2 patients were diminished, however, they showed markedly different effects. Val. maintained his clearance at approximately the same level until the urine output fell to about 1.2 cc. per minute, while in the case of Wol., fall of urine volume to 1.2 cc. per minute was accompanied by a drop of 40 per cent in the urea clearance below its value when urine flow was 3 or 4 cc. It appears that in Val. a daily excretion of 1.7 liters per 24 hours (1.2 cc. per minute) sufficed to obtain nearly

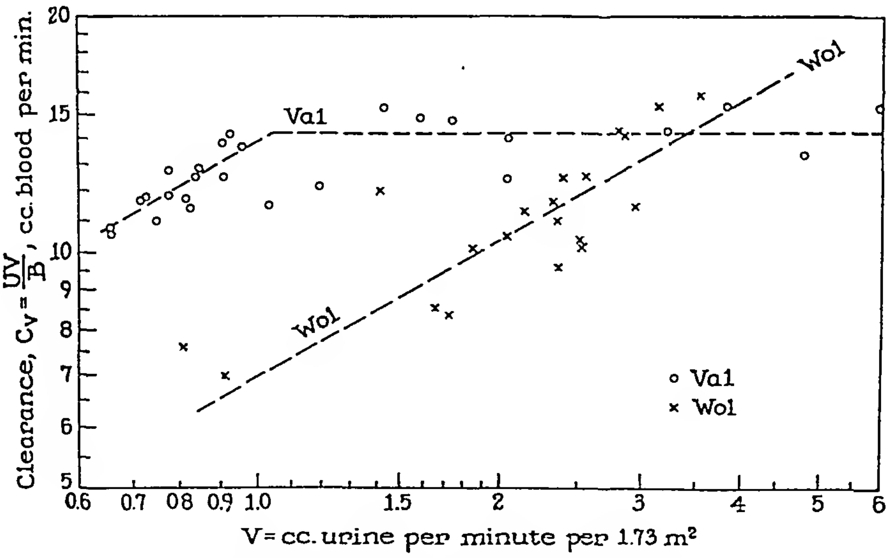

FIG. 2. DIFFERENT EFFECTS OF URINE VOLUME FLOW ON UREA CLEARANCE IN 2 NEPHRITIC PATIENTS

maximal efficiency of urea excretion, while in Wol. 3 times as great a volume was needed.

SUMMARY

The "maximum" and "standard" urea clearance formulae of Möller, McIntosh, and Van Slyke have been compared with formulae proposed by Bing, by Williams, and by Dole for estimating the effect of urine volume on urea clearance. The accuracy of the respective formulae has been estimated by comparing the constancy with which the maximal clearance, obtainable with high urine volume, could be calculated from clearances observed with lower urine volumes by the respective formulae for each of a number of normal and nephritic subjects.

The formulae of Bing and of Williams proved to be less accurate than those of Möller *et al* and of Dole.

The conceptions of Dole's theoretically derived formula have been used to explain, from increased permeability of damaged renal tubules, the different effects of urine volume on urea excretion in different nephritic subjects, and the loss in nephritis of ability to excrete urine of high urea concentration.

Examples are given indicating that, by observing the effect of urine volume on urea clearance in nephritic patients, it may be possible to estimate the urine volume flow required for optimal urea excretion.

THE INFLUENCE OF ORALLY ADMINISTERED ALKALI AND ACID ON THE RENAL EXCRETION OF QUINACRINE, CHLOROQUINE AND SANTOQUINE[1]

By JOSEPH W. JAILER, MORRIS ROSENFELD, and JAMES A. SHANNON

(From the Research Service, Third Medical Division, Goldwater Memorial Hospital, and the Department of Medicine, New York University)

(Received for publication July 17, 1947)

Haag and Larson (1) demonstrated in 1942 that in the case of nicotine the extent of urinary excretion of a chemical may be related to the reaction of urine. They emphasized the importance of taking into consideration the dissociation constant of a drug and the relative reabsorbability of the free and dissociated base. Extending these studies to the urinary excretion of quinine in man, Haag, Larson and Schwartz (2) found in 1943 that the urinary output could be doubled by passing from an alkaline to an acid urine and they ascribed the difference to greater resorption of quinine from the urinary tract when the urine is alkaline.

In connection with studying the behavior of newer antimalarial drugs in man, the extent of the influence of urinary acid-base balance upon renal excretion was re-examined. Parallel studies by Emerson and Dole (3) indicated that renal clearance of quinacrine is subject to 100-fold variations due principally to 2 variables, the urinary pH and the renal plasma flow. Work conducted at the same time by the Army Malaria Research Unit at Oxford (4) emphasized the striking parallelism between urinary excretion of quinacrine and ammonia. They found that the ratio of urinary quinacrine to urinary ammonia is directly proportional to the plasma quinacrine concentration. Trager and Hutchinson (5) in 1946 similarly found the urinary excretion of quinacrine to be closely correlated with the urinary excretion of ammonia.

The present investigation was designed to ascertain the effect of oral ingestion of alkali and acid upon the renal excretion of this general type of organic compound. The substances selected for study were quinacrine, chloroquine (SN-7618), and santoquine (SN-6911).

METHODS AND MATERIALS

The patients utilized in this study were from the middle and older age groups. No restriction was placed on the diet or upon water intake during the observations and the patients were permitted the freedom of the ward. All drugs were administered orally and according to a single general dosage pattern. A high initial dose was administered during the first 24 hours and this was followed by the serial administration of smaller maintenance doses. Several days were allowed to elapse for the stabilization of the plasma drug concentration before observations were begun.

Alkali was administered orally in the form of sodium bicarbonate at a total daily dose of 20 grams. This was given in doses of 2.5 grams at 2-hour intervals during the day for 7 doses and once during the night. Acid was administered orally in the form of ammonium chloride at a total daily dose of 8 grams. The dosage schedule was the same as for the bicarbonate, each dose being 1.0 gram.

Plasma and urine estimations were performed by methods developed by Brodie. Quinacrine was determined fluorometrically by the single extraction procedure using ethylene dichloride (6); the alkaline wash was used in the urine determinations but not in the plasma determinations. The ethylene dichloride extract was made acid with trichloracetic acid (Masen [7]). Santoquine was estimated by the colorimetric procedure depending upon a salt formation with methyl orange (Brodie *et al* [8]).

The recently developed specific method (1947) for the analysis of chloroquine (9), involving the use of heptane and alkaline washes, was not yet available at the time of the present study. The procedure used involved the extraction of chloroquine with ethylene dichloride at pH 11, followed by the return of the drug to dilute acid. The acid solution was buffered at pH 9.5 and subjected to ultra-violet irradiation for a 1-hour period. Concentration was estimated by measurement of fluorescence generated by the irradiation. This procedure includes in the measurement interfering degradation products of chloroquine which are found in plasma to the extent of 20 to 50 per cent. However, it is quite specific for urine since only negligible amounts of these degradation products appear in urine.

[1] This work was carried out under a contract recommended by the Committee on Medical Research between the Office of Scientific Research and Development and New York University.

Urine pH was determined in all cases on freshly voided urine samples using a glass electrode. No precautions were taken to maintain CO_2 tensions in the transfer of fluid. Consequently the data on urinary pH must be taken as close approximations rather than precise estimations of the pH of bladder urine. During the period of alkali administration the urinary pH rose to values between 7.5 and 8.0; during the acid period the pH fell to values of 4.0 to 5.0.

RESULTS

Quinacrine

The experimental data obtained on 4 patients receiving maintenance doses of 0.2 and 0.3 grams of quinacrine dihydrochloride are summarized in Table I. The amounts and concentrations noted are expressed in terms of free base. The control values for the renal excretion of quinacrine varied from 1 to 3 per cent of the daily dose. Excretion was reduced to 0.07 to 0.3 per cent of the daily dose during alkalinization and increased to 2 to 6 per cent during acidification. There was in individual cases a 14- to 25-fold increase in going from one state to the other. As is to be expected, such a change is not reflected in the plasma quinacrine concentration since the extent of renal excretion in relation to the oral dose is low in all cases. The plasma level of quinacrine remained roughly constant in 1 patient who was at equilibrium before the observations were begun, and increased as a more or less linear function of time in the 2 who had not as yet achieved an equilibrium plasma quinacrine concentration.

Chloroquine

The experimental data obtained on 5 patients receiving 0.2 or 0.4 grams of chloroquine daily are summarized in Table II. The daily excretion, in terms of percentage of the daily dose, was high in all patients as compared to quinacrine. This varied in the case of chloroquine, from 15 to 50

per cent in the control periods; was reduced to 7 to 20 per cent during alkalinization and was increased to 20 to 90 per cent during acidification.

Santoquine

Observations on santoquine were limited to a single individual. However, they were designed to stress the effects of changes in the renal excretion of drug upon the maintenance of the plasma santoquine concentration while on a constant drug intake. Each phase of alkali and acid administration was of 5 days' duration and 2 complete cycles of alkali-acid treatment were obtained (Table III).

It should be noted that a large portion of the daily dose of santoquine is excreted in the urine. This was perhaps more in the patient utilized than is usual. During the control period average renal excretion accounted for 41 per cent of the daily dose. This was decreased to an average of 16 per cent during the first alkalinization and increased to an average of 64 per cent during the first acidification. Similar results were obtained during the second cycle.

As is to be expected in such a circumstance, the plasma santoquine concentrations reveal a cycle which can be correlated with the intervals of low and high renal excretion. During the alkaline phase of low drug excretion, the plasma level slowly rose; during the acid phase of high excretion, the plasma level fell.

DISCUSSION

It is apparent from the data that the renal excretion of the anti-malarial drugs is dependent upon a series of variables in addition to the concurrent plasma concentration. These variables are of sufficient importance in the determination of the renal drug excretion, that the latter may not be used directly as an approximation method to estimate the general level of the plasma drug concentration.

The refinement introduced by the British workers (4) involving the simultaneous measurement of urinary ammonia and quinacrine does permit of an indirect determination of plasma quinacrine from measurements on urine alone. It appears to us that ammonia excretion may be governed by urinary acid-base balance in a manner similar to the other weak organic bases, such as the anti-malarial drugs. The ammonia measurement provides an index of variation in urinary acid-base balance. By taking the quinacrine concentrations in relationship to ammonia excretion, the Oxford workers were able to eliminate the variable of pH. Trager and Hutchinson (5) seem to ascribe a causal role to ammonia in promotion of urinary excretion; it appears far more likely that ammonia and quinacrine excretions are concomitantly altered in a similar manner by urinary changes in hydrogen ion concentration.

The experimental data are interesting for yet another reason. It must be assumed that at least a portion of the drug eliminated by the kidneys is excreted by a process other than glomerular filtration. This follows from a consideration (in the case of quinacrine) of the extent to which it is bound to the non-diffusible constituents of plasma (some 80 to 90 per cent of the total) and the observed rates of excretion. The mechanism responsible for such tubular excretion as occurs ap-

pears to be quite different from those responsible for the tubular excretion of such substances as phenol red, creatinine, diodrast, etc. The latter manifest considerable stability whereas this does not obtain for the tubular excretion either of quinacrine or of chloroquine and santoquine.

Data are not available with which to define the mechanisms involved though there is sufficient to warrant certain reasonable speculations. It is suggested that a small portion of the excreted anti-malarial drug is filtered at the glomerulus, the amount determined by the glomerular filtration rate, and the concentration of unbound drug in plasma water. A second portion is considered to be added to this in the proximal segment by a process of active tubular excretion similar to the conventional processes considered above. The combined filtered and secreted drug is presented to the distal segment of the nephron in concentrated form due in part to the reabsorption of water in the proximal tubule and loop of Henle. In the distal segment, a process of adjustment of hydrogen ion concentration takes place followed by equilibration of drug across the tubular membrane. The data are in keeping with the assumption that free base is more freely diffusible across the cells of the distal segment than the monoacidic and diacidic salts of the drugs studied. Such being the case there may be expected to be net gain or loss of drug depending upon the relation between the hydrogen ion concentration of the tubular urine and that of peritubular fluid (*ca.* 7. 34). Alkalinization of the tubular urine would increase the proportion of drug in the form of free base and in this way would promote reabsorption; acidification would counteract reabsorption by reducing the proportion of free base. A somewhat similar mechanism has been suggested to cover the renal tubular excretion of neutral red in the amphibian kidney (10).

The observation of Trager and Hutchinson (5) that the plasma quinacrine level rose soon after oral ingestion of large doses of ammonium chloride, would seem to provide another basis for the altered urinary excretion. The elevation in plasma level observed in their experiment is of brief duration and is in keeping with the increased plasma levels observed in dog experiments (11) in which acute acidosis was produced by CO_2 administration. The plasma quinacrine measurement in the present study revealed no significant changes in level since by design the blood sampling and ammonium chloride administration were timed to elicit only sustained changes. The promotion of urinary excretion of quinacrine by ammonium chloride appears to us not to be secondary to plasma drug elevation but rather a direct result of the acid urine counteracting drug reabsorption in the tubules.

Relatively large changes in excretion rate are expected to be reflected in changes in the plasma drug level on a constant regimen of oral dosage only when the absolute rate of excretion of the substance is high. This phenomenon is brought out strikingly in the patient receiving santoquine. During the acid periods drug excretion amounted to as much as 50 to 75 per cent of the orally administered dosage. The effective dosage was thereby reduced to ½ or ¼ of the actual administered dose. During the alkaline period, the per cent of drug excretion was small, namely 20 per cent of the ingested dose. Under these circumstances, the effective oral dose was as high as 80 per cent of the actual administered dosage.

Quinacrine excretion, though markedly altered by acid-base changes, remains in all circumstances such a small percentage of the orally administered dosage that changes in renal elimination would not be reflected in the maintained plasma level. The changes in drug excretion, from 0.2 per cent during the alkaline period to 4 per cent in the acid period, would not reduce the effective oral dosage to an appreciable extent. The actual measurements on quinacrine plasma levels in the present experiment showed no cyclic fluctuation in acid and alkaline phases as were observed with santoquine.

One therapeutic implication of the above results is obvious. When toxicity is encountered during the administration of certain anti-malarial drugs, acidification of the urine by ammonium chloride would promote renal excretion of the drug. Effectiveness of such therapy should be good only with drugs of high excretion rate such as chloroquine and santoquine. With a drug like quinacrine which is excreted in the urine to only a slight degree even upon acidification, such therapy should have little value.

SUMMARY

1. The oral administration of ammonium chloride increases the renal excretion of quinacrine, chloroquine and santoquine in individuals on a constant maintenance dose of the drugs. Sodium bicarbonate given in a similar manner causes a retention of these drugs.

2. Changes in renal excretion are reflected in changes in plasma level only when the absolute rate of excretion of the substance is high.

PROCEEDINGS OF THE THIRTY-NINTH ANNUAL MEETING OF THE AMERICAN SOCIETY FOR CLINICAL INVESTIGATION HELD IN ATLANTIC CITY, N. J., MAY 5, 1947

The Antihemophilic Principle of Normal Plasma. BENJAMIN ALEXANDER, Boston, Mass. (Introduced by S. L. Gargill).

A method devised in our laboratories, for the quantitative measurement of the antihemophilic factor in normal plasma, has been applied to a study of some of its physiological and biochemical properties. The method is based upon the observation, now extended to include a total of 5 hemophiliacs, that the relationship between the logarithm of the amount of plasma added in vitro to hemophilic blood and the logarithm of its clotting time is linear.

The effects of normal plasma on hemophilic blood both in vivo and in vitro are constant and equivalent. The intravenous administration of 150 to 200 cc. of plasma 3 to 4 times weekly to 4 hemophiliacs has proved effective in the prevention of hemorrhage for periods of 6 to 16 months. Intramuscular plasma is much less effective in lowering the clotting time.

The antihemophilic potency of 46 non-hemophilic plasmas was uniform with a standard deviation of 0.3 in terms of an average of 1.0. The antihemophilic factor is largely retained by a Berkefeld filter but passes through a Seitz. The substance is no longer freely present following blood coagulation.

Frozen plasma remains fully potent for over six months but liquid refrigerated plasma (5° C.) loses half of its activity in 5 weeks, 90 per cent in 2½ months. At 37° C. one half is lost in 10 hours, 85 per cent in 24 hours. The rate of deterioration is uninfluenced by platelets or by the admixture of hemophilic plasma, but is much more rapid in whole blood, or normal plasma-whole hemophilic blood mixtures incubated at 37° C. In the hemophiliac 93 per cent of the antihemophilic factor of infused plasma disappears within 13 hours.

Mixtures of normal and hemophilic plasma have a greater antihemophilic potency in vitro than normal plasma alone whereas hemophilic plasma is inert. The enhanced potency is referable to the hemophilic platelets.

These observations are of value both in the clinical management of hemophilia and in further elucidation of the mechanism of blood coagulation.

Mechanisms Underlying Pulmonary and Cardiac Complications of Electrically Induced Convulsions in the Treatment of Psychosis. M. D. ALTSCHULE and (by invitation) K. J. TILLOTSON, Boston, Mass.

Convulsions induced by electroshock are accompanied by maximal forced expiration. During the seizure salivation occurs, and roentgenograms suggest also that bronchial secretion is likewise increased at this time. Maximal inspiration at the end of the seizure causes the aspiration of this material and gives rise to atelectasis more commonly than is suspected. Infection may localize in an atelectatic area and result in abscess formation. Increase in intrathoracic pressure during seizures exerts a force on the outside of the coronary arteries which prevents an increase in difference between the internal and external pressures on the walls of these arteries; brittle coronary arteries are thereby protected. Also, the changes in intrapleural pressure retard passage of blood from the periphery into the heart; this change is reflected in an increase in peripheral venous pressure. As a consequence of diminished venous return the heart becomes smaller than normal and its work is decreased. After the end of the convulsion, the cardiac work is increased, judging by changes in circulation time. The rush of blood from the periphery into the right auricle and great veins after the convulsion gives rise to cardiac arrhythmias which are vagal in type.

The Mechanism of Control of Extravascular Fluid Formation by Normal Human Serum Albumin in Cirrhosis and Idiopathic Hypoproteinemia with Normal Renal Function. S. HOWARD ARMSTRONG, JR., and (by invitation) SAM T. GIBSON, Boston, Mass.

In three patients periods of baseline control have exceeded six months, during which observations on water, salt, and nitrogen balances, plasma volume, protein distribution in serum and extravascular fluids, and differential osmotic pressure measurements yielding the effective osmotic pressure of the serum as against the extravascular fluid have been made.

When the course during control period suggested that the disease process was static for purposes of the experiment, albumin administration was started.

Cessation of formation of extravascular fluid has been observed when the differential osmotic pressure attains the level of normal osmotic pressure for man. Fluid formation recurs when this pressure falls to original levels. The variables unrelated to osmotic pressure do not appear to have first-order significance. In the effect in these patients without significant protein loss in the urine, the amount of albumin required to maintain this differential pressure is far less than the initial amount required to attain it. From the amounts used, together with the nitrogen balances, rough estimates have been made of tissue protein depletion which must be met before blood proteins rise in these patients.

Whereas the albumin has appeared to eliminate the disability of being waterlogged in these selected patients, the studies are not sufficiently wide to permit any conclusions on the effect of therapy on the underlying course of the disease.

*Vascular Spiders and Palmar Erythema in Pregnancy** WILLIAM B. BEAN and (by invitation) MORRIS W. DEXTER and ROBERT C. COGSWELL, Cincinnati, Ohio.

An extension of studies on vascular spiders and palmar erythema which may complicate liver disease has been made to determine the incidence, progress and fate of

* Aided by a grant from the U. S. Public Health Service.

these vascular changes during and after uncomplicated pregnancy. Observations on 274 colored and 178 white women have been made at each routine visit to the Obstetric Prenatal Clinic; 70 colored and 26 white women have been observed shortly after delivery and 6 weeks later. Including the earliest definite lesions, vascular spiders have been found in 65 per cent of white women and 15 per cent of colored women. Palmar erythema was detected in 58 per cent and 32 per cent respectively; and both types of vascular changes existed simultaneously in 43 per cent and 10 per cent. Incomplete data on the time of appearance of lesions indicate that they may begin at any time during pregnancy. Since many patients made their first clinic visit late in pregnancy very few known lesions were seen before the fifth month. In more than two-thirds of the patients the acquired vascular spiders and palmar erythema had disappeared by the 3rd to 5th days following delivery, and a few more had vanished by the time of the 6-week follow-up visit. Studies of liver function and urinary excretion of steroid hormones are in progress.

*Physiological Studies in Congenital Heart Disease** RICHARD J. BING, LEROY D. VANDAM, and FRANK D. GRAY, JR., Baltimore, Md. (Introduced by E. Cowles Andrus).

One hundred eighty patients with congenital heart disease of the cyanotic group were studied. Pulmonary capillary flow was measured using the indirect Fick principle. Formulae for the determination of the volume flow through the pulmonary artery, the systemic capillaries, and through the aorta were devised from results obtained by catheterization of the heart. Similarly, the amount of mixed venous blood perfusing the lung (effective pulmonary blood flow), the size and direction of the intracardiac shunt, and the volume of collateral circulation to the lung were measured.

The effect of a standard exercise test on circulatory and respiratory functions was studied.

In tetralogy of Fallot the intracardiac shunt was directed from right to left. Large collateral circulation to the lung was present in most cases.

The arterial oxygen saturation was found to be related to the percentage of total mixed venous blood perfusing the lung. The systolic pressure in the right ventricle was elevated, and peripheral resistance varied with the logarithm of the systemic flow.

The basal metabolic rate was below normal. During the exercise test the ratio of oxygen consumption per liters of ventilation and the arterial oxygen saturation declined.

The Blalock operation was followed by an increase in the pulmonary capillary flow, the effective pulmonary blood flow, and the arterial oxygen saturation.

In Eisenmenger's complex the pulmonary artery flow was normal. Both systolic and diastolic pressures in the pulmonary artery were elevated. During the exercise test the ratio of oxygen consumed per liters of ventilation increased, and the arterial oxygen saturation declined.

The Effect of Ouabain on the Dynamics of the Circulation in Patients with Congestive Heart Failure. RICHARD A. BLOOMFIELD, BERNARD RAPOPORT, J. PERVIS MILNOR, WALTER K. LONG and J. GILMER MEBANE (by invitation) and LAURENCE B. ELLIS, Boston, Mass.

The effect of ouabain upon the circulation in congestive heart failure was studied in a series of patients by utilizing the intracardiac catheterization technique. Cardiac outputs, by the direct Fick method, were determined before and at 1 to 2 hours after administration of ½ to 1 mg. of the drug through the catheter. Simultaneous recordings through Hamilton manometers were made at frequent intervals over the same period of time of the peripheral venous, femoral arterial, and right intraventricular pressures; in addition, where possible, registration of the pulmonary arterial pressure was also done. Changes in heart rate were for the most part of a small order and did not explain observed alterations in other measurements. In those patients with congestive heart failure in whom the administration of ouabain was followed by a significant rise in the cardiac output no consistent or significant pattern of peripheral venous pressure change was observed; in fact, in some of the patients with marked increases in cardiac output the venous pressure was unchanged. In most patients there was an early and at times sustained rise in the systemic blood pressure. The data obtained failed to substantiate the view that the primary effect of the cardiac glucoside was due to a peripheral action on the venous pressure. The significance of the changes observed in the cardiodynamic measurements, including peripheral and right intracardiac pressures, is discussed, and it is concluded that they are consistent with a transfer of blood from the pulmonary and venous pools to the systemic side of the circulation.

High Penicillin Plasma Concentration by the Use of Caronamide, a Compound That Inhibits Penicillin Excretion by the Renal Tubules. WILLIAM P. BOGER (by invitation), CALVIN F. KAY and (by invitation) SYLVAN H. EISMAN and ELMER E. YEOMAN, Philadelphia, Pa.

The reversible and physiologic inhibition of penicillin excretion by the renal tubules following the oral administration of caronamide, 4'-carboxy-phenylmethanesulfonanilide, has recently been described. It has been shown that when penicillin is administered parenterally or orally, the resultant plasma concentrations can be enhanced from two to seven times by reasonable caronamide doses given orally.

This work was stimulated by the necessity of attaining high penicillin plasma concentrations for the treatment of a patient suffering from subacute bacterial endocarditis due to a streptococcus viridans highly resistant to both streptomycin and penicillin. Very high plasma concentrations of penicillin have been achieved (fourteen to forty units of penicillin per cubic centimeter), following the oral administration of caronamide every three hours and the intramuscular injection of 500,000 units of penicillin every three hours. Dose-response curves following the injection of penicillin have been compared in control and caronamide treatment periods in order that the enhancement effect of caronamide could be evaluated. The peni-

cillin plasma concentrations have been correlated with the quantities of penicillin recovered in the urine, the plasma concentration of caronamide, the renal clearance of penicillin, and the glomerular filtration rate as determined by mannitol clearance.

Estimated Hepatic Blood Flow and Bromsulfalein Extraction in Normal Man During the Pyrogenic Reaction. STANLEY E. BRADLEY and (by invitation) NEAL J. CONAN, New York, N. Y.

The present study was undertaken to determine whether hepatic circulatory adjustments and/or hepatic cellular dysfunction develop in man during the pyrogenic reaction. The cardiac output and the renal blood flow increase even when fever is prevented by antipyretic drugs, and, since renal hyperemia is not sufficient to account for the increment in cardiac output, it may be presumed that the hepatic circulation is also increased. Recently it has been found that bromsulfalein (BSP) retention occurs during fever. This phenomenon may be attributed to (1) hepatic ischemia with reduced delivery of BSP to the liver or (2) diminished ability of hepatic cells to remove the dye from blood perfusing the liver.

The hepatic blood flow (EHBF) was estimated as the bromsulfalein clearance and BSP extraction was determined directly using the technique of hepatic venous catheterization. Studies were made upon normal human subjects prior to, and following, intravenous administration of typhoid vaccine.

Within one to two hours after pyrogen was given EHBF increased significantly in nearly every case (300 per cent above the control level on one occasion). Despite hepatic hyperemia and the resulting increase in BSP loading the removal of BSP from the blood decreased by as much as 50 per cent. This effect was apparently attributable to a striking reduction in BSP extraction by the liver. Premedication with aminopyrine prevented fever but did not alter the responses.

On several occasions, the hepatic venous pressure was observed to rise as hepatic hyperemia developed.

Streptomycin and Tuberculous Tracheo-Bronchitis. A Bronchoscopic Study of Healing Lesions. LYMAN A. BREWER III, EMIL BOGEN and ROBERT L. BRERETON, San Fernando, Calif. (Introduced by J. M. Hayman, Jr.).

Visible lesions are especially suitable for the early evaluation of therapeutic effects in tuberculosis. Thirteen tuberculous patients with persistent, severe, tracheal or bronchial granulating or ulcerative lesions were selected from more than a hundred referred for this purpose. They were intensively treated with streptomycin, both intramuscularly and by aerosol, at the San Fernando Veterans Administration Hospital for periods ranging from one week to three months. Biweekly bronchoscopic examinations showed prompt disappearance of the lesions in every case. Only one instance of recurrence of an ulcer in the tracheo-bronchial mucosa has been seen since the treatment has been discontinued. Pulmonary cavities in these patients remained open, and temporary symptomatic improvement in other lesions in the lungs were not sustained. Special clinical and laboratory studies before, during and after the treatment period help clarify the phenomena observed. This study indicates that streptomycin is a valuable therapeutic agent in the treatment of the most severe types of active tuberculous tracheobronchitis.

Streptomycin in the Treatment of Draining Tuberculous Sinuses. BENJAMIN L. BROCK, Oteen, N. C. (Introduced by Arthur M. Walker).

One of the most dramatic results in the treatment of tuberculosis in man has been obtained following the use of streptomycin in draining tuberculous sinuses.

Sixty draining sinuses, proved to be tuberculous either by culture or biopsy, originating for the most part in bone or cartilage in eleven negro patients and one white patient have been treated with streptomycin over a period of from 90 to 150 days.

A daily dose of 1.8 gm. of streptomycin, or 0.3 gm. every four hours was given intramuscularly.

Nine (15 per cent) of the 60 sinuses closed within one week to four weeks and nine (15 per cent) closed within six weeks to eight weeks after streptomycin was begun. It required between ten weeks and twelve weeks for thirty (50 per cent) of the sinuses to close and the remaining eleven (approximately 20 per cent) closed within thirteen to twenty weeks after streptomycin therapy was instituted. Only one sinus remains following surgical drainage but it is almost closed.

The longest time which has elapsed since closure of a sinus is seven months, one week after therapy was begun; the shortest time one month. The average time since closure of all the sinuses is 3.8 months.

Where necrotic bone, or cartilage, as for example in a rib, is removed and where small abscesses under the skin, or large psoas abscesses in the groin are widely drained in conjunction with streptomycin therapy, arrest of the process with closure of the sinus occurs within a relatively short time.

Certain reactions to streptomycin are described and several outstanding clinical signs of improvement are discussed. Photographic illustrations are available.

Analysis of Peritoneal Washings for Protein, Non-Protein Nitrogen and Phosphorus During Studies on Nitrogen and Fluid Balance in Treatment of Acute Uremia by Peritoneal Lavage. HERBERT R. BROWN, JR., JACOB HOLLER and HELEN E. VAN ALSTINE, Rochester, N. Y. (Introduced by Samuel H. Bassett).

A woman of 25 years who developed acute anuria during the course of glomerulonephritis was treated for 21 days by continuous peritoneal irrigation using the method of Fine. The procedure was terminated by death of the patient. During the interval of study it was possible to (a) keep a fairly complete nitrogen balance (b) get rid of severe edema (c) increase the plasma CO_2 from 20 to 60 volumes per cent and (d) reduce the level of NPN in the blood.

A very considerable amount of protein (731 gm.) was recovered from the peritoneal washings. The mechanism of this was thought to be the establishment of partial

equilibrium between the perfusing solution and the patient's interstitial fluid. Increased capillary permeability, believed to occur in acute nephritis, may have been a contributing factor to protein transudation in the early phase of lavage.

The overall picture of the N balance (exclusive of three small stools and losses from the skin) may be tabulated as follows:

NITROGEN BALANCE

Nitrogen Intake		
Whole Blood (Intravenously)	63.3 gm.	
Plasma (Intravenously)	99.6 gm.	
Aminoids (orally)	76.5 gm.	
Special formula (orally)	36.6 gm.	
Total	276.0 gm.	276.0 gm.
Nitrogen Output		
Peritoneal Drainage		
(a) NPN	140.8 gm.	
(b) Protein N	117.0 gm.	
Gastric Suction (Wangensteen)	92.5 gm.	
Urine	4.4 gm.	
Total	354.7 gm.	354.7 gm.
Difference (Nitrogen loss)		78.7 gm.

Rates of Turnover of Radiosodium in the Blood and Urine of Normal Subjects and Patients with Congestive Heart Failure. GEORGE BURCH and PAUL REASER, New Orleans, La.

The rates of turnover of sodium in the blood and urine of 10 normal subjects, 12 patients with various degrees and stages of congestive heart failure and 6 patients with miscellaneous clinical states were determined for a period up to 120 minutes with Na^{24} ($t_{\frac{1}{2}} = 14.8h$). The subjects were on a regular hospital or a low salt diet (1.7 gm. NaCl). Most of the patients with congestive heart failure were receiving the usual therapy for congestive heart failure without the use of diuretics.

The Na^{24} was injected in one antecubital vein and blood was collected from the other at 5–10 second intervals for 3 minutes. The intervals between collections were increased as the study progressed. Urine was collected simultaneously and separately from the pelvis of each kidney by means of catheters. The urine was collected at intervals varying from a few seconds to a few minutes, depending upon the rate of urine flow.

The results showed a very rapid rate of Na exchange between the blood vessels and tissue spaces, being several times 7,000 grams Na per day. The rate of diffusion was so rapid that the rate of mixing and circulation time were too slow to permit accurate measurements of the Na exchange, much of the Na having already escaped from the blood before a complete recirculation. The nature of the curves of Na^{24} level in the blood were quite different from those reported for dogs in which samples were collected from arteries. The differences in blood Na levels between the normal and congestive heart failure subjects could be accounted for by the volume of the water in the Na compartments.

The urine concentrations of Na of the normal subjects were essentially the same as for the blood. That of the patient with congestive heart failure was uniformly lower but varied with the phase of the congestive heart failure and the Na in the diet. The "Na clearances" in the patients with congestive heart failure were lower than those in the normal subjects. The Na^{24} appeared in the urine of all subjects within 1.5 to 3.5 minutes after injection.

The data show an impairment of sodium excretion in congestive heart failure due largely to renal dysfunction.

Miliary and Meningeal Tuberculosis Treated with Streptomycin. PAUL A. BUNN, Washington, D. C. (Introduced by Thomas McPherson Brown).

From May 1946 until February 20, 1947, 60 cases of proved meningeal and miliary tuberculosis, or a combination of both, have been treated in 38 Veterans Administration hospitals. The number of cases in each group, the death and survival rates according to the time treated, and the number who are living after completion of an assigned course of streptomycin are shown in the figure.

Disease	Number of cases	Dead, 27, following treatment days		Living, 33, following treatment days		Treatment "completed"
		0–7	15–120	10–30	30–125	
Meningitis	24	8	5	8	3	0
Miliary	17	0	2	2	10	3
Meningitis and miliary	19	5	7	0	4	3
Totals	60	13 (22%)	14 (23%)	10 (17%)	17 (28%)	6 (10%)

Only those cases falling into the classification of acute disseminated miliary tuberculosis and those with classical signs of meningitis are included. Without specific antibacterial therapy, the expected mortality of each group would approximate 100 per cent.

Of the 6 cases who have completed treatment to date, 4 are to all intents and purposes normal—both clinically and psychologically. The fifth continues to have active pulmonary tuberculosis and the sixth has developed irreparable brain damage.

The clinical improvement, the laboratory findings and the roentgenographic changes in all cases during the period of therapy have been recorded and are extremely impressive in most instances. Complete x-ray clearing of all miliary lesions in the lungs has been demonstrated on occasions.

Many evidences of toxicity to streptomycin have been recorded. Among these are three cases who developed complete deafness and one in whom there was bone marrow depression.

The dosage of streptomycin has varied from 1.2 gm. to 4 gm. daily given in divided doses. The duration of treatment has been variable. The material has been continuously administered for as long as 160 days, but in most,

if the patient survives, therapy was stopped at the end of 120.

The Effect of Age on Phosphate Fractions in the Heart of the Rat. GUS G. CASTEN,* and M. F. MASON, Dallas, Texas. (Introduced by Tinsley R. Harrison).

A comparison has been made between young adult male rats (about 3 months old) and elderly male rats (about two years old) in regard to the content of the heart in various phosphate fractions. No significant difference was found in regard to the inorganic phosphate or the adenosine triphosphate. Striking differences were observed in the creatin phosphate fraction which was about twice as great in the young as in the older rats. Since the creatin phosphate constitutes the reserve from which adenosine triphosphate, the direct source of energy, may be derived under conditions of stress, the findings are in general agreement with the conception that aging is associated with a decline in the reserve power of the heart. The reasons why heart and skeletal muscle (as judged from the work of others) differ in respect to the effect of age on creatin phosphate content are not clear.

Further studies dealing with the effect of experimental heart failure on the various phosphate fractions are in progress.

Sulfathiazole as a Substitute for Inulin in Determining the Glomerular Filtration Rate. DON W. CHAPMAN, and S. A. PEOPLES, Houston, Texas, (Introduced by James A. Greene).

An accurate method for measurement of glomerular filtration has been developed, by which a larger number of patients can be studied more quickly, and is simple enough for routine clinical studies.

Sulfathiazole was given orally and its clearance compared with that of inulin. Urine specimens were obtained by catheterization at twenty or thirty minute intervals, and blood samples were drawn at the mid-points of each interval. The urine and plasma were analyzed for sulfathiazole by the method of Bratton and Marshall and the plasma albumin by the method of Greenberg. The free plasma sulfathiazole was calculated from the total plasma sulfathiazole, from the concentration of plasma albumin by means of the adsorption formula

$$\frac{\text{Free Sulfa}}{\text{Total Sulfa}}=\frac{1}{K\times \text{Albumin Conc.}+1}, \quad \text{where} \quad K=0.45.$$

The K value was obtained from simultaneous clearance studies of inulin and sulfathiazole in humans.

Maximum deviation of simultaneous clearance of inulin and sulfathiazole in 25 patients was 11 per cent, and an average deviation of 6 per cent. The data show that sulfathiazole clearance is as reliable as inulin clearance in patients with normal and with reduced renal function.

Study of Standard Metabolism in Relation to Degenerative Processes in the Aged. MARGARET CHIEFFI, St. Louis, Mo. (Introduced by William B. Kountz).

A detailed study was made on about 500 patients over 40 years of age. Some of these were followed over an extensive period, up to eight years, and were studied repeatedly.

The individuals were either residents in a chronic disease hospital or were visitors to a private clinic. The result of the studies showed the individuals to form a series varying from those with earliest signs of degeneration (which on repeated study were found to be progressive) to those with advanced degenerative changes.

Many interesting variations were noted in a study of the different tests. Changes in the basal metabolism seemed to be the most significant and the results will be considered.

In those individuals with early degenerative changes the metabolism was usually low, varying from -10 to -28 and averaging about -15.

The individuals with advanced degenerative changes and with residuals of diseases such as coronary artery disease, intracranial lesions etc. frequently show an elevated basal metabolic rate not only as compared with the first group but even compared with the normal standard. Repeated studies in these individuals showed a rising metabolic rate.

Results of attempts to modify the metabolism by feeding experiments and administration of hormones will also be discussed.

Rapid Quantitative Assay of Proteolytic Enzyme Inhibitors in a Fibrinogenolytic System and the Significance of the Plasma Inhibitor in Experimental Peritonitis in the Dog. DONALD G. C. CLARK, New Haven, Conn. (Introduced by John S. Lockwood).

Preliminary investigation of experimental peritonitis in the dog has suggested that the level of proteolysin inhibitor in the plasma is a factor in the ability of the animals to survive the disease. In this work 29 pairs of dogs were subjected to peritonitis; one of each pair was prepared by the daily injection of protease for 5 days prior to operation in an attempt to raise the level of proteolysin inhibitor, as suggested by the work of Grob, while the other of each pair was used as a control. The difference in mortality was significant, 5 dogs dying from the prepared group (17.2 per cent) and 20 from the control series (68.9 per cent).

Since the difference in mortality appeared to be a result, at least in part, of the much more marked production of fibrin around the abscess in the treated animals, as shown at autopsy, it was felt that the effect of the proteolysin-inhibitor system on the stability of fibrinogen might be the significant factor. This, together with the fact that fibrinogen is highly sensitive to the action of proteolysins such as trypsin, led to the development of an assay method employing fibrinogen as the substrate.

In the method serial dilutions of serum from the animal are allowed to react with a known amount of trypsin for a fixed period to allow the proteolysin and proteolysin inhibitor to react together. Then a standard quantity of

lysin-free fibrinogen is added. The formation of a clot upon addition of thrombin, after a standard period of incubation at 37 C., indicates that the trypsin has been inhibited, and affords a clear-cut end-point; no clot forms if the quantity of inhibitor has been insufficient to block the added trypsin. Temperature, pH, and timing of the various phases of the reaction must be carefully controlled.

The normal dog shows a level of inhibitor equivalent to from 300 gamma to 450 gamma crystalline soy bean trypsin inhibitor (Kunitz) per ml. serum. Following injections of protease, however, the inhibitor level at first falls and then returns to the initial level with increasing speed on each subsequent injection. The length of the recovery period decreases from about 9 hours after the initial injection to about 1 hour after the fifth injection. Also, in most animals the titre increases gradually with each successive injection to about double the original value. In about one-quarter of the animals studied this absolute increase did not develop.

It seems probable that a stable equilibrium between plasma protease and its inhibitor is a factor in the effective deposition of fibrin within the peritoneal cavity, and in recovery from peritonitis.

The Effect of Castration and Di-ethyl Stilboestrol in a Patient with Myelophthisic Anemia Secondary to Carcinoma of the Prostate. Robert R. Commons (by invitation) and Maurice B. Strauss, Framingham, Mass.

Severe myelophthisic anemia may be the first and outstanding manifestation of carcinoma of the prostate with widespread skeletal metastases. Three such cases have been observed, in none of which were prostatic symptoms presenting.

The first two of these patients, observed prior to the introduction of castration and female sex hormone administration in the treatment of prostatic cancer, died within a few months of diagnosis, with their anemia controlled only by blood transfusion. The third patient was castrated after a three weeks intensive course of liver and iron therapy had been accompanied by a further decline in blood values. Five mg. of di-ethyl stilboestrol was then administered by mouth daily. No other treatment was employed. Bone pain, ascribable to metastatic skeletal involvement, disappeared within four weeks. No reticulocyte increase occurred but a definite slow rise in red blood cells and hemoglobin occurred from an original level of 1,990,000 erythrocytes per cu. mm. and 5.1 gm. of hemoglobin per 100 cc. to values of 3,530,000 and 11.0 gm. two months after the institution of treatment. Nucleated red blood cells, which had been present in the proportion of 1 to 100 leukocytes, disappeared from the peripheral blood.

Since neither castration nor the administration of diethyl stilboestrol has been reported to produce increases in red blood cells and/or hemoglobin in man or animals, it appears probable that one or both of these procedures so affected the cancerous metastases in the bone marrow of this patient that more normal hematopoiesis took place. It is of interest that in spite of the striking change in the blood values, x-ray examination failed to show any change in the extent or severity of the bone changes.

The Effect of the Upright Posture upon Hepatic Blood Flow in Normal and Hypertensive Human Subjects. James W. Culbertson (by invitation), Robert W. Wilkins, Franz J. Ingelfinger and Stanley E. Bradley, Boston, Mass.

Hepatic blood flow was estimated in seven normal and twelve hypertensive subjects by means of the bromsulphalein clearance technique with hepatic venous catheterization. Arterial pressure and pulse rate were recorded at two-to five-minute intervals throughout the two-hour test.

Each subject was placed supine on a tilt-table and studied first in a horizontal position, then after being tilted upright (75°), and then in the horizontal position again. Serial pairs of peripheral and hepatic venous blood samples were drawn at five- to ten-minute intervals, three or more for each tilt-table position unless syncope intervened during the upright study.

Values for estimated hepatic blood flow in both groups of subjects before tilting fell within normal range and averaged 1400 ml. per minute per 1.73 sq. m. of body surface. After the tilt to upright the values decreased sharply by 15 to 60 per cent, with an average approaching 40 per cent and no significant difference observed between normal and hypertensive individuals. Following return of the table to the horizontal position hepatic blood flow increased, rising toward or above the pre-tilt control rate.

These results are interpreted as indicating that splanchnic vasoconstriction occurs in the upright position, since the decreases in blood flow could not be accounted for by significant changes in blood pressure.

An Objective Method for Evaluating the Anti-Asthmatic Effect of Several Sympathomimetic Amines in Man. John J. Curry, Boston, Mass. (Introduced by Francis C. Lowell).

The effectiveness of various anti-asthmatic compounds usually has been determined by analyzing the subjective response of large groups of patients. Measurements of increase in vital capacity following the administration of various drugs during the acute asthmatic attack have also been made. Both types of study, however, are subject to unaccountable variations and are difficult to evaluate.

It has been shown that a quantitative decrease in the vital capacity may be produced in certain asthmatic subjects, during periods when they are relatively asymptomatic, by the parenteral administration of histamine and acetyl-beta-methyl choline. Various sympathomimetic amines, anti-histamine compounds and anti-cholinergic agents protect these subjects against the reduction in vital capacity in a characteristic fashion. These findings suggested that the degree of such protection, afforded by various anti-asthmatic drugs, might furnish an objective method for assaying their effectiveness in the treatment of asthma.

In the present study, using this method, several sympathomimetic amines were compared with ephedrine sulfate. Only one compound, beta-o-methoxyphenyl isopropyl methylamine, compared favorably with ephedrine. This was of interest since the compound has little pressor

or C.N.S. stimulating effect. Clinical studies in a group of asthmatic patients supported the results of the assay and the validity of the method.

Relative Importance of Tonicity and of Extracellular Volume in Salt Depletion Shock. T. S. DANOWSKI, A. W. WINKLER and J. R. ELKINTON, New Haven, Conn.

Studies have been conducted to determine whether salt depletion shock is mediated primarily through hypotonicity or through a decrease in the volume of the extracellular fluid. Previously reported experiments indicated that in the salt depleted animal restoration of extracellular and plasma volume without replacement of salt failed to improve the circulation. The results suggested that the hypotonicity and associated cellular overhydration had a deleterious effect *per se*.

In the present experiments hypotonicity of body fluids in the presence of a normal salt content was produced in 3 nephrectomized dogs by the infusion of glucose solution. Changes in the electrolyte and water content of plasma, extracellular fluid, and of cells were calculated and alterations in the hemodynamics (cardiac output, circulation velocity, and mean arterial pressure) were measured.

Those animals in whom body fluids had been diluted resembled those depleted of salt in that hypotonicity was present. They differed, however, in that the extracellular volume was expanded rather than contracted, and despite the hypotonicity, the circulatory efficiency was unimpaired or improved.

In 2 other animals salt depletion shock was produced by the Darrow-Yannett technique. Subsequently a diuresis was induced by intravenous urea solution and the hypotonicity which resulted from the salt depletion was corrected. The extracellular fluid volume declined further, however, and despite the restoration of isotonicity the cardiovascular function did not improve.

It is concluded that within certain limits both tonicity and extracellular volume, *i.e.*, the amount of salt present, must condition the development of salt depletion shock.

Streptomycin in the Treatment of Pulmonary Tuberculosis. NICHOLAS D. D'ESOPO, STANTON T. ALLISON, BENJAMIN L. BROCK, W. A. CASSIDY, and ARNOLD SHAMASKIN, Baltimore, Md. (Introduced by James Bordley III).

120 cases of pulmonary tuberculosis were treated for 4 months with 1.8 grams of streptomycin intramuscularly daily. Patients were selected on the basis of stationary or progressive lesions with an important exudative component during a pre-treatment observation period of at least 3 months. The majority were far-advanced.

Mean blood levels of 18 micrograms and 10 micrograms of streptomycin per cc. after 1 and 4 hours respectively were obtained.

Decline in fever, increased appetite, gain in weight, and a marked decrease in sputum amount were consistently observed.

Resolution of lesions, to a greater or lesser extent, was noted in 77 per cent. In 18 per cent the degree of resolution was striking. No new lesions developed under treatment, nor did established lesions progress. The most favorable effect was seen in cases of predominantly exudative disease. Cavities tended to become smaller, but unequivocal closure was infrequently observed.

Sputum or gastric cultures became negative in 30 per cent of patients.

Toxicity was manifested by subjective vertigo in 90 per cent, an abnormal urinary sediment in 50 per cent, and a transient rash in 10 per cent. Treatment was discontinued in 3 cases.

After 6 weeks the tubercle bacilli of 27 per cent showed in vitro resistance to concentrations of streptomycin obtained at this dosage; and at 4 months 53 per cent developed resistance. In the great majority resistance developed abruptly.

Streptomycin is most useful in controlling symptoms and the recent exudative lesion. It is suppressive rather than definitive therapy. The development of resistant organisms is a disadvantage since there is an inverse correlation between resistance and therapeutic response.

Cardiac Oxygen Metabolism. J. E. ECKENHOFF, J. H. HAFKENSCHIEL and M. HARMEL, Philadelphia, Pa. (Introduced by Francis C. Wood).

In spontaneously breathing dogs lightly anesthetized with nembutal, coronary blood flow was measured by the bubble flowmeter technic and cardiac metabolism determined by a method previously described. In an attempt to elucidate the inter-relationships of coronary flow, arterial pressure, cardiac output, cardiac efficiency and cardiac oxygen metabolism, three groups of experiments were performed in which (1) arterial pressure, (2) cardiac output or (3) arterial oxygen content was primarily altered. In (1) and (2) coronary flow consistently followed cardiac oxygen consumption and in (3) coronary flow was found to increase as needed to meet cardiac oxygen requirements. The data indicate that the coronary vessels, like the cerebrals, possess an effective intrinsic control in relation to the metabolic requirements of the tissue supplied. Cardiac efficiency tended to vary directly with cardiac output and inversely with arterial blood pressure. Since coronary venous blood under the conditions of these experiments normally contained only 4 to 6 vol. per cent oxygen, there is obviously little room for removing appreciably larger amounts of oxygen. Agents intended to accomplish this are therefore open to question. The heart was found to be safeguarded from dangerous anoxia by three mechanisms: (1) decreased tonus in the coronary vessels, (2) diversion of a relatively larger fraction of the cardiac output to the coronary circulation, (3) decreased cardiac work with a resultant decrease in oxygen demand.

The Administration, Utilization and Excretion of a Mixture of Amino Acids in Man. R. D. ECKHARDT and T. L. MURPHY (by invitation), and C. S. DAVIDSON, Boston, Mass.

The 10 per cent solution of the ten "essential" amino acids used in these studies was prepared by complete acid hydrolysis of casein, was rendered free of aspartic and glutamic acids, and was fortified with dl-tryptophane, dl-

methionine and glycine. In over 150 injections reactions were rare, and none of a pyrogenic nature was observed. Injections of 500 cc. (50 gm. amino acids) in 10–15 minutes rarely induced vomiting, although transient nausea occurred in approximately one-fourth of these cases. At a slower rate (one hour), even nausea was rare. Thrombosis of the infusion vein did not occur.

The blood amino acid level returned to within normal limits by four hours after the infusion, although it was often slightly above the pre-injection level. During this time, the maximum loss of the injected amino acids occurred (average 8 per cent). Urinary amino nitrogen excretion did not correlate with the rate of infusion, but was roughly proportional to the amount given and to the total 24-hour urine nitrogen.

Comparison was made between the percentage composition of the essential amino acids administered and excreted (microbiological assay). Lysine, methionine, phenylalanine and valine were excreted in approximately the same percentages as administered; histidine, threonine and tryptophane, in two to three times greater percentages; and arginine, leucine and isoleucine proportionately less.

The Restoration of Thermal Balance During Acclimatization to Work in a Hot Dry Environment. LUDWIG W. EICHNA, (by invitation) CHARLES R. PARK, NORTON A. NELSON, EDWARD D. PALMES, STEVEN M. HORVATH and WALTER B. SHELLEY and WILLIAM B. BEAN, Fort Knox, Ky.

When man first works in a hot environment his body temperature rises to abnormally high levels and disability often results. When acclimatized to the heat he performs the same work easily and with a lower, or normal, temperature. The methods of partitional calorimetry were used to determine the mechanisms responsible for this reduced heat retention.

Thermal balances were determined in 3 nude men as they acclimatized to work in a hot, dry (desert type) environment.* With acclimatization the bodily heat content fell; with deep tissues heat content reaching normal values but that in the peripheral tissues (skin) remaining above normal. Approximately 90 per cent of the total decrease in heat retention with acclimatization was due to increased evaporative cooling (increased secretion and evaporation of sweat); the remaining small decrease (10 per cent) resulted from a slight fall in metabolic heat production. Because of the increased evaporative cooling the skin temperature fell with acclimatization. This led to increased heat gains from the environment by convection and radiation as acclimatization developed. These increased external heat gains amounted to approximately 50 per cent of the increase in evaporative cooling and to that extent decreased the efficiency of the increased evaporative cooling in lowering the body temperature. However, the lower skin temperature promoted heat loss from deep to peripheral tissue by conduction and increased the cooling gradient for the blood brought to the skin. This permitted a reduced peripheral blood flow to the skin and thereby a more stable general circulation.

* Dry bulb temperature 102° F., wet bulb temperature 80° F.

The Mechanism of Blood Destruction in Congenital Hemolytic Jaundice. CHARLES P. EMERSON, JR., and SHU CHU SHEN (by invitation), THOMAS HALE HAM and WILLIAM B. CASTLE, Boston, Mass.

Twenty-nine patients with congenital hemolytic jaundice were studied with particular reference to the nature of the red cell abnormality and the role of the spleen in this hemolytic syndrome. When subjected to sterile incubation *in vitro,* their red cells exhibited abnormally prompt increase in osmotic and mechanical fragilities. In certain individuals with minimal signs of hemolytic disease, who were members of the affected families, this increased mechanical fragility and susceptibility to incubation were the only evidences of red cell abnormality.

Eleven patients with congenital hemolytic jaundice were subjected to splenectomy. Red cells derived from the peripheral blood and from the splenic pulp were compared with respect to their osmotic and mechanical fragilities, and response to incubation. Similar studies were carried out on five patients subjected to splenectomy for conditions other than congenital hemolytic jaundice. Their red cells behaved like normal red cells. However, in all the cases of congenital hemolytic jaundice, the splenic pulp contained a high proportion of red cells that were markedly susceptible to hemolysis in hypotonic solutions and to mechanical trauma when compared to those in the peripheral blood. Post-splenectomy studies of the peripheral blood indicated a rapid disappearance of that portion of the heterogenous red cell population previously exhibiting the most marked increase in osmotic fragility and a return of the mechanical fragility of the blood nearly to normal.

Five patients were given several days before splenectomy massive transfusions of compatible blood possessing immunologic properties which distinguished it from the blood of the recipient. Employing selective agglutination technics it was ascertained that, in contrast to the patient's red cells, the osmotic fragility of these donor cells, including those separated from the splenic pulp, had remained unaltered. Finally, the ratio of patient's cells to donor's cells was found to be distinctly greater in the splenic pulp than in the peripheral blood, suggesting that selective retention of the patient's red cells had occurred. These data indicate that the hemolytic activity of the spleen, in congenital hemolytic jaundice, may derive solely from the fact that this organ serves as a locus of "erythrostasis," a process which *in vitro* demonstrably results in the rapid deterioration of the inherently defective red cells characteristic of the disorder.

The Effect of Diabetes and Insulin on Glucose Tm. SAUL J. FARBER and EUGENE Y. BERGER (by invitation), and DAVID P. EARLE, JR., New York, N. Y.

A high renal threshold for glucose in diabetics has generally been attributed to a low glomerular filtration rate in the presence of a normal glucose reabsorptive capacity. Glucose Tm, or maximum amount of glucose that can be reabsorbed per unit of time, is quite constant

for an individual under standard conditions. Smith *et al.* found the average glucose Tm of normal women to be 303 mgm. per minute ($\sigma = 55.3$). Glucose Tm's determined in normal subjects in this laboratory have fallen within this range. Observations on a limited number of middle aged female diabetic patients have shown an average glucose Tm of 433 mgm. per minute (Range = 401 to 460). The glomerular filtration rates of these patients were normal. The average ratio of filtration rate to glucose Tm was 0.270 as compared to the normal value of 0.395 ($\sigma = 0.0617$).

The continuous intravenous administration of small amounts of insulin to both normal and diabetic subjects resulted in a decrease in glucose Tm in all but one experiment. The average glucose Tm during insulin administration was 10 per cent under control values. Single injections of insulin resulted in transient decreases in glucose Tm of similar magnitude.

Studies on the Rate of Excretion of Water and Electrolyte by Young Infants. Gladys J. Fashena, Dallas, Texas.

Normal infants in the first six months of life, when given isotonic sodium chloride solution parenterally at the rate of 1 per cent of body weight per hour for five hours, excrete the excess loads of water, sodium, and chloride more slowly than adults. In twenty-four hours the average sodium excretion is 75 per cent of the load and the average chloride excretion 91 per cent of the load. The velocity quotients for sodium range between 0.03 and 0.06, for chloride between 0.04 and 0.07 and for water between 0.02 and 0.1. Two infants, recently recovered from dehydration and acidosis, show further impairment of their ability to excrete electrolyte. In these the velocity quotients of sodium and chloride were in the neighborhood of 0.01 and 0.02 respectively and both subjects became slightly edematous during the experiment. It is not known how frequently this type of response follows an episode of dehydration and acidosis and further studies on this point are in progress.

Methemoglobin Reconversion in the Erythrocyte. Clement A. Finch, Howard A. Eder, and Ralph W. McKee, Boston, Mass. (Introduced by George W. Thorn).

Hemoglobin in solution is spontaneously converted to methemoglobin. In the normal erythrocyte this is prevented by a system deriving its energy from carbohydrate metabolism. Studies of a patient with congenital methemoglobinemia have shown an intrinsic defect of the erythrocyte with complete failure of the normal reconversion mechanism. In the absence of cell reconversion, reducing substances appear to regulate the hemoglobin-methemoglobin equilibrium. The role of reducing substances was studied in this patient. It was also observed that methylene blue was able to activate in this patient the cell reconversion mechanism and the immediate and long term effects of methylene blue were studied. The effectiveness of ascorbic acid and methylene blue therapy has been evaluated in different etiological types of methemoglobinemia.

*The Effectiveness in Experimental Syphilis of Penicillin in Peanut Oil-Beeswax Given in Sixteen Daily Injections.** William L. Fleming, Boston, Mass.

Seventy male rabbits inoculated intratesticularly with the Nichols strain of *T. pallidum* were proven to be syphilitic by demonstration of typical spirochaetes from testicular chancres. Eight weeks after inoculation they were treated with sixteen daily intramuscular injections of calcium penicillin suspended in peanut oil containing 4.8 per cent of beeswax by weight volume. Ten rabbits were treated at each of seven total dosage levels: 250, 500, 1,000, 2,000, 4,000, 8,000, and 16,000 units per kilogram. The concentration of penicillin had to be varied in order to administer the different dosages and was of necessity lower than that of the Romansky Formula. Proof of cure or treatment failure was determined by the dark-field examination of chancres or lesions suggestive of infectious relapses, and by lymph node transfers six months after treatment.

Results indicate that the C.D./50 (minimal dose necessary to cure 50 per cent of rabbits) was between 1,000 and 2,000 units per kilogram. This indicates effectiveness in the same order of magnitude as samples of a crude commercial penicillin and of crystalline penicillin G previously assayed after administration in intramuscular injections of aqueous solution every three to four hours for ninety-six hours.

Studies on the Relation of the Serum Albumin to the Formation of Bone Matrix. Anne P. Forbes, Boston, Mass. (Introduced by Fuller Albright).

Osteoporosis is defined as that form of demineralized bone where the defect is in laying down the bone matrix. It has certain clinical characteristics which make its differentiation from other forms of demineralized bone certain. A case is presented with all the characteristic criteria of this disease in which the usual causes (post-menopausal state, disuse, Cushing's Syndrome, malnutrition, et cetera) were not present. The studies include metabolic balances of calcium, phosphorus and nitrogen in relation to the levels of the serum proteins. Various therapeutic regimens were tried. These included therapeutic abortion, plasma by vein, serum albumin by mouth and by vein, high and low protein diets, large doses of Stilbestrol, and Vitamin A. The evidence suggests that bone matrix formation is influenced by the serum albumin level.

Chemical and Electrophoretic Analyses of the Tissue Proteins in Shock from Tourniquet Injury or Burns. Charles L. Fox, Jr., and Dan H. Moore, New York, N. Y. (Introduced by A. R. Dochez).

Experiments were performed to test whether plasma proteins accumulate in tissues traumatized by tourniquetting or burning. Single hind legs of mice were injured by the application and release of tight tourniquets or scalding. When swelling was greatest and shock profound, both hind legs were amputated at the groin and the entire leg analyzed for water and total nitrogen.

* Done under an U.S.P.H.S. Research Grant.

For electrophoretic analysis, similar legs were extracted in chilled buffer.

Injured legs did not contain more protein than contralateral, uninjured legs. If the fluid gained by the injured legs were chiefly plasma, approximately 10 to 20 per cent (20 to 50 mg.) more protein might be expected.

Electrophoretic analyses of the injured leg fluid disclosed no component with the mobility of albumin. Instead a faster, new component appeared; this was resolved from plasma albumin in artificial mixtures. In the ultracentrifuge, its sedimentation constant was greater than albumin.

These chemical, electrophoretic, and ultracentrifugal analyses dispute the view that plasma proteins accumulate in tissues injured by tourniquetting or scalding.

The Ventricular Gradient in Fever. A. S. FREEDBERG and M. J. MCMANUS, Boston, Mass. (Introduced by H. L. Blumgart).

Published studies of the electroardiographic changes during infections stress the occurrence of ST and T wave abnormalities. In these reports, however, it is often impossible to distinguish the effects of fever per se from those of myocardial changes due to many other factors commonly present in infectious disease. The method of Wilson *et al.* for determining ventricular gradients was therefore applied to 3 standard limb lead electrocardiograms obtained during fever induced by intravenous injection of typhoid vaccine in 9 human subjects.

The ST segment depression and T wave inversion occurring in typhoid vaccine fever are (a) primary and (b) secondary. The latter may be related to increased rate and/or a change in heart position. The former resemble the changes observed after digitalis administration and indicate a physiologic alteration in the myocardium related to the induced fever. In two patients pronounced shift in ventricular gradient direction occurred in the chill and flush phase. This indicates a local alteration in duration of the excited state, similar to that observed in local myocardial ischemia. These alterations in ventricular gradient consequent to fever must be considered in the interpretation of T wave and ST segment changes in febrile states, both endogenous and physically induced.

Assay of Urinary Estrogens by Ultraviolet Absorption Spectrophotometry. HARRY B. FRIEDGOOD and (by invitation), JOSEPHINE B. GARST, Pasadena, Calif.

Previous studies have demonstrated that ultraviolet absorption spectrophotometry can be applied to the quantitative determination of pooled or single samples of crystalline estrone, estradiol and estriol by virtue of the type of absorption curves and concentration-extinction relations which these hormones exhibit under controlled experimental conditions. Further investigations with this quantitative technic have disclosed that current chemical methods do not effect a clean-cut separation of the androgens from the estrogens or of estriol from the estrone-estradiol fraction. The significant losses of estrogens involved in these manipulations have been difficult, if not impossible, to estimate accurately because of the relative lack of sensitivity of the colorimetric and bioassay methods of quantitation as compared with that of ultraviolet absorption spectrophotometry. On the basis of these findings, a new method has been developed for the accurate separation and assay of the three estrogens in aqueous-alcoholic solution. A study has been made of the factors involved in the application of ultraviolet absorption spectrophotometry to the extraction and separation of the estrogens from urine—with particular reference to the removal of the background material which interferes with the quantitative reading of the estrogen curves.

The Relationship between Calcium and Digitalis Glycoside in Respect to Their Action upon the Embryonic Duck Heart. MEYER FRIEDMAN and (by invitation) RENÉ BINE, JR., San Francisco, Calif.

The embryonic duck heart was found to be similar to the mammalian heart in its response to excess digitalis glycoside (Lanatoside C.), in that it reacted to the presence of the latter drug by (1) acceleration of rate, (2) increased force of contraction and (3) appearance of arrhythmia. This particular property of the embryonic heart, together with its ability to beat weakly but persistently in the complete absence of calcium or in an excess of the latter, allowed an unique opportunity for the study of the relationship between calcium and digitalis glycoside in their effects upon the heart. The absence of an extrinsic nerve supply to the embryonic heart (at stage of development, used) allowed such a study to be strictly of the cardiac musculature, alone.

The completed studies indicated that the action of calcium alone was completely dissimilar to that of digitalis, irrespective of the concentration of the former. Furthermore, it was found that the calcium ion and the digitalis glycoside employed, bore no synergic relationship to each other in respect to their individual or combined effects upon the heart. Finally, it was discovered that the characteristic action of digitalis was not inhibited by the complete absence of the calcium ion.

Arterial Pressure Pulse Waves in a Patient with Coarctation of the Aorta. MORTON GALDSTON (by invitation) and J. MURRAY STEELE, New York, N. Y.

Arterial pressure was recorded with Hamilton manometers simultaneously in radial and femoral arteries of a middle aged patient suffering from coarctation of the aorta. The usual pressure differences were observed (radial 215–225/100 mm. Hg; femoral 150/100 mm. Hg).

Of greater interest than these differences was the remarkable similarity between pulse waves from the left radial and left subscapular collateral artery, in spite of entirely different physical arrangements of the arterial tree distal to the points from which these pressure waves were recorded, as observed at autopsy. The radial arteries were of normal origin and distribution. The enlarged, tortuous subscapular arteries joined enlarged 5th and 6th intercostal arteries which entered the aorta below the coarctation. The main collateral vessels emptied into enlarged 3rd and 4th intercostal arteries just

below the coarctation, the lumen of which measured 0.5 cm.

Since variations in form of pressure curves in the arterial tree are considered to be influenced partly by waves reflected from distal arterioles and to a lesser degree by standing arterial waves, the similarity of the radial and collateral artery pulse waves is difficult to explain. A similar form of pulse wave has been demonstrated in another patient with coarctation of the aorta and in patients with hypertension when the artery was partially constricted above the point of recording.

Studies of the Relationship of Niacin and Tryptophane in Human Metabolism. GRACE A. GOLDSMITH and (by invitation) HERBERT P. SARETT, New Orleans, La.

Metabolic balance studies were conducted for six weeks in three persons on corn or wheat diets, which provided 38 or 43 gm. of protein, 5.5 or 6.0 mg. of niacin, 0.3 or 0.5 gm. of tryptophane, and about 2500 calories, 0.7 mg. of thiamine and 0.5 mg. of riboflavin daily (calculated). The corn diet included 190 gm. of degerminated corn meal and grits and 60 gm. of white unenriched flour; the wheat diet, 250 gm. of the white flour. The urinary excretion of riboflavin and thiamine decreased rapidly on the basal diets and remained low throughout the experiment, while that of niacin was unchanged. The daily output of N^1 methylnicotinamide was 2 mg. or less on the wheat diet and decreased further on the corn regimen. After ten days of the basal corn or wheat diet, 5 gm. of dl-tryptophane was administered daily for 8 days. This resulted in an increased daily excretion of 6 to 12 mg. of N^1 methylnicotinamide.

A test dose of niacin, thiamine, and riboflavin was given at the end of the tryptophane experiment. The urinary excretion of N^1 methylnicotinamide was normal, of riboflavin, low normal and of thiamine, very low in two and normal in one patient. No signs of vitamin B complex deficiency developed and no significant change in serum proteins or in the blood picture occurred during this study.

Findings suggest that tryptophane is an important precursor of niacin in humans and may contribute to the body stores of this vitamin.

Studies of Immunity in Brucellosis: The Bactericidal Action of Human Blood Against Brucella. WENDELL H. HALL (by invitation) and WESLEY W. SPINK, Minneapolis, Minn.

The information available concerning the role of humoral antibodies in brucellosis is confusing. The present study has revealed that the killing action of normal human blood for Brucella does not require the presence of leukocytes. The effective antibody in serum is heat-stable, and complement is necessary for its optimum bactericidal action on Brucella. *Br. abortus* (16 strains) was more readily killed than *Br. suis* (3 strains) or *Br. melitensis* (1 strain).

Bactericidal tests were performed by adding serial dilutions of Brucella to standardized amounts of fresh serum and incubating the mixtures for 24 hours. No killing of *Br. abortus* was obtained with sera from 10 infants 4 to 16 months of age. Sera from older children had the same action as those from adults. Forty-five adult sera killed 18 to 180,000 *Br. abortus* cells (strain 524) per ml. of serum (median 15000). Twenty-eight sera without agglutinins for Brucella from 14 individuals having dermal hypersensitivity for Brucella killed 18 to 18,000 Brucella (median 5000). The bactericidal power of 89 sera containing agglutinins from 26 patients having positive intradermal Brucella tests but no demonstrable bacteremia ranged from 0 to 1,800,000 (median 500). Forty-six sera from 13 patients having bacteremia due to *Br. abortus* killed only 0 to 180 organisms (median 36). The low bactericidal action of the latter group exhibited a pro-zone phenomenon in that the action was greatly increased by diluting out the sera and adding infants' sera for complement. This pro-zone phenomenon appears to be due to an excess of antibody. The killing action of normal sera having a high bactericidal titer is inhibited by the addition of sera from patients with bacteremia.

Pathogenesis of Pneumonia Secondary to Influenza. CARL G. HARFORD and (by invitation) HELEN V. LEIDLER, St. Louis, Mo.

Mice with sublethal influenza viral infection of the lung succumb more readily than normal mice to bacterial infection induced by inhalation of fine droplets containing pneumococci. A study of this phenomenon was designed to elucidate principles applicable to the general problems of respiratory infection.

Although it is known that marked multiplication of virus occurs in the lungs of mice within twenty-four hours after inoculation, microscopic lesions from the virus are not present at this early stage. On the other hand, histological lesions in the lung due to viral action are fully developed five days after inoculation.

Bacterial counts of the left lobes of the lungs of normal mice have shown a marked reduction in the number of pneumococci within six hours after inhalation and a similar reduction has been found in mice with twenty-four hour viral infections. In contrast, bacterial counts of the lungs of mice with five day viral lesions have demonstrated growth within six hours.

These observations indicate that the effect of the virus in lowering resistance to secondary bacterial infection is not dependent on the presence or multiplication of the virus in pulmonary tissue but is associated with the histological lesion produced by viral action.

The Pathogenesis of Circulatory Failure in Rocky Mountain Spotted Fever: Alterations in the Blood Volume and Thiocyanate Space at Various Stages of the Disease. GEORGE T. HARRELL and (by invitation) JERRY K. AIKAWA, Winston-Salem, N. C.

Previous investigation has shown that peripheral circulatory collapse in Rocky Mountain spotted fever is accompanied by a drop in serum proteins and the development of generalized edema.

Serial determinations of the blood volume and "extravascular thiocyanate space" were done at intervals during the course of the disease, and were compared with the

serum protein levels and with the intake and output of fluid. The blood volume was found to drop simultaneously with an increase in thiocyanate space; the magnitude of the alteration in the thiocyanate space was greater than that in the blood volume. These changes occurred between the tenth and the twelfth days of rash, and could be correlated with the clinical severity of the disease; a return to normal values took place early in convalescence, and was accompanied by diuresis.

The drop in serum proteins was preceded by an increase in urinary nitrogen excretion and could be partially alleviated by a very high-protein diet. Capillary permeability was altered in the disease, so that protein, electrolytes, and water escaped into the interstitial spaces. These changes occurred in 6 patients who received specific therapy in the form of hyperimmune antiserum or PABA, as well as in 7 patients who received supportive therapy only.

Similar alterations in blood volume and thiocyanate space have been produced experimentally in rabbits with serum sickness. An allergic mechanism may be responsible for the alteration of capillary permeability, although allergy in rickettsial diseases has not yet been demonstrated. Proper replacement of protein and the avoidance of excessive administration of crystalloids should help to prevent circulatory and respiratory failure. These principles of supportive therapy are probably applicable to other infectious diseases.

Penicillin Protection Against Bacterial Endotoxins. WALTER D. HAWK and ALDEN K. BOOR, Chicago, Ill. (introduced by C. Phillip Miller).

Penicillin provides a certain degree of protection for mice against intraperitoneal injections of the endotoxins of several gram negative bacteria.

The endotoxins against which a penicillin effect has been demonstrated have been prepared from meningococcus, gonococcus S. Paratyphi A., S. Paratyphi B., Shigella paradysenteriae, S. Enteriditis, S. Aertryeke and A. Aerogenes. Organisms are grown on solid media, harvested, washed in saline, lysed by dilute alkali (pH 8.0) sterilized by heat and finally cultured for proof of sterility. Graded doses of this endotoxin are given to mice intraperitoneally in order to determine its LD50 respectively for penicillin-treated and for untreated mice.

It is evident from a careful review of the data, that when penicillin is given in adequate amounts during the period preceding and shortly after endotoxin, a definite increase in LD50 follows.

Injection of control mice with the various materials used as vehicles for penicillin affords no protection.

Autopsy cultures of a representative number of mice have given no evidence of terminal infections to account for the higher mortality among controls.

Protection has evidently been provided, by means of penicillin administration against the endotoxins of all of the above named organisms. This result has not been apparent with the endotoxin of Shigella Shigae nor with several non-bacterial poisons tested.

The mechanism of this effect of penicillin cannot at present be explained.

Study of Folic Acid for Maintenance Therapy in Pernicious Anemia. ROBERT W. HEINLE and (by invitation) JANET T. DINGLE and AUSTIN S. WEISBERGER, Cleveland, Ohio.

Forty-one patients with pernicious or allied anemia were maintained on folic acid therapy for periods to one year. In 32 patients followed longer than six months, hematologic relapse occurred in nine who received intramuscular injections of 50 or 150 mg. at three- to six-week intervals. Relapse did not occur in any patient receiving daily oral doses of 10 to 40 mg.

Hematologic improvement occurred in six of the 41 patients. Three received daily oral therapy and three were given 45 or 50 mg. intramuscularly every two or four weeks.

Six patients in relapse responded adequately and have been maintained in good hematologic remission with folic acid.

Three of the 41 patients developed neurologic relapse while in hematologic remission. This complication was explosive and rapidly progressive in one. Liver extract therapy arrested the neurologic relapse in these patients.

It is concluded that daily oral therapy with ten or more mg. of folic acid maintained hematologic remission in these patients whereas intermittent intramuscular therapy permitted relapse in some cases. The occurrence of neurologic relapse indicates that folic acid is not a complete substitute for liver extracts, so that the latter must remain the treatment of choice for pernicious anemia.

Arterial Catheterization of the Left Ventricle, Left Auricle, and Pulmonary Vein. HARPER K. HELLEMS * (by invitation), LEWIS DEXTER and (by invitation), FLORENCE W. HAYNES, Boston, Mass.

Venous catheterization has made possible exploration of the right side of the heart and pulmonary artery, but has not been applicable to investigation of the dynamics of the left side of the heart and pulmonary vein. In the past, these chambers have been almost immune to investigation except by difficult and time-consuming procedures.

In the present study, a No. 6 French radiopaque catheter, with a curved tip as used for venous catheterization, has been introduced into the carotid artery of anesthetized dogs and guided fluoroscopically into the aorta, left ventricle, left auricle, and pulmonary vein. This may be accomplished without a change of respiratory rate, pulse rate, and arterial blood pressure. Although it is usually an innocuous procedure, damage to valves and endocardium has sometimes occurred. It has, therefore, not been deemed safe in patients.

In animals, changes in the pressure dynamics of the left side of the heart and pulmonary vein under conditions of cardiac stress will be discussed.

* Life Insurance Medical Research Fellow.

Changes in the Efficiency and Dynamics of Respiration in Experimental Congestion of the Lungs. HOWARD E. HEYER, JAMES HOLMAN and GEORGE T. SHIRES,* Dallas Texas (Introduced by Ben Friedman).

Experimental pulmonary congestion was produced in dogs by rapid venous infusion of 0.9 per cent solution of sodium chloride or by sodium chloride-sodium bicarbonate buffer solutions. Intrapleural pressure fluctuations increased markedly in total amplitude while mean intrapleural pressure rose toward atmospheric levels, and intrapleural pressure during expiration rose above atmospheric in every animal. Respiratory efficiency was determined by the tidal exchange produced for each centimeter change in intrapleural pressure. Efficiency of respiration and tidal exchange fell progressively with venous infusion, and rose rapidly when hyperpnea was induced by carbon dioxide inhalation. The changes accompanying pulmonary congestion were constant and were independent of alterations in hydrogen ion concentration or serum CO_2 tension. Vagotomy prevented acceleration of breathing during venous infusion but did not prevent the marked decrease in respiratory efficiency. Active participation of expiratory muscles was necessary to achieve optimal tidal exchange in the congested lung, since abolition of expiratory movements by lower cervical cord section caused marked diminution in tidal exchange. These findings were interpreted as being due to a marked increase in rigidity of the congested lung, so that tidal exchange was accomplished at the expense of a marked increase in activity of respiratory muscles, with a total greater change in intrapleural pressure. During extreme pulmonary congestion, even though intrapleural fluctuations increased markedly, tidal air diminished sharply, suggesting that (in addition to rigidity of the lung) alveolar space was encroached upon by the congested capillaries, or that the alveolar space was diminished in size by transudation of edema fluid.

Serum Sickness Due to Crystallized Bovine Albumin. JAMES T. HEYL (by invitation) and CHARLES A. JANEWAY,† Boston, Mass.

During experiments to test the possible value of albumin crystallized from bovine plasma by the method of Cohn and Hughes as a possible blood substitute, there was an opportunity to observe a severe and rather unusual form of serum disease in twenty-four patients. An intravenous dose of 25 grams of albumin was given to a group of 60 volunteers. Twenty-four of these developed symptoms. The striking clinical features of the disease were as follows: (1) long incubation period (10 to 33 days); (2) variation in severity from a very mild illness to a protracted one (4 to 6 weeks) with high fever; (3) the frequency of purpura, signs of hepatic and renal damage, and cardiac symptoms with electrocardiographic changes. Death occurred in one instance, and necrosis of the myocardium was found.

Immunological studies in the whole group indicated that bovine serum albumin, in man, as in experimental animals, is a relatively poor antigen in terms of its capacity to induce the formation of antibodies detectable by either the skin test or the precipitin test. In normal humans, as in animals, bovine albumin disappears very slowly from the circulation, whereas in certain instances of serum disease its disappearance was greatly accelerated. In some cases of severe serum sickness, recovery occurred before the disappearance of the bovine albumin from the circulation and antibodies never appeared. The relationship of the symptoms in the patients to the immunological phenomena will be discussed, as this experience with a disease caused by a measurable foreign protein without the power of multiplication raises many interesting questions concerning the pathogenesis of infactious diseases due to living agents.

Effect of Anxiety on the Cardiac Output. JOHN B. HICKAM, and WALTER H. CARGILL, Atlanta, Ga., (Introduced by Julian Ruffin).

Anxiety causes a marked increase in cardiac output. Twenty-three unselected medical students were studied immediately before and 24 hours after an important academic examination. As measured by the ballistocardiograph, the group showed an increase in cardiac output of approximately 50 per cent over the composed level. The greastest increase was 180 per cent.

Studies with the technique of intracardiac catheterization measuring the cardiac output by the Fick Principle were carried out on hospital patients. Anxiety was spontaneous or induced by suggestions; relative composure was obtained by reassurance, with or without light sedation. The data demonstrated that anxious individuals at rest may maintain a cardiac output which is much in excess of composed individuals, but without a corresponding increase in oxygen consumption. If an anxious person does sufficient work to increase the oxygen consumption to a level of 250 to 400 cc. per minute per square meter, the cardiac output may not be increased . Indeed, in certain subjects light work may cause the output to fall below that present in the resting but anxious state.

Studies on patients with left ventricular failure demonstrate that stimulus (work) which normally increases the cardiac output does not have this effect in severe heart failure. Instead the pulmonary pressure rises, presumably because of damming up of blood behind the failing left ventricle.

Reflex stimuli normally resulting in an increase in cardiac output would be expected to cause in patients with left ventricular failure a rise in pulmonary pressure. This offers a rational explanation for the precipitation of attacks of acute pulmonary edema by emotional stimuli and by reflex stimuli from the pleura or peritoneum during the removal of fluid by paracentesis.

Streptomycin; an Antibiotic Effective Against Some Forms of Clinical Tuberculosis. H. C. HINSHAW and (by invitation) W. H. FELDMAN, Rochester, Minn.

The present status of streptomycin therapy in experimental tuberculosis of guinea pigs under varying conditions is briefly described and evidence presented to indicate that this drug is a highly effective antibacterial agent, even when utilized under unfavorable experimental conditions. The clinical possibilities and limitations of streptomycin for treatment are discussed briefly. Evaluation is based on experience with treatment of approximately 125 patients with different types of tuberculosis during the previous two and a half years. Clearly recognizable therapeutic effects are noted in many types of the disease, including tuberculous meningitis; miliary tuberculosis; progressive, exudative pulmonary tuberculosis; ulcerating tuberculous lesions of the larynx, trachea and larger bronchi; tuberculous draining sinuses, and tuberculosis of the genito-urinary tract. The effect of streptomycin appears to be limited to a suppression of the infectious process. The permanence of results may depend on whether or not natural healing may be achieved during the few months of effective action prior to the appearance of drug-resistant strains of Mycobacterium tuberculosis.

Extent of Vasodilatation Induced in Different Vascular Beds After Systemic Autonomic Blockade with Tetraethylammonium. S. W. HOOBLER, ROSALIE B. NELIGH, GORDON K. MOE, S. DON MALTON, SAUL COHEN, and H. T. BALLANTINE, JR., (by invitation) and R. H. LYONS, Ann Arbor, Mich.

In normotensive and hypertensive subjects injection of tetraethylammonium results in a temporary decrease in the total peripheral resistance as manifested by a reduction in mean arterial pressure and a maintained or increased cardiac output. The blood flow through vascular beds believed to be normally under some degree of vasomotor tone is markedly increased. The volume flow of blood in the hands and feet as measured by the venous occlusion plethysmograph increases significantly above resting levels following the administration of 500 mg. of the drug and exceeds the levels achieved by other vasodilating drugs and may occur despite a marked decrease in arterial pressure. Blood flow seldom reaches the levels seen after sympathetic block with metycaine or after heat to the trunk, suggesting that a complete autonomic blockade is not produced. On the other hand there is a rise in cutaneous circulation as judged by increase in skin temperature of the hands and feet frequently with abolition of the temperature gradient. After sympathetic denervation of the extremity the blood flow is not further increased by administration of this drug. Induced vasoconstrictor reflexes in the hands and feet are reduced or abolished after tetraethylammonium. Blood flow in the forearm is only slightly increased after administration of the drug. Renal blood flow as measured by para-amino hippurate clearance is unaffected despite variable reductions in arterial pressure in hypertensive and normal subjects. It is suggested that increase in blood flow through various vascular beds following tetraethylammonium depends on the presence of neurogenic vasoconstrictor tone in these areas.

Sickle Cell Anemia. I. The Structural Defect of the Erythrocytes in Sicklemia. WILLIAM H. KELLY and (by invitation) P. K. SWITZER, GEORGE MANGAN, WILLIAM M. MCCORD and B. F. CULP, Charleston, S. C.

Preliminary studies are in process of completion to show that the error of construction of erythrocytes in sicklemia resides in the cell membrane or stroma.

The erythrocytes in sicklemia exhibit an increased hematocrit value when reduced, whereas, with normal red cells the reading is equal or tends to be reduced under the same conditions.

An analysis of samples shows the increase in the hematocrit value of reduced sicklemic erythrocytes is attended by at least a proportionately greater amount of intercellular fluid. This indicates that the reduced red cells of sicklemic blood are not of increased size but possess a greater viscosity than oxidized normal or sicklemic erythrocytes.

A comparison of the cell shadows from laked sicklemic and visual erythrocytes by the above technic showed apparently identical differences.

Cerebral Blood Flow and Metabolism in Diabetic Acidosis and Coma. SEYMOUR S. KETY, B. DAVID POLIS, CARL S. NADLER and CARL F. SCHMIDT, Philadelphia, Pa. (Introduced by Isaac Starr).

Quantitative measurement of cerebral blood flow and metabolism of 13 patients in profound diabetic acidosis or coma was made by means of the nitrous oxide method. On admission the mean values for blood glucose, arterial CO_2 content, and arterial pH were 560 mg. per 100 cc., 12 volumes per cent and 7.06 respectively. No significant differences with respect to age, blood pH, CO_2, glucose electrolyte patterns or cerebral blood flow were demonstrable between patients who recovered and those who succumbed. Those who recovered exhibited higher cerebral oxygen consumption, better mental function, higher blood pressure and lower blood ketone concentration. A reduction in cerebral oxygen consumption of 40 per cent from the normal was associated with failure to respond to treatment and death within 12 hours. These data, hitherto unobtainable, permit an evaluation of numerous factors held to play a role in the cerebral depression and frequent irreversibility of this condition. Correlation of cerebral oxygen consumption with some of these functions reveals the following: poor correlation with blood glucose, CO_2, total base or chloride concentrations, or with cerebral blood flow; a just significant correlation with arterial hydrogen ion activity ($r = 0.43 \pm \sigma_r\ 0.187$); the best correlation was obtained with blood ketone concentration ($r = -0.65 \pm \sigma_r\ 0.132$).

The Rate of Conduction in the Human Atrium. C. E. KOSSMANN, and (by invitation) A. R. BERGER, J. BRUMLIK and S. BRILLER, New York, N. Y.

The classical experiments of Lewis and his associates in which they demonstrated that the rate of electrical conduction in the dog's atrium is 1,000 mm. per second were repeated, with modifications, in man.

By means of two string galvanometers and an electrode passed into the right atrium through an antecubital vein,

intraatrial potentials at various levels between the cavae were recorded simultaneously with a standard lead. Distances between levels were measured radiographically by two techniques. Times of intrinsic deflections were measured using a fixed wave in the simultaneous lead as a reference point. In three men with normal sized hearts the calculated rates of conduction in the right atrium were 2,275 mm. 2,666 mm. and 1,866 mm. per second respectively.

Assuming that the spread of excitation through the atria is uniform and knowing that the mean duration of the P wave in the human electrocardiogram is 0.08 second, the distance from the region of the sino-auricular node to the farthest reaches of the atria, most probably the tip of the left atrial appendage, is calculated to be approximately 18.5 cm. Measurements on models, on cross-sectional anatomical drawings, and on fresh human hearts at necropsy indicate that the distance in question is approximately 15 to 22 cm., and that the anatomical considerations are in accord with the physiological observations.

The conclusion reached is that in a sinoatrial rhythm electrical excitation travels two or more times faster in the human than in the canine atrium.

Calcinosis, Scleroderma and the Anti-Stiffness Factor. John Lansbury, Rosalind Wulzen, Lawrence W. Smith and William J. van Wagtendonk, Philadelphia, Pa. (Introduced by Richard A. Kern).

The anti-stiffness factor was detected by Wulzen and Bahrs in greens and isolated from raw cream and cane juice by van Wagtendonk and Wulzen. Guinea-pigs lacking it develop muscular stiffness and degeneration and eventually deposits of calcium between muscle fasciculi, around joints, under the skin and in parenchymal organs. The anti-stiffness factor reverses the early changes. It appears to be a regulator of phosphorus metabolism.

This communication describes the roentgen appearance of the calcifications and compares them with the deposits found in human calcinosis. Striking similarities to both circumscribed and interstitial types are noted. (These are associated with scleroderma and dermatomyositis in humans.) The lesions induced by excess vitamin D are compared and excluded as the cause of both animal and human lesions.

Since the lesions induced at will in guinea-pigs by deficiency in the anti-stiffness factor are roentgenographically identical with those of human calcinosis, we postulate that a deficiency of this or similar substances may be one of the factors in the pathogenesis of human calcinosis and possibly scleroderma and dermatomyositis.

The Effects of Radiation on Hemopoiesis. Is there an Indirect Effect? John S. Lawrence and (by invitation) William N. Valentine and Andrew H. Dowdy, Rochester, N. Y.

Twenty-six successful cross circulation experiments (carotid-to-carotid anastomoses) were performed between a normal cat and one which had received 1500r whole body radiation at some interval up to eighty-two hours before cross circulation. In seven experiments, one animal was radiated at the time the carotid anastomoses were functioning, the normal partner being shielded during radiation. The total and differential leukocyte counts of the normal cat were followed for approximately twenty-eight days after cross circulation was discontinued.

The data were not considered to support the thesis of indirect effects *peculiar* to radiation mediated via the circulation. A trend toward slightly lowered absolute lymphocyte counts in normal animals after cross circulation was not considered significant and in no instance did leukopenia develop in the normal animal. A review of the medical literature revealed no convincing support for indirect radiation effects.

The clinical impression that leukopenia results in humans given repeated radiation either over non-hemopoietic tissue or over very limited amounts of hemopoietic tissue needs to be very critically reviewed.

Clinical Hypoprothrombinemia: A Study of Factors A and B of Prothrombin. Jessica H. Lewis and Ivan L. Bennett, Jr., Atlanta, Ga. (Introduced by Eugene A. Stead, Jr.).

Clinically, hypoprothrombinemia may be due to one or more of the following causes: (1) vitamin K deficiency, due to poor diet or poor absorption, (2) severe liver damage, (3) administration of drugs (dicoumarol and salicylates), and (4) idiopathic or unexplained hypoprothrombinemia.

Quick (1943) and Feissly (1943) have shown that the prothrombin reaction is dependent upon the presence of at least two substances in normal plasma. Factor A is reduced by aging or heating plasma and Factor B is reduced in vivo by administration of dicoumarol or in vitro by absorption with aluminum hydroxide or barium sulfate. Standard methods of preparing Factor A and Factor B plasma are presented and attempts are made to characterize these factors by the effects of heat, pH, and Ca^{++} ion on each. Employing preparations of these factors, studies were made on plasma obtained from patients with the various types of prothrombin deficiencies.

As examples of each type of prothrombin deficiency patients manifesting symptoms of obstructive jaundice, Laennec's cirrhosis, dicoumarolization, and idiopathic hypoprothrombinemia are presented.

Our patient suffering from idiopathic hypoprothrombinemia is unique in our experience and among the rare published cases. The onset was abrupt at age 29 with almost complete disappearance of Factor B of prothrombin, the Quick prothrombin time being prolonged to 10 minutes with a whole blood coagulation time prolonged to 60 minutes. Fibrinogen and formed elements of the blood were normal. The patient received massive dosage of vitamin K, with simultaneous return of circulating prothrombin. Under observation she has maintained normal prothrombin without treatment for 60 days.

In all four types of prothrombin deficiency there was demonstrable a similar defect, that is, reduction of Factor B with apparently normal Factor A. Administration of vitamin K either as synthetic 2-methyl-1,4-naphthohydroquinone-diphosphoric acid ester tetrasodium salt

(synkavite) or 2-methyl-3-phytyl-1,4-naphthoquinone (vitamin K-1) caused rapid regeneration of Factor B unless severe liver damage was present.

These investigations suggest that vitamin K is necessary for the formation of Factor B of prothrombin. Since no clinically demonstrable deficiency of Factor A was found in these patients, the role of vitamin K in relation to this factor is problematic.

The Direct Isolation of Mumps Virus in Chick Embryos. GLEN R. LEYMASTER and THOMAS G. WARD, Baltimore, Md. (Introduced by Thomas B. Turner).

Successful direct isolation of mumps virus has not been reported in this country, so far as the authors are aware. Mumps virus has been isolated in this laboratory by chick embryo inoculation, from 4 of 5 patients ill with parotitis during the first four days of illness. Two of these strains have been inoculated into monkeys, which developed clinical and serological evidence of mumps. Each strain was re-isolated from monkey parotid by embryo inoculation.

Penicillin and streptomycin are added to the patient's saliva to a final concentration of 250 and 2500 units per milliliter, respectively. One-tenth milliliter of the saliva-antibiotic mixture is then inoculated into the amniotic sac of seven day old embryos.

After seven days incubation at 35° C., amniotic fluid and membranes are removed. The fluid is tested by chick cell hemagglutination. Positive fluids are re-inoculated. The amniotic membranes of negative specimens are ground with their respective amniotic fluids, and re-inoculated. Three passages are carried out before a specimen is considered negative.

Identification of the virus as mumps is accomplished by hemagglutination inhibition and complement fixation tests, using amniotic fluid as antigen.

Further laboratory studies, including neutralization tests in embryos, are now in progress.

Fluorometric Measurement of Plasma Quinidine and its Correlation with Cardiac Effects in Man. ARTHUR J. LINENTHAL, STANLEY ULICK and LAWRENCE A. PATTERSON, Boston, Mass. (Introduced by Joseph E. F. Riseman).

Measurement of the fluorescence of quinidine provides a simpler and more sensitive means of determining its concentration than has previously been available.

In man, within fifteen minutes after a single oral dose, quinidine can be detected in the plasma. Maximum levels are reached in 1 to 3 hours and may be maintained for 2 to 3 hours. Appreciable amounts remain after 8 to 12 hours. Average peak concentrations after single doses of 0.2, 0.4 and 0.6 gm. are, respectively, 0.8, 1.3 and 2.0 mg. per liter.

When the same dose is repeated every two hours, *i.e.* at the peak response to the preceding dose, the concentration increases with the first four or five doses only. A further increase in concentration can be attained more effectively by increasing the size of the individual dose than by increasing the frequency of administration.

When the same dose is repeated every 6, 8 or 12 hours, peak concentrations are similar and do not increase. With the more frequent administration the level is better maintained between doses.

Suitable plasma concentrations for the therapy or prophylaxis of cardiac arrhythmias can thus be attained by planned doses according to one of the general schedules described above.

Plasma concentrations parallel closely the effect on the heart as measured by the rate of oscillations in auricular fibrillation, and by the Q-T duration. This correlation affords a new quantitative approach applicable to the clinical and pharmacological study of this cardiac drug.

The Application of the Isotope Technique to the Study of the Rates of Formation of Blood Constituents in Man. IRVING M. LONDON, DAVID SHEMIN, and D. RITTENBERG, New York, N. Y. (Introduced by R. West).

The feeding of glycine labeled with N^{15} to humans results in the incorporation of N^{15} in the serum proteins and the heme of red blood cells as well as in other body constituents. Glycine is the nitrogenous precursor of the protoporphyrin of hemoglobin. The N^{15} is incorporated in the red blood cell during the deposition of hemoglobin, and the labeled porphyrin remains in the cell until the cell disintegrates. The porphyrin is not subsequently reutilized for hemoglobin synthesis. Accordingly, the isotope technique affords a unique method for studying the kinetics of red cell formation and for determining the average life span of the human red cell. This life span has been found to be 127 and 128 days in two normal adult men. Data on the rates of generation and on the life span of red cells in a patient with pernicious anemia and in another with polycythemia vera have been obtained which may clarify certain factors in these disease processes. Serial measurements of N^{15} concentration in electrophoretically separated fractions of serum proteins have yielded information on the relative rates of elaboration of these proteins. Correlative studies of N^{15} concentration in urinary urea, ammonia and uric acid have provided further information on protein and purine metabolism.

The Relation of the Rh Factor in Cirrhosis of the Liver. FRANK S. LOVINGOOD, Philadelphia, Pa. (Introduced by Franklin R. Miller).

Of the various factors listed as contributing to the production of cirrhosis of the liver, erythroblastosis fetalis and the familial tendency are probably mentioned least often. One is able to find several reports of each type in the literature.

Recently twenty cases of cirrhosis of the liver have been studied; 45 per cent or nine patients were found to be Rh negative and 55 per cent or eleven patients were Rh positive. The percentage of Rh negative patients seems significant.

Cirrhosis that follows icterus gravis neonatorum is probably due to an antigen antibody reaction. The mother forms antibodies against the Rh agglutinogen of the fetus. The antibody passes into the fetal circulation resulting in hepatic damage.

The development of the Rh negative and familial cirrhosis may be identical in that the development may be

due to incompatibility between a Rh positive mother and a Rh negative fetus. Infants born under such circumstances, as well as those born with icterus gravis neonatorum, probably begin life with decreased hepatic reserve and, therefore, are more prone to develop clinical cirrhosis of the liver later in life. The time of development will depend on the degree of initial damage, as well as the degree of further damage from infection, ingestion of alcohol or poor dietary measures.

A Study of the Mechanism of Nephrotic Edema. JOHN A. LUETSCHER, JR., Baltimore, Md.

The association of hypoproteinemia, sodium retention, and edema in nephrosis is well known, but the fundamental mechanisms leading to these manifestations are obscure. The decreased colloid osmotic activity of the plasma may facilitate the development of edema, but is not necessarily related to the presence or absence of clinical edema.

The repeated administration of concentrated human serum albumin to patients with nephrosis increases the concentration of albumin and the colloid osmotic activity of plasma. The consequent large shift of fluid into the plasma minimizes the rise in protein concentration despite the greatly increased circulating protein. These impressive circulatory changes are followed by smaller and sometimes ineffectual changes in the renal excretion of salt and water. The glomerular filtration rate is generally increased, and the proportion of sodium reabsorbed is greatly diminished. The moderate diuresis of sodium is not necessarily correlated with increased urine flow or with excessive proteinuria, and is not reproduced by the administration of mannitol, an osmotically active and unreabsorbed substance.

Spontaneous diuresis in nephrosis is distinctively different from the diuresis induced by the administration of albumin in that the plasma volume and protein concentration may change only slightly during a spontaneous diuresis, while the proportion of sodium reabsorbed by the renal tubule is diminished even more than after albumin therapy.

It is concluded that the reabsorption of an excessive proportion of sodium by the renal tubule is responsible for the intractable edema of nephrosis, and that the restoration of the total circulating protein to nearly normal levels does not immediately lead to diuresis. The relationships between hypoproteinemia, edema, and renal function are being further investigated.

The Pharmacologic Promotion of Evacuation from the Post-Vagotomy Retentive Stomach. THOMAS E. MACHELLA and (by invitation) HORACE H. HODGES and STANLEY H. LORBER, Philadelphia, Pa.

One of the complications which had developed following section of the vagus nerves for peptic ulcer has been gastric retention. This has occurred especially in those patients who have not had a gastroenterostomy or who do not have an adequately functioning one. For the relief of retention, additional surgery, some form of gastroenterostomy, has had to be performed.

It has been found possible to avoid surgery in each of six patients with post-vagotomy gastric retention by promoting gastric evacuation by means of the parasympathomimetic drug, urethane of B-methyl choline (Urecholine).

The drug is administered orally after each of the main meals of the day in dosage of 6 to 10 mg. The patients have remained free of symptoms of retention while taking the drug but not when a "placebo" was substituted. Within 5 to 10 minutes of a subcutaneous injection of a 5 to 10 mg. dose, peristaltic activity in the antrum of the stomach can be demonstrated roentgenologically or by means of a recording balloon. The drug does not give rise to a significant increase in free hydrochloric acid providing the patient is permitted to swallow saliva or if the stomach contains neutralizing food substances.

Osmotic Factors Influencing the Formation of Ascites in Patients with Laennec's Cirrhosis of the liver. HAROLD MANKIN and ALICE LOWELL, New York, N. Y. (Introduced by Arthur J. Patek, Jr.).

Effects of experimental alteration of the colloid osmotic pressure of the plasma and ascitic fluid and of the intraperitoneal hydrostatic pressure were studied in 10 patients with cirrhosis and ascites. The colloid osmotic pressures of the plasma and ascitic fluid were measured directly in an Hepp osmometer. The ascitic fluid volume was measured by an adaptation of the Evans Blue dye technique.

In each patient the difference between the colloid osmotic pressures of the plasma and the ascitic fluid remained approximately constant through periods of 3 months to 1 year. Following (1) alteration of the intraperitoneal hydrostatic pressure by abdominal paracentesis, (2) increase of the colloid osmotic pressure of the plasma during mercurial diuresis, (3) decrease of the colloid osmotic pressure of the plasma after the oral administration of salt solution, or (4) decrease of the colloid osmotic pressure of the ascitic fluid by the intraperitoneal injection of physiological saline solution, there were temporary changes in the rates of fluid and protein exchange between the plasma and ascitic fluid which served to restore the pre-existing constant difference between the colloid osmotic pressures of the plasma and ascitic fluid.

The results are interpreted as consistent with the Starling hypothesis describing osmotic equilibrium between transudates and the plasma.

A Study of the Plasma and Tissue Globulins in Myelomatosis. NICHOLAS H. MARTIN, Boston, Mass. (Introduced by James L. Gamble).

In a patient with multiple myeloma, the total plasma proteins were estimated as 10.9 grams per 100 mls. plasma. By electrophoretic analysis, 65 per cent of the total moved with the mobility of γ-globulins. There was no apparent excess of α or β globulins. This γ-globulin was separated from the other plasma proteins and compared with γ-globulin from normal human plasma. It moved as a discrete well-defined entity having a mobility of the order of 1.1×10^{-4} cm/volts/sec. Nevertheless it

was heterogeneous in the ultracentrifuge, having a pattern quite unlike that of γ-globulins obtained from normal plasma. Moreover, it precipitated from an acetate buffer, ionic strength, 0.01 mols/L and of pH 6.0. In this also it differed from γ-globulin from normal human plasma.

The patient died in hospital, and a diagnosis of multiple myeloma was confirmed at autopsy. Tumor tissue was taken at autopsy, frozen, washed free of blood, and saline preparations examined. Ultracentrifugal studies showed the presence of abnormal globulins similar to those identified in the plasma. Similar globulins, though in much smaller amounts, were identified in the splenic pulp. Examination of control tissues from a normal individual treated in the same way, gave no indication of the presence of these globulins.

It is suggested that the γ-globulin circulating in the plasma of patients suffering from myelomatosis is abnormal and arises from the tumor cells.

Streptomycin in the Treatment of Tuberculosis in Humans. WALSH McDERMOTT, CARL MUSCHENHEIM, and SUSAN HADLEY, New York, N. Y. (introduced by David P. Barr).

Since January, 1946, a clinical and laboratory investigation of the treatment of tuberculosis in humans has been conducted. More than fifty patients have been treated with a uniform preparation of streptomycin sulfate. The drug was prepared from crystalline material and is believed to be at least 95 per cent pure. The experimental series includes fourteen patients with acute hematogenous tuberculosis or meningitis and approximately forty individuals with pulmonary disease. The majority of the latter infections were either caseo-pneumonic or predominantly exudative in type. Approximately two-thirds of the series have been observed for periods of six to twelve months after the institution of the antibacterial therapy.

The course of the infection before, during and after streptomycin therapy has been studied by frequent clinical, roentgenological and bacteriological observations. Histologic studies of the nature of the tuberculous lesions have been made on the tissues of five individuals who had received streptomycin for periods ranging between 90 and 300 days before death.

The in vitro streptomycin sensitivity of tubercle bacilli isolated from each patient at biweekly intervals has been determined in Dubos media. The development of in vitro drug resistance appeared after four to eight weeks of therapy in the majority of patients from whom tubercle bacilli could still be cultured at that time. A definite correlation was found between the streptomycin sensitivity of a patient's organism in vitro and the response of that particular infection to the continued administration of the drug.

The institution of streptomycin therapy was associated, in every instance, with a definite and sometimes dramatic effect upon the course of the tuberculous infection. In certain forms of the disease, notably in acute hematogenous tuberculosis, a high incidence of relapse resulted from the development of drug-resistant strains of tubercle bacilli. The most uniformly satisfactory results were observed in the treatment of early exudative infections, moderately or far advanced in extent and which were usually associated with thin-walled cavities.

"Forward Failure": The Mechanism of Cardiac Edema Formation in Subjects with Normal or High Cardiac Outputs. ARTHUR J. MERRILL and WALTER H. CARGILL, Atlanta, Ga. (Introduced by Paul B. Beeson).

Previously presented evidence favoring the forward failure concept of edema formation in advanced heart failure consists of the following: (1) Marked reduction in renal plasma flow and filtration rate which is independent of venous pressure levels and closely related to inadequacy of cardiac output. (2) Filtration rates below approximately 70 cc. per min. result in a critical reduction of the amount of salt and water presented to the tubules. (3) Almost complete reabsorption by the tubules occurs with a net retention of salt and water and consequent edema formation. The cause of edema in patients with low cardiac reserve, but an adequate resting cardiac output and renal function, has not been explained; nor has edema associated with a high cardiac output, as in thyrotoxic heart disease.

The present work deals with a study of the effect of light exercise on the renal blood flow of patients in whom light exercise would be expected to bring out inadequacy of cardiac reserve. It was necessary that they have a high enough renal plasma flow and filtration rate to make possible a demonstration of significant reduction with exercise. Seven of 10 cardiac subjects had a fall in filtration rate with exercise which approached the critical level of 70 cc. per min. Of 9 normal individuals, none had an appreciable fall in filtration rate, though a few showed a substantial decrease in renal plasma flow.

In thyrotoxicosis the cardiac output parallels the BMR. Eight thyrocardiac patients with mild and moderate failure showed no striking change in renal plasma flow and filtration rate. One with severe failure in the presence of a high cardiac output had marked diminution in renal blood flow and filtration rate; these rose to normal as the BMR fell. One other patient with severe failure had a low renal blood flow but the filtration rate was normal.

Thus it appears that while there is no fixed level of cardiac output at which the renal plasma flow and filtration rate fall, reductions may occur when the tissue demands exceed the ability of the heart to respond. If the filtration rate becomes sufficiently low, retention of salt and water (edema) occurs.

Possible mechanisms of the renal shutdown are mentioned.

*Renal Blood Flow and Sodium Excretion Studies in Congestive Heart Failure.** REUBEN MOKOTOFF and GEORGE ROSS, New York, N. Y. (Introduced by Louis Leiter).

A study of the renal plasma flow, glomerular filtration rate, and sodium excretion in congestive heart failure was

* Aided by a grant from the Martha M. Hall Foundation and the Committee on Scientific Research of the American Medical Association.

undertaken, since it has been postulated that cardiac edema is the result of failure of the kidney to excrete sufficient amounts of sodium and water. We found, in a series of 16 cases of chronic congestive heart failure due predominantly to rheumatic heart disease, that the mean "effective" renal plasma flow was 30 per cent and the mean glomerular filtration rate 65 per cent of normal. The mean filtration fraction was increased to 36.7 per cent as compared to 16.6 ± 1.5 per cent in our group of 14 normals. Five rheumatic cardiacs not in heart failure had normal glomerular filtration rates, renal blood flow and sodium clearances.

In 2 congestive failure cases in which 4 per cent sodium chloride was given, there was an excretion rate of 1 per cent and 1.5 per cent during the test period as compared to 7.4 per cent and 9 per cent in two normal patients under similar test conditions. The decreased sodium excretion found in congestive heart failure is due to a diminished filtration rate and not to an increased tubular reabsorption since the rate of reabsorption is the same for the cardiac in failure and for the normal and is a direct function of the glomerular filtration rate. It will be shown that the following equation expresses, as a first approximation, the relationship between the rate of tubular reabsorption (T) and the glomerular filtration rate (C_m):

$$T = P_{Na} C_m$$

where P_{Na} Equals the plasma concentration of sodium and represents the slope of the line. Physiologically induced variations in the filtration rate from 100 to 219 cc. in the normal and from 60 to 90 cc. in the cardiac also reveals constancy in the rate of sodium reabsorption. This amounts to a mean of 13.3 millimols per 100 cc. of glomerular filtrate under our experimental conditions.

Our findings are consistent with the views as outlined by Stead and Merrill that in chronic congestive heart failure there is a decreased sodium load presented to the tubules for reabsorption, which fact is responsible for the series of events—increased blood volume, increased venous pressure—leading to cardiac edema.

Use of Chemotherapeutic and Antibiotic Agents in the Isolation of Viruses from Contaminated Sources. HERBERT R. MORGAN, Boston, Mass. (Introduced by Maxwell Finland).

This is part of a study designed to test the usefulness of certain chemotherapeutic and antibiotic agents as aids in the direct isolation of viruses in eggs from contaminated sources such as sputum, urine and feces. Psittacosis virus was used since it occurs in the nasal secretions and feces of its natural host. A standard preparation of seed virus was used throughout the study and varying dilutions of the virus and different amounts of the test agents were injected into the eggs by the yolk sac route.

Sulfadiazine and penicillin were found to inhibit the growth of the virus while streptomycin and tyrothrycin had no appreciable effect. Streptomycin alone and in combination with tyrothrycin was found useful for the isolation of psittacosis virus from fecal material on direct injection of eggs via the yolk sac route, both with virus added to normal human feces and from the feces of mice infected with psittacosis virus by the intravenous route. P-aminobenzoic acid and folic acid were found to counteract the inhibitory action of sulfadiazine, but had no effect on the multiplication of the virus. Cysteine HCl itself had no effect on the virus. When injected as long as 4 hours after the penicillin and virus, cysteine HCl inhibited the action of the penicillin on the growth of the virus.

A Study of Forty Patients Who Died in Liver Coma. T. L. MURPHY, T. C. CHALMERS and R. D. ECKHARDT, Boston, Mass. (Introduced by George R. Minot).

A study is presented of 40 autopsied patients who died in coma within the past two years, all of whom had severe primary liver disease. The coma was precipitated by infection in seventeen, and hemorrhage in three. No extra-hepatic factor was found in the remaining twenty ("pure coma").

The clinical and liver function studies of the patients in "pure coma" did not differ significantly from their pre-coma studies nor from those of other patients with severe liver disease not in coma. The concentrations of blood non-protein nitrogen, glucose, chloride, carbon dioxide combining power, bilirubin, and phenols, although frequently abnormal, were not sufficiently altered to account for the coma. Determinations of plasma alpha amino nitrogen in comatose patients were normal.

Confusion and delirium for which sedatives were used often preceded the coma, and in six of the uncomplicated cases such sedation induced deep sleep which merged imperceptibly into coma.

Except in two patients in whom concentrated glucose temporarily lightened coma, the administration of intravenous dextrose, vitamin B complex, liver extract, protein hydrolysate and prophylactic chemotherapy failed to alter the coma. In the past two years there have been no patients with severe liver disease alone who recovered from coma. After prolonged treatment two have recovered from coma secondary to sedation. Two patients with infection which induced coma recovered after similar parenteral nutrition and control of infection.

It is concluded that although clinical and laboratory examinations do not elucidate the etiology of liver coma, sedation as well as infection and hemorrhage is an important contributing factor. Intravenous glucose, B complex vitamins, liver extract and protein hydrolysates are therapeutically supportive but are not specific analeptics.

Correlation of Electrocardiographic and Pathologic Findings in Infarction of the Lateral Wall of the Left Ventricle. GORDON B. MYERS and (by invitation) HOWARD A. KLEIN and BERT E. STOFER, Detroit, Mich.

Lateral infarction was established by necropsy in ninety cases. Pathologic examination included coronary injection with radio-opaque mass, section by Schlesinger technique or transverse slices, roentgenogram, and multiple microscopic blocks. Standard limb and Wilson precordial leads were available in every case and Goldberger extremity leads were obtained in eighty cases.

Anterior infarction extending into the lateral wall of the apex was found at necropsy in forty-six cases. Lateral extension was manifested by abnormal Q waves in $V_{5,6}$ and usually in aV_L, whereas infarction confined to the anterior wall was manifested by abnormal Q waves in $V_{2,3,4}$. Lateral extension from posterior infarction was found in twenty-five cases. A diagnosis of lateral extension could be made from V_6 or aV_L in eleven cases and of posterior infarction from aV_F in seventeen of twenty cases. Primary lateral infarction was present in nineteen cases. Infarcts confined to the lateral aspect of the apex were recognizable from the pattern in $V_{5,6}$ and aV_L, whereas those localized to the lateral aspect of the base could usually be suspected from aV_L and confirmed by high precordial leads.

The infarct was generally maximal in or limited to the subendocardial layer and the thickness could be estimated from depth and duration of the Q wave. Infarcts confined to the subepicardial layer were accompanied by abnormalities in the T, but not in the Q wave.

The correlation of electrocardiographic and autopsy findings will be brought out by the presentation of illustrative cases.

Measurement of the Hepatic Blood Flow in Man. J. D. MYERS, Atlanta, Ga. (Introduced by W. M. Nicholson).

Measurement of the hepatic blood flow in normal males has been undertaken utilizing a method based on "the Fick principle" with urea as the test substance. The urea concentration has been determined in (1) femoral arterial blood, which has been assumed to have the same urea concentration as hepatic arterial and portal venous blood, and (2) hepatic venous blood which has been obtained by direct catheterization of the right hepatic veins by the procedure of Warren and Brannon. The urea determinations have been done by a modification of the urease method of Van Slyke and Cullen with an accuracy of ± 0.2 mg. of urea per 100 cc. of blood. Urine has been quantitatively collected and assayed for urea by the same procedure.

In fasting, normal, young males, the arterial urea concentration has generally been constant over the period of study, *i.e.* about two hours. Accordingly, the urinary excretion of urea during this period is considered equal to the production of urea by the liver. The excretion of urea in the urine has varied between 12.1 and 16.4 mg. per minute, and the hepatic vein — femoral artery urea difference has ranged from 0.5 to 1.2 mg. of urea per 100 cc. of whole blood. The calculated hepatic blood flows per minute,

$$\frac{\text{Urinary excretion (hepatic production) of urea per minute}}{\text{Hepatic vein} - \text{Femoral artery urea difference}}$$

range from 750 to 1,620 cc. per square meter of body surface. Concomitant determinations of cardiac output have shown these hepatic blood flows to represent 19 to 45 per cent of the entire cardiac output.

Estimated splanchnic oxygen consumptions (femoral artery — hepatic vein oxygen difference × hepatic blood flow) vary between 27 and 77 cc. of oxygen per minute, which represents from 11 to 31 per cent of the total oxygen consumption at rest.

Comparison is made of the data for liver blood flow by the urea method with data obtained simultaneously by the bromsulphthalein method of Bradley *et al.*

The Improved Demonstration of Circulating Antibodies in Hemolytic Anemia by the Use of a Bovine Albumin Medium; Parallelism with Survival Time of Transfused Red Cells. JACOB NEBER, Boston, Mass. (Introduced by William Dameshek).

Circulating antibodies were investigated in the sera of seventeen patients with various hemolytic syndromes by a modification of the tube agglutination technique in which 20 per cent bovine albumin solution completely replaced normal saline as a diluting and suspending medium.

In five cases of idiopathic acquired hemolytic anemia a circulating warm antibody was demonstrated with the albumin technique, although in four of these cases, antibody could not be demonstrated in a saline medium. Three patients with congenital hemolytic anemia not in crisis showed no antibody, but in one of these patients during a hemolytic crisis a warm autohemolysin was demonstrated in bovine albumin only.

Two patients with sickle cell anemia, two with severe Mediterranean anemia, one with acute hemolytic anemia caused by chemical exposure, one with paroxysmal nocturnal hemoglobinuria, two patients with hypersplenic hemolytic anemia, and one patient with the symptomatic hemolytic anemia of subacute lymphatic leukemia failed to show circulating antibodies.

Parallel determinations of the survival time of transfused red cells by the Ashby technique showed a distinct correlation with the presence of antibodies. The survival time was greatly diminished when antibodies were demonstrable. Performance of both types of tests proved of distinct diagnostic and prognostic value.

Studies on the Control of Hepatitis Virus in Blood and Blood Products. JOHN R. NEEFE, and (by invitation) JOSEPH STOKES, JR., SYDNEY S. GELLIS, and MERCER A. BLANCHARD, Philadelphia, Pa

The transmission of hepatitis viruses by intentional or accidental parenteral introduction of blood or its products is a serious current problem and promises to be one of equal, or possibly greater, importance in the future. Its present magnitude is indicated by the fact that the chiefs of service in some leading hospitals will no longer permit the use of pooled plasma (including the large supplies of surplus Red Cross plasma) in their patients. The obvious need for the development of methods for inactivation and control of the hepatitis viruses in blood or its products has led to the preliminary studies summarized herein.

1. In a cooperative study conducted in conjunction with the Harvard Plasma Fractionation Group, a serum hepatitis virus in human serum albumin solution apparently was inactivated, without rendering the albumin solution unsatisfactory for human use, by heating the experimentally contaminated albumin solution for 10 hours at 60° C. after stabilizing it with acetyl tryptophane and sodium caprylate. As this method is compatible with large scale production, it appears that, until proved otherwise, human

albumin solutions so treated can be considered free of the risk of virus hepatitis and that this valuable blood product, at least, could be salvaged safely from the large stores of pooled plasma suspected or known to be contaminated with a hepatitis virus.

2. The demonstrated protective effect of gamma globulin against infectious hepatitis has led to investigation of its protective effect against serum hepatitis. No protective effect was apparent when 10 ml. of gamma globulin and 2 ml. of plasma (known to contain a serum hepatitis virus) were injected simultaneously at separate intramuscular sites. No neutralizing or protective effect was apparent when 2 ml. of the plasma were mixed with 1 ml. of gamma globulin and allowed to stand for 4 hours at room temperature before intramuscular injection of the mixture into volunteers. The results of the clinical trials in army hospitals have suggested that quantity and/or time of injection may be important factors in the protective effect of gamma globulin against serum hepatitis. As the same factors might account for the lack of apparent protective effect in the experimental study described, these factors have been taken into consideration in a subsequent study now nearing completion. Twenty-one volunteers have been injected with plasma known to contain a serum hepatitis virus. Thirteen to sixteen ml. of gamma globulin have been injected at monthly intervals into 7 of these men starting 1 month after the plasma injection. Another 7 men serve as controls for the first group injected with globulin and for a third group of 7 men each of whom was injected with a mixture of the plasma and gamma globulin (3 ml. plasma and 10 ml. of gamma globulin, mixed and stored for 3 hrs. at room temperature and for 24 hrs. at 4° C before injection). The results of this study will be presented and discussed together with the results of the studies outlined above.

The Effect of Coronamide in Inhibiting Penicillin Excretion. R. F. Parker and (by invitation) R. Albright, Cleveland, Ohio.

Penicillin injected intramuscularly or intravenously is rapidly excreted in the urine, largely as the result of renal tubular activity. A number of attempts have been made to increase the concentration of penicillin in the blood, and to prolong the effect of a given dose by suppressing the tubular secretion of the drug. Coronamide (4 carboxyphenyl-methane sulfonanilide) has recently been proposed as a nontoxic compound which specifically suppresses tubular secretion of penicillin. The present study is an attempt to evaluate its efficiency in routine clinical use in patients having normal kidney function, and in those suffering from various forms of renal disease.

A Comparison of the Pressor Activity of Desoxycorticosterone Acetate in Normotensive and Hypertensive Subjects. George A. Perera and (by invitation) David W. Blood, New York, N. Y.

Previous studies demonstrated that desoxycorticosterone acetate (DCA), administered to patients without hypertension or adrenal disease, may be associated with increases in blood pressure. Significant changes were apparent only after several weeks of drug injection.

Observations were made on ten normotensive subjects and twelve patients with uncomplicated hypertensive vascular disease maintained on a constant regimen and after a preliminary baseline period. The administration of DCA for one week (5 mg. subcutaneously twice daily) failed to alter the blood pressure significantly of any of the normotensive group. In contrast, definite elevation of systolic and diastolic readings took place in one to four days in the hypertensive individuals, the mean systolic rise being 24 mm. of mercury at the end of six days, the mean diastolic rise being 15 mm.

Alterations in weight, hematocrit, serum volume and electrolytes, urine volume and chlorides were comparable in both groups. Ballistocardiographic tracings were unchanged in one hypertensive subject following a marked rise in blood pressure after DCA.

Although prolonged administration of DCA may give rise to a gradual increase in blood pressure in normotensive subjects, an accelerated response to DCA may be found in hypertensive vascular disease.

Measurement of Renal Blood Flow and Glomerular Filtration During Variations in Blood Pressure Related to Changes in Emotional State and Life Situation. John B. Pfeiffer and Herbert S. Ripley, New York, N. Y. (Introduced by Harold G. Wolff).

Renal blood flow and glomerular filtration were ascertained by clearance measurements of para-aminohippuric acid and inulin respectively in ten human subjects with early hypertension. After a suitable control period in which subjects were reassured and made as comfortable as possible, topics of great significance in the life situation were abruptly brought up for discussion. In each instance the subject responded to the interview with a significant elevation of systolic and diastolic pressure but none gave evidence of fright or panic. Often their attitude was one of apparent calm and restraint during the period of elevated blood pressure. Evidence of renal arterial constriction was adduced in all cases during or after the interview. In four of the subjects a decrease of 20 percent or more in renal plasma flow occurred, one of these displaying also a significant decrease in glomerular filtration. In five of the subjects, despite elevation in systemic arterial pressure, no significant change in renal blood flow was found. In two of these an elevation of glomerular filtration occurred.

Subjects in whom lowering of blood pressure was induced by injection of tetraethylammonium chloride a significant increase in renal blood flow was noted. Similar lowering of blood pressure associated with increase in renal blood flow occurred when feelings of security were induced with the aid of sodium amytal.

The Excretion and Reabsorption of Bicarbonate by the Normal Human Kidney. Robert F. Pitts, Syracuse, N. Y. (Introduced by James A. Shannon).

The renal excretion and reabsorption of bicarbonate was studied in three normal subjects over a range of plasma concentration from 18 to 39 millimols per liter. Plasma bicarbonate was reduced by the ingestion of ammonium chloride, raised by the intravenous infusion of sodium bi-

carbonate. Blood was drawn from a cutaneous vein after heating the arm in water at 47° C.; both blood and urine were collected with precautions to prevent loss of carbon dioxide. The thiosulfate clearance was used as a measure of glomerular filtration rate. Carbon dioxide and pH measurements on plasma and urine permitted the calculation of bicarbonate contents and carbon dioxide partial pressures.

At plasma concentrations below 25 millimols per liter, the tubular reabsorption of bicarbonate was essentially complete. At plasma concentrations above 25 millimols per liter, the rate of excretion of bicarbonate progressively increased. There appears to be a limitation of the capacity of the tubules to reabsorb bicarbonate, the maximum quantity reabsorbed in the several subjects varying between 2.6 and 3.0 millimols per 100 cc. of glomerular filtrate.

The acidity of the urine varied between pH 4.48 and pH 7.80; the partial pressure of carbon dioxide in the urine varied from about 30 to nearly 200 mm. Hg. The more alkaline the urine, the higher was the partial pressure of carbon dioxide.

Hypoelectrolytemia in Peritonitis. S. RAPOPORT and (by invitation) I. A. SYLLM, N. NELSON, W. A. BRODSKY and K. DODD, Cincinnati, Ohio.

A decrease in the concentration of chloride and frequently of sodium has been described in tuberculosis, congestive heart failure, and in febrile diseases such as lobar pneumonia and typhoid fever.

In the present study, a lowering of the serum chloride and sodium, often accompanied by elevation of CO_2 content and pH, has been observed in children with peritonitis following rupture of the appendix. In some critically ill patients hypocalcemia was found. Clinically hyperpnea, a mild degree of edema, and decreased awareness of the surroundings were noted at the time of the appearance of the plasma changes. The disturbance of the electrolytes occurred within one or two days after the onset of the peritonitis and was self-limited in cases with a favorable outcome.

On an intake of 50—250 millimols of sodium chloride daily the urinary concentration of chloride and sodium was 20—60 millimols per liter; the hypoelectrolytemia persisted and retention of the sodium and chloride occurred.

The Pathogenesis of Hypercalcemia in Multiple Myeloma. ARNOLD J. RAWSON, Philadelphia, Pa. (Introduced by F. William Sunderman).

The calcium partition was studied in sera obtained from normal individuals and from patients with multiple myeloma. In normal sera the average value of calcium bound to albumin was found to be 0.95 (s.e. = 0.045) mg. of calcium per gm. of albumin, and that of calcium bound to globulin, 0.74 (s.e. = 0.033) ml. of calcium per gm. of globulin. In the sera of patients suffering from multiple myeloma the calcium binding property of albumin was increased to as much as six times the normal; the concentration of diffusible calcium and the calcium binding property of globulin in these sera remained within the normal range of values. Our studies indicate that when hypercalcemia is observed in patients with multiple myeloma, the increase is due to the calcium bound to protein. This increase in bound calcium is dependent upon two factors: (a) the increased calcium binding power of the serum albumin, and (b) the increased concentration of globulin, with approximately normal calcium binding property.

Renal Tubular Back-Diffusion Following Anuria. JULES REDISH, JOSEPH R. WEST and BETTY W. WHITEHEAD (by invitation) and HERBERT CHASIS, New York, N. Y.

A negative value for $T_{m_{pah}}$ was observed two and three and one half weeks following anuria in a patient with sulfathiazole intoxication. This negative T_m indicates not only that the tubular cells had lost their ability to excrete PAH, but that a portion of the PAH filtered by the glomeruli was escaping from the tubular urine by back-diffusion.

Observations extending from two to ninety-two weeks from the onset of anuria showed a pattern of glomerular and tubular recovery. Glomerular filtration was markedly reduced for three weeks following the onset of anuria and then returned abruptly to the normal range. Tubular excretory capacity was impaired for some weeks thereafter.

The data show the limitations of clearance measurements of filtration rate, renal blood flow and maximal tubular excretory capacity in the diseased kidney; and they suggest that a common mechanism, renal vasoconstriction with ischemia, may operate to produce glomerular and tubular changes during and after a period of anuria, whether the anuria is associated with diffuse glomerulonephritis, post-transfusion reaction, sulfathiazole intoxication, crush syndrome, shock or ureteral trauma.

Clinical and Experimental Observations on the Lability and Range of Blood Pressure in Essential Hypertension, with Special Reference to Physiologic Mechanisms and Significance of Various Pressor and Depressor Tests. MORTON F. REISER (by invitation) and EUGENE B. FERRIS, Cincinnati, Ohio.

Important in selecting the type of therapy for the patient with essential hypertension is a careful evaluation of the "neurogenic factor." As part of a comprehensive clinical, physiologic, and psychiatric study of essential hypertension, data pertinent to this problem has emerged. Comparative results in 107 pressor and depressor tests (1) performed on twenty-three patients indicate that extreme caution must attend their interpretation in the individual case.

Variations of blood pressure in response to emotional or environmental stimuli may equal or exceed those elicited by the usual pressor and depressor tests. The patient's response to different tests, or the same test repeated, may vary considerably, and there may be significant response to only a few of many procedures. There is no constant correlation between degree of reactivity to pressor tests and clinical lability.

In four patients with malignant hypertension, reductions in pressure to or very near normal occurred, three in re-

sponse to sympathetic block, one spontaneously. This together with other data (2) to be presented suggests that neurogenic factors play a significant contributing role even in this stage.

Preliminary studies utilizing the differential effects on blood pressure and cold pressor test of procedures which block neurogenic responses in different portions of the arteriolar bed have been helpful in leading toward a better understanding of the basic physiologic mechanisms involved and in explaining some of the apparent incongruities (3) of results which make selection of patients for sympathectomy so difficult.

(1) Test procedures used singly or in various combinations include: cold pressor; breath holding; postural changes; provocative interviewing; ammonia inhalation; hyperventilation plus carotid sinus massage; environmental manipulation; caudal, spinal, pentothal and gas-oxygen-ether anesthesia; and parenteral administration of the tetraethylammonium ion.

(2) In four instances we have observed the development of malignant hypertension and hypertensive encephalopathy in direct response to known environmental situations which, when appraised in the light of the psychiatric history, had specific psychological meaning for the patients.

(3) *E.G.*, in some patients who exhibit spontaneous downward variations in blood pressure to normal levels, spinal or caudal anesthesia may fail to produce such a satisfactory fall in pressure. When, in this circumstance, the tetraethylammonium ion, which effects a total autonomic block, is able to reproduce the fall to normal it seems probable that extra splanchnic arteriolar resistance may be playing an important role.

A Specific Cutaneous Test for the Immune Response to Herpetic Infection. Harry M. Rose and (by invitation) Eleanora Molloy, New York, N. Y.

Chick embryos inoculated by the yolk sac route with the virus of herpes simplex develop a high titer of virus in the chorioallantoic fluid. Antigens for cutaneous testing were prepared from this infected, undiluted fluid by inactivating the virus at 56° C. Such antigens contain little egg protein and provoke a minimal number of non-specific dermal reactions.

Cutaneous tests were performed on 44 patients with herpes antigens and with control antigens prepared from normal chorioallantoic fluid. The blood of each patient was examined for neutralizing antibody to herpes virus by the method of chorioallantoic membrane inoculation with serum-virus mixtures.

Twenty-nine patients whose sera contained antibody gave positive cutaneous tests with herpes antigen and negative tests with control antigen. Thirteen patients, mostly children, whose sera were devoid of antibody gave negative cutaneous tests with both antigens. In one patient the cutaneous tests were negative although the serum contained antibody. In another patient the tests could not be interpreted because of marked sensitivity to egg protein.

There appears to be a high degree of correlation between positive cutaneous reactions to herpes antigens, as herein described, and the presence of circulating antibody to herpes virus.

Recognition of Metastatic Neoplasm in Bone Marrow. R. W. Rundles, Durham, N. C. (Introduced by D. T. Smith).

Invasion of the bone marrow by neoplasm may produce refractory anemias, sometimes with immature granulocytes or nucleated red blood cells in the circulating blood, hemolytic anemias, thrombopenic purpura, as well as diffuse bone pain, destructive skeletal lesions, etc. Diagnosis may be extremely difficult when the primary tumor escapes recognition or if involved tissue is not accessible for biopsy.

The possibility of recognizing tumor implants in bone marrow was studied in 40 patients having malignancies with local spread or distant metastases. Marrow was obtained from the ribs or sternum by combined aspiration and needle trephine preferably in areas of increased bone tenderness. Spread films were stained by Wright's stain A positive diagnosis of metastatic neoplasm was made in 14 cases. The malignant cells occurred singly, in sheets, and in clumps among other bone marrow elements. The presence of neoplasm in the marrow was confirmed by sections of tissue obtained by trephine, biopsy and necropsy.

Neoplastic implants in the bone marrow were found in patients before definite roentgen, peripheral blood, or blood chemical abnormalities appeared. Serial biopsies were readily obtained and were used to follow the response of prostatic metastases to orchidectomy and estrogenic therapy, the response of breast cancer to androgenic hormones, and other malignancies treated with nitrogen mustard compounds or radiation therapy.

Pitressin Test of Coronary Insufficiency. Arthur Ruskin, Galveston, Texas (Introduced by George M. Decherd).

Pitressin, a well-known experimental coronary vasoconstrictor, was used in human subjects both intramuscularly (2 cc. or 40 pressor units) and intravenously (0.75 cc. in subjects of average weight) for the electrocardiographic demonstration of coronary insufficiency. The not infrequent untoward symptoms—nausea, vomiting, abdominal discomfort—were easily controlled. In normal individuals EKG changes were limited to bradycardia, ectopic beats and slight S–T segment depressions.

In cases of definite clinical angina pectoris positive tests were found in 8 of 12 cases. The number of positive Master two-step tests in these 12 patients was 7. Our electrocardiographic criteria of coronary insufficiency were fairly rigid: S–T depressions totalling 3 mm. or more in the 4 commonly used leads, or T_1, T_2, or T_4 changes from positive to flat, diphasic or negative T waves. All 10 cases of suspected pseudo-angina, with indefinite clinical features, had negative pitressin and Master tests. Patients with abnormal EKG's prior to the test were found to be subject to the same criteria in both groups as were those with normal control tracings.

In view of the close parallelism between the effects of exercise and pitressin in individuals with and without clinical angina pectoris, pitressin may be used by cardiologists to confirm the clinical suspicion of coronary pain. The above results form a further link in the evidence for both coronary spasm and relative myocardial ischemia as theoretical bases for clinical anginal pain.

Microchemical Studies of Human Urinary Estrogens. W. T. SALTER and (by invitation) M. JANE OESTERLING, New Haven, Conn.

Studies of estrogen excretion in various types of patient and normal controls have been conducted on 6-hour to 12-hour samples of urine. The normal adult human male excretes only about 10 micrograms of estrogenic substances daily. Near menstruation, some women approach closely the male value. In the intermenstruum, however, female values rise steadily toward the time of ovulation. At this crisis, the peak of excretion temporarily may reach 90 micrograms. In certain sterile women, the male level may prevail continuously. In other sterile women, the estrogen level may be normal, but overshadowed by high "androgens." Therefore it is useful to know the ratio of antithetical steroids (estrogens vs. 17-ketosteroids) in the identical 6-hour sample of urine, as well as the absolute levels of either. The "antithetical ratio" of normal males is usually less than 1.0. In normal females, it is usually above 2.0 and at ovulation may reach 9. In female adrenal virilism and in Cushing's syndrome the ratio is usually in the male range. In female pseudohermaphroditism, however, the high "androgen" excretion may be balanced by a high estrogen value. In prostatic disease, high ratios are found. Thus studies of steroid balance may be useful in precise diagnosis.

Nitrogen Metabolism and Nutritional Studies in Chronically Ill (Metabolically "Debilitated"), Undernourished Patients. VICTOR SCHENKER and L. G. JOHNSON (by invitation), and J. S. L. BROWNE, Montreal, Canada.

The nitrogen metabolism, nutrition, and clinical course have been followed in a series of hospital patients with various chronic diseases (pulmonary tuberculosis, rheumatoid arthritis, bronchiectasis, peptic ulcer), and with varying degrees of weight loss. Representative experimental results are presented.

All subjects were placed on controlled dietary regimes over certain periods of time. Experimental diets varied as to total content of protein and calories (Prot. 100–200 gm./ day; Cals. 2,500–3,500/ day).

On these food intakes all subjects gained weight; the majority showed general improvement clinically with increased strength and feeling of well-being.

All showed abnormally low rate of urinary nitrogen excretion (with a consequent high nitrogen retention—unattributable to raised blood N.P.N.), which has been shown to characterize the metabolically "debilitated" individual. In many instances, however, nitrogen retention continued at the same rate even after considerable amounts had been stored over prolonged periods of time, and increase in body weight ceased. Further, in a number of cases, the total nitrogen retained, calculated as "tissue-protein," was found to be greatly in excess of the actual total gain in weight. Factors which may be responsible for these anomalies are discussed.

Radioiodine Excretion in the Gastric Juice and Saliva of Man. LEON SCHIFF and (by invitation) CHARLES D. STEVENS, HAROLD H. STEINBERG, CARL W. KUMPE and PAUL STEWART, Cincinnati, Ohio.

The excretion of radioiodine in the gastric juice and in the saliva of 35 individuals was followed at ten-minute intervals for two hours after the intravenous administration of 0.01 *mM* (1.5 mg.) of NaI and 4 microcuries of radioiodine per kgm. of body weight. Plasma levels of 0.04 to 0.08 *mM* of iodine per liter 15 minutes after the injection declined to 0.01 to 0.02 *mM* by 1½ hours after injection.

The concentration of radioiodine in gastric juice following the injection usually rose to 20 to 40 times the plasma concentration. The concentration in the saliva also rose to similar levels, frequently exceeding the concentration in the gastric juice.

The concentration of radioiodine in both the gastric juice and the saliva showed great variability from individual to individual, as well as upon repeated tests on a single individual. The variability in radioiodine excretion in the gastric juice was not related to the pH of the juice, nor to its volume, nor to the amount of visible mucus in it.

No definite relation has been observed between any gastric disorders and the excretion of radioiodine in the gastric juice.

*The Metabolism of Americium (Element 95) in the Rat.** K. SCOTT, D. AXELROD, and H. COPP (by invitation), and J. G. HAMILTON, Berkeley, Calif.

Solutions of $Am(NO_3)_3$ were administered to 200-gram rats by intramuscular injection and by stomach tube. The stomach tube series were sacrificed at 4 days, and the animals which received the americium by intramuscular injection were sacrificed at 1, 4, 16, 64, and 256 days. The absorption from the digestive tract was too small to be detected, indicating that less than 0.01 per cent of the administered dose was absorbed. The americium that was absorbed following intramuscular injection was accumulated primarily in the liver and skeleton. The initial accumulation in the liver represented nearly 65 per cent of the total amount absorbed from the site of intramuscular injection. The corresponding value of americium deposition in the skeleton was approximately 25 per cent. Within 16 days over two-thirds of the americium had left the liver and by 64 days less than 5 per cent remained in that organ. The content of americium in the skeleton remained constant up to and including the 256-day interval; evidently it becomes extremely firmly fixed in bone. Excretion was chiefly by way of the digestive tract and was roughly equivalent to the rate and degree of loss from the liver. Radio-auto-
